ABSTRACT

There is a need to explore ways in which current assessment tools can be enhanced to measure the true environmental impact of systems delivering products and services. The objective of this paper is to present an integrated energy, water and food (EWF) resource model that illustrates the interdependencies between different systems and sub-systems. The sub-systems considered in the environmental performance assessment of a proposed food production system in Qatar include: the food sub-system encompassing the production and application of fertilizers and the raising of livestock; the water sub-system which is represented by the reverse osmosis (RO) desalting process for water production and the energy sub-system, which considers power production utilizing combined cycle gas turbine (CCGT), solar Photovoltaics (PV) and biomass gasification integrated combined cycle (BIGCC). Life Cycle Assessment (LCA) forms the basis of the integrated EWF modelling tool and is used to evaluate the performance of the proposed food system.

Keywords: Energy, Water, Food, Nexus, LCA

1. Introduction

Food systems can no longer be analyzed as traditional linear systems. In fact, they have evolved into complex interconnected systems with social, economic and environmental dimensions. Every food system considers their product in terms of its utilization, availability and accessibility capacity, all of which are key components of food security defined as “when all people, at all times, have physical economic access to sufficient, safe and nutritious food to meet their dietary needs and food preferences for an active and healthy life” (FAO, 1996). Ericksen (2008) states that the characteristics of any given food system should be comprised of; the interaction between and within the bio-geophysical and human environments, the activities that take place within the food system and the outcomes which are directly related to the degree of attainable food security.

The challenge to overcome global food insecurity will only become more challenging as the world’s population increases to nine billion and food production capacity is challenged with increasing; land competition, resource scarcity and effects of climate change becoming apparent. It is imperative that food production systems develop in order to alleviate global hunger and to do so in a way that is environmentally and socially sustainable (Godfray et al., 2010). To this regard, it has been suggested the world will need to mobilize food systems to increase their total production capacity by 70 % to 100 % (World Bank, 2008). Although Godfray et al. (2010) stipulate that there is no simple solution to feed nine billion people, they do suggest a series of enabling strategies which need to be part of the overall mobilization initiative and they include; expanding aquaculture, closing the yield gap, increasing production limits, reducing waste and accommodating the changing diets.

The mobilization of food systems to meet the challenge of feeding the growing population will need to take the form of what is known as “sustainable intensification”. A strategy that is necessary in ensuring environmental integrity whilst increasing agricultural production (Godfray et al., 2010). Today, agriculture is the largest consumer of fresh water with a 70 % share of global water utilization in which the current population is appropriating 54 % of the accessible fresh water reserves. Furthermore, agriculture holds a 13.5 % share in global GHG emissions. In addition, there are upstream industrial activities that are of sole benefit to agricultural practices that need to be considered. The production of nitrogen based fertilizers which are equivalent to an additional 0.8 % of GHG emissions is one such activity (Brentrup and Pallière, 2008).

There is a need to adopt a systems approach when increasing agricultural production. For instance, Ericksen (2008) undertakes a holistic approach to food system design as illustrated in Figure 1. The system considers the drivers, interactions and feedback loops related to delivering food security. The objective of a systems approach is to identify key processes and determinants that influence outcomes within complex systems.

Figure 1.Food system components (Ericksen, 2008).

The framework considers the interactions between the human and natural environments in addition to whole chain inputs into the system with a food security focus for its outputs. Extending this framework based on the EWF nexus would strengthen the representation of natural resource inputs by considering their interdependencies and linkages with the environment. In this respect, the objective of this paper to present an assessment tool which can describe any system utilizing EWF resources in terms of its sub-systems. The approach required to develop such a model largely depends on the degree of resolution required. In addition, the nexus tool should be modular and so that complex systems are accurately represented allowing to identify inefficiencies easily. The modular nature of the tool ensures that the technical, spatial and temporal differences that exist between different systems and unit operation effects can be accounted for by modifying appropriate parameters of the component unit processes. The ultimate objective of the tool is to assist policy makers in answering key questions regarding the utilization of resources and the impact a particular policy may have on the environment. This paper will consider the fundamental question concerning the environmental burden in the provision of food in water-scarce countries such as Qatar. Although the cross-cutting tool integrates the utilization of EWF resources in one resource model and estimates the performance of any given system delivering a product or a service on atmospheric, terrestrial and marine eco-systems, this study only reports the impacts in terms of global warming potential (GWP). A study of the environmental burdens on terrestrial and marine eco-systems, including those related to marine eco-systems from desalination processes, are reported in earlier work by the authors (Al-Ansari et al., 2014).

Qatar is an arid country that suffers from a severe lack of natural water resources. Given that it is a small country home to approximately two million people, it possesses a disproportionate distribution of natural resources. This characteristic will affect Qatar’s ability to become fully self-sufficient, as with any nation, resulting in a degree of dependence on global trade to satisfy domestic food requirements. Qatar’s situation is particularly interesting; this is because whilst it has an abundance of energy reserves, it has a severe shortage of fresh water and arable land. It is also situated in a volatile region with extreme security risks and is part of a global community that is vulnerable to the effects of climate change, which will eventually exacerbate its natural disabilities. Annual freshwater extraction from aquifers is four times the rate of natural recharge of 50 Mm^3/y. The depletion is driven by agriculture which only accounts for 8 % of domestic consumption, and is leading to greater salination of aquifer water. Consequently, fossil fuel powered desalination provides more than 99 % of Qatar’s water demand providing up to 539 Mm^3/y. In 2012, Qatar’s electricity generating capacity reached 9,000 MW and is expected to rise with increasing population growth. The total arable land in the Gulf Cooperation Council (GCC) countries is in the order of 1.7 % and as a result imports at least 80 % of their food requirements. In a business as usual scenario food imports will continue to increase in proportion to population growth estimated at 14 %. The case study presented considers an expansion in Qatar’s domestic food system to a production a target of 40 % from the current 8 % using a specific crop profile by the year 2025 and a re-configuration through technology differentiation represented by the sub-systems.

2. Methods

The EWF nexus utilises Life Cycle Assessment (LCA) in order to compile the inputs and outputs for the food system and evaluate the potential environmental impacts in the delivery of its products throughout its life time.

The objective of LCA is to understand and evaluate the magnitude and significance of the potential environmental impacts of a product system. The four main stages of LCA according to ISO 14040 are: the Goal and Scope definition; the Life Cycle Inventory (LCI) analysis; the Impact Assessment (LCIA); and the Interpretation of the results. The Goal and Scope definition states the aim of an intended LCA study, the system boundary, the functional unit and the resolution (level of detail) in relation to this aim. The LCI analysis is the phase which quantifies the input/output relationships and compiles an inventory of input/output data for all component processes involved in the life cycle of the system under study. The nexus tool presented employs the CML 2001 baseline impact categories (including GWP), category indicators and characterisation methods. Inventory data are assigned to categories via the characterisation factors. In this particular case study, the nexus system functional unit is a particular crop profile measured in tonnes of output where the individual sub-systems are also considered in terms of their respective reference units and scaled accordingly, so as to serve the selected crop profile.

The model represented in this study is an extension of earlier work presented by the authors (Al-Ansari et al., 2014). The EWF nexus is defined as a series of sub-system LCI models that are developed to quantify material flows, natural resource and energy consumption at component unit process level. The LCI models are built using a combination of mass balance models, literature emission factors and engineering calculations which are validated using published literature and industry data. The flexible structure of the LCI database, provided through modularisation, enables the practitioner to choose component unit processes so that different technological options can be considered without the need for redesign or loss of information. The nexus modelling system presented here has adopted a food perspective with the objective of evaluating the environmental impact when increasing domestic food production. The rationale behind the crop profile choice, which includes greenhouse, open field vegetables and fruits, is not the subject of this study.

The analysis presented here is conducted for three modes of operation and three scenarios all of which serve to deliver the same functional unit and are evaluated in terms of their global warming potential. The baseline scenario uses fossil fuel to power the entire EWF nexus system using a CCGT. The second scenario integrates solar PV to power the RO desalination plants. The third scenario uses solar PV to power the RO desalination plants and fertilizer production facilities including their respective water requirement. The conventional mode of operation does not utilize manure for re-use within the system. The second mode integrates a BIGCC for power generation. The final operating mode utilizes the gasification by-product biochar for the enhancement of agricultural productivity in addition to the power generated from the BIGCC.

Energy requirements for pumping and distribution of water, food processing facilities, irrigation and administrative buildings and the embodied energy of equipment are not considered for simplicity. Emissions associated with the import of crops outside the crop profile consumed domestically are not considered. Land occupation for desalination facilities, power plants and fertilizer production facilities are not considered in land footprint calculations. Waste water treatment and reclaim is not considered in this study as it is assumed that in Qatar there are social barriers which prevent the use of treated water for food crops.

2.1. Energy sub-system

Energy is the main driver of the EWF nexus system. Three energy related sub-systems have been developed to power the EWF system. This section details the sub-systems which consider power generation using non-renewable natural gas fuel, renewable solar energy and the opportunity to generate energy from the gasification of the waste manure product from the food sub-system.

2.1.1. Combined cycle gas turbine

The combined cycle gas turbine (CCGT) model developed by Ibrahim and Rahman (2012) is based on a Brayton cycle based topping cycle and Rankine cycle bottoming cycle and is used to determine the power output of a turbine for any given composition of natural gas. The model considers the effect of operating parameters, such as peak pressure ratio, gas turbine peak temperature ratio, isentropic compressor efficiency and air fuel ratio, on the overall plant performance. The model uses a reference unit of 1 MWh, assumes a fuel to air equivalence ratio at 0.85 and calculates a total thermal efficiency in the range of 50-60 % in line with predicted values. Furthermore, the LCA model developed by Korre et al. (2012) which can be used to evaluate the performance of various CCGT power generation plant configurations has been integrated with the thermal efficiency calculations in order to complete the LCI database with a spectrum of emissions from power generation as illustrated on Figure 2.

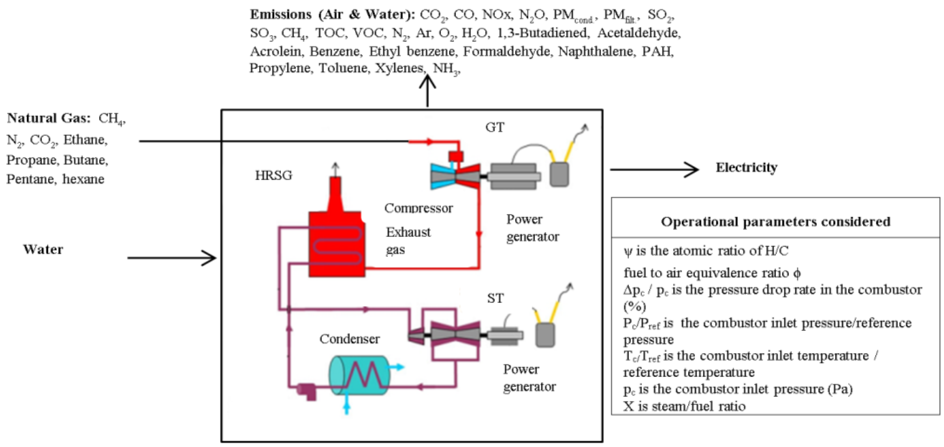

Figure 2. CCGT LCI model unit processes, inputs and outputs.

2.1.2. Solar photovoltaics

This study considers the procedure described by the RET screen model for the development of the solar PV sub-system (RETScreen, 2004). A 100 MW power plant utilizing monocrystalline-silicon modules is considered as the reference unit for this sub-system. The model calculates a daily global horizontal irradiance which is then then converted into an electricity generation potential using the PV module efficiency, the average module temperature, the nominal operating cell temperature, the clearness index and the area of the module. The life cycle emissions for solar PV which are released during other phases during the lifetime of the PV module (Fthenakis, 2011) are also considered. These include the fossil-fuel energy required to produce materials for solar cells, modules and the smelting, production and manufacturing facilities. It is assumed that PV modules are manufactured using power from a CCGT power plant and the natural gas consumption is aggregated over a 30 year life time.

2.2. Water sub-system

With increasing demand for water in isolation to power and improved anti-fouling/scaling membranes, the use of the RO desalting process is increasing. Furthermore, the specific energy requirement of RO systems is significantly lower than other desalination technology options resulting in a lower fuel requirement for a given desalting capacity. For instance thermal desalting systems such as Multi-Stage Flash (MSF) consume specific mechanical equivalent energy of about 4 kWh/m^3 of desalinated water, and heat energy in the range of 20 kWh/m^3, whilst RO desalting systems reduce the total energy requirement to 4-6 kWh/m^3 (Darwish and Al-Najem, 2000). Darwish et al. (2009) explored the true impact on the environment by considering the actual fuel consumption and the associated emissions from the provision of water from a variety of different power and water configurations. This study developed models for mechanically driven reverse osmosis desalting systems using the mechanical energy supplied from the CCGT and PV power plants. Water consumption in energy production is also considered. The water utilisation factors for a closed loop CCGT power plant and PV (negligible) used are based on Mielke et al. (2010).

2.2.1. Reverse osmosis

The RO model developed as part of this study (Figure 3) consists of a one stage pass system using an SWC 4+ membrane and calculates the power and fuel requirement per m^3 of desalinated seawater (Wilf and Awerbuch, 2007). The energy requirement is calculated using the net driving pressure (NDP). It is the driving force through a semi-permeable membrane which is defined as the fraction of the applied pressure in excess of the average osmotic pressure of the feed and any pressure losses within the system. The long term impact on the

Arabian Gulf, which is the body of water in which seawater is extracted from, can be found in Al-Ansari et al., (2014).

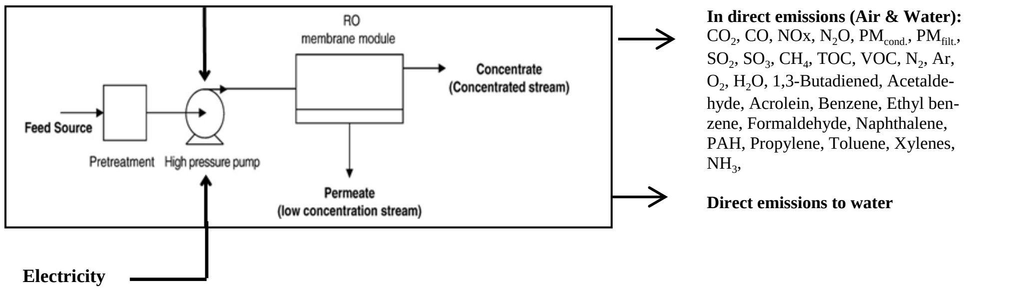

Figure 3. RO LCI model, inputs and outputs.

2.3. Food sub-system

The food nexus element encompasses fertilizer production and key agriculture practices such as the application of fertilizer and the raising of livestock.

2.3.1. Fertilizers

With respect to fertilizers, only the production and application of urea is considered in the quantification of emissions. Figure 4 illustrates the LCI model developed which integrates mass balance calculations with plant data and emission factors to calculate the emissions and resource consumption for ammonia and urea production. The electricity requirement encompasses the power required to drive the process and to convert water into steam.

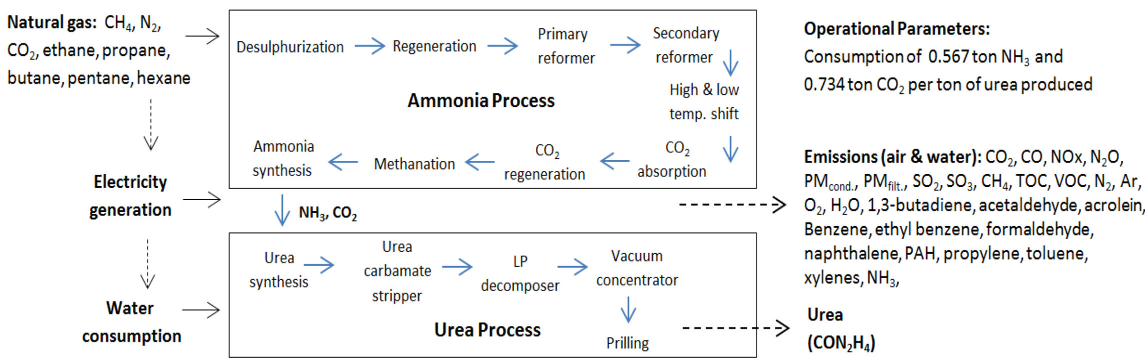

Figure 4. Ammonia and urea processes LCI model, inputs and outputs

2.3.2. Emissions from agriculture

It is estimated that the largest source of emissions from within the agriculture sector stem from crop and livestock production with an estimated 5 billion tonnes CO_2eq/yr. As such, the LCI developed for the agriculture sub-systems encompasses processes from both the raising of livestock and crop production (FAO, 2014).

2.3.2.1. Crop production

The emissions from crop production considered in this study include those from the application of urea fertilizer. Regarding the GHG emissions from fertilizer application, updated emission factors from the work of Brentrup and Pallière (2008) are utilised. The emissions include; urea hydrolysis (the release of CO_2 after application, equivalent to the CO_2 fixed during production), direct N_2O from use, indirect N_2O via NH_3, indirect N_2O via NO_3 and CO_2 from liming.

2.3.2.2. Livestock management

It has been estimated that livestock production represents approximately 18 % of the world's anthropogenic GHG emissions (Weiss and Leip, 2012). Furthermore, wastes from animal production systems contribute as much as 30 – 50 % of the global N_2O emissions from agriculture. Methane and nitrous oxide (CH_4, N_2O) emissions from manure management both contribute to global warming, whilst volatilization of ammonia (NH_3) contributes to acidification. The quantification of the GHG fluxes for all emission sources follow the IPCC (2006) tier 1 guidelines which include; methane emissions from enteric fermentation and manure management, direct and indirect N_2O emissions from manure management. The study assumes a scenario in which the manure is stored rather than applied on land.

2.3.3. Waste management

The environmental impacts from manure can be reduced if the manure is recycled into useful products that are utilised within the system. This paper considers the gasification of manure as the waste management option of choice. Gasification is a process in which organic matter (manure) is decomposed into syngas which can be used in power generation or converted into high value products (Cantrell et al., 2007). A mass balance based fixed bed gasification model using air and steam as the gasifying medium was developed (Thanapal et al., 2012; Gordillo and Annamalai, 2010). The process is governed by a series of primary heterogeneous chemical reactions (carbon-steam, Boudouard, hydrogasification, water-gas shift, methanation) which are both endothermic and exothermic and occurring at different rates (Priyadarsan et al., 2004, Gordillo and Annamalai, 2010). The operational parameters considered in the model include the equivalence ratio (ER), steam to fuel ratio (S/F) and feed composition. The model assumes that dairy manure is a representative composition for all livestock manure (Gordillo and Annamalai, 2010). The energy required for pre-gasification, moisture vaporization and the separation of nitrogen using an air separation unit (ASU) is considered in the input. Furthermore, this study assumes that the manure is collected every two months reducing the manure emissions by a factor of six in line with the LCA study developed conducted by Wu et al. (2013). Emissions from the collection of manure, its transport to and from industrial sites and the handling equipment are not considered.

Biochar is a nutrient rich by product which has the potential to reduce GHG emissions through carbon sequestration, N_2O emission reduction when applied soil, displacement of commercial fertilizer and enhancement of the agronomic efficiency. Uzoma et al. (2011) in a study regarding the effect of biochar on the productivity on sandy soils confirmed that the use of biochar improves the physio-chemical properties of coarse soil, nutrient uptake potential of the crop and its water use efficiency (WUE). The study concludes that application of biochar at mixing rates of 10, 15 and 20 tonnes per hectare increased WUE by 6 %, 139 % and 91 % respectively. Furthermore the study demonstrated that the application of biochar affects the plant nitrogen (N) uptake in addition to the other nutrients. Increasing plant N uptake through biochar amendment improves N fertilizer use efficiency especially in sandy soils which is the prevalent soil type in Qatar. At the optimum application rate of 15 kg/ha the N uptake increased by approximately 53 %. For this study, the effects of a conservative 50 % water and fertilizer reduction on the GWP through the application of biochar at rates of 15 kg/ha are examined. The quantity of biochar produced is assumed to be 20 % of dry matter in the manure Wu et al. (2013).

2.3.3.1. Biomass Integrated Gasification Combined Cycle (BIGCC):

The gasification process produces a low calorific syngas which can be used in traditional combined cycle gas turbines configurations. Whilst it is possible to design and build greenfield CCGT systems based on syngas fuels, it is also possible to co-fire gasified product with natural gas (Rodrigues et al., 2003) and modify existing facilities to utilize syngas as the fuel for power generation (Chacartegui et al., 2013, Kim et al., 2011). The combined cycle gas turbine sub-system described in section 2.1.1 is thermodynamically reconfigured to utilize the syngas from the gasified manure by changing turbine operating temperatures in addition to incorporating the syngas properties including composition with a corresponding heating value. Figure 5 illustrates the coupling of a dryer, ASU, gasification unit and a CCGT to form a BIGCC system. The BIGCC operates with an efficiency of approximately 35 % with a gasification temperature of 800 °C. The efficiency takes into account the energy for pre-gasification and the energy input into the ASU. The syngas produced contains a heating value of 9,100 kj/kg. In practical applications mechanical modifications would need to be made to the combustion chamber, gas turbine and the bottoming cycle (Chacartegui et al., 2013, Kim et al., 2011). Air emissions were based on mass balance calculations and emission factors (Mann and Spath, 1997). Energy requirement for the generation of steam has been accounted for. Furthermore it is assumed that auxiliary systems such as the dryer and ASU utilize power from within the system and not from an external source.

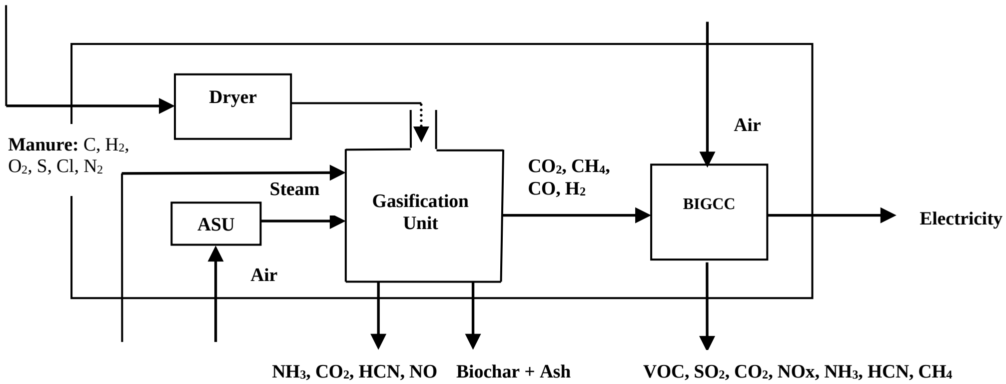

Figure 5. Gasification of manure for power generation system diagram.

3. Results and discussion

This study explored three fixed scenarios for the nexus configuration delivering a certain food production profile for the state of Qatar under three operating modes. It is important to note that the energy saving potential from the BIGCC is evenly distributed amongst all energy using sub-systems within the nexus rather than as a full allocation to one individual sub-system. Furthermore, the same assumption applied to the livestock management sub-system with respect to carbon neutrality is applied to the BIGCC. Therefore, CO_2 emissions released from the BIGCC are not considered in lifecycle emissions as it is considered to have been extracted from the atmosphere. Furthermore, in the LCA conducted by Mann and Spath (1997) on biomass power it was concluded that over 90 % of N_2O emissions in the gasification process was a result of livestock management which was considered as part of this study. As such, it is assumed that N_2O emissions from the gasification process are nill.

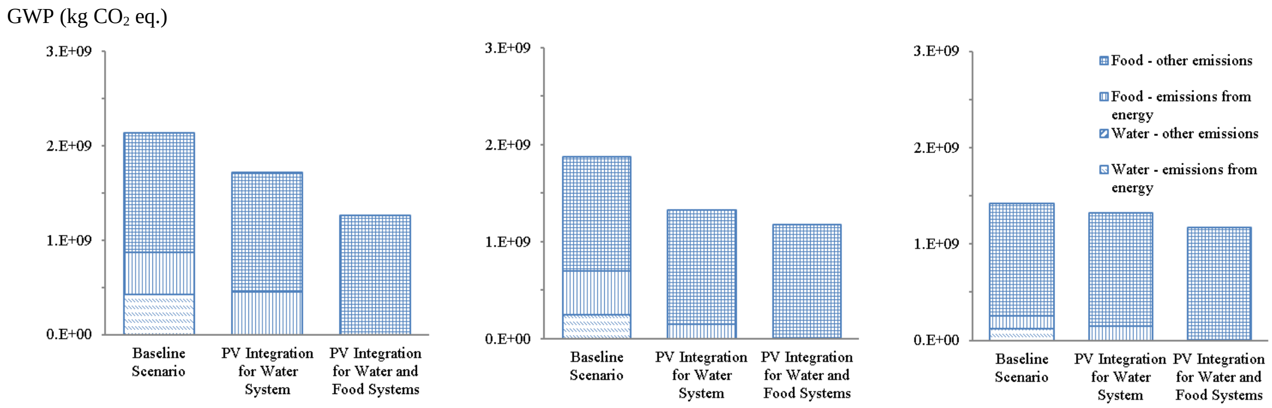
The main performance parameters from the BIGCC are illustrated on Table 1. The recycling of manure has the capacity to provide 30 – 40 % of the nexus energy requirements resulting in a natural gas saving of approximately 1.5×10^5 tonnes annually in terms of energy equivalence.

Table 1. Gasification performance parameters.

Gasification performance	Value
BIGCC operating efficiency	~ 35 %
Nexus energy substitution potential	~ 30 - 40 %
Natural gas equivalent	~ 1.5×10^5 kg/yr.
Total biochar production	~ 400,000 tonnes/yr.
CO_2 emission rate (calculated)	~ 900 kg/MWh
CH_4 emission rate (Mann and Spath, 1997).	0.00027 kg/MWh

Furthermore, the generation of biochar is significantly large in the range of 400,000 tonnes annually. Although research on the effects of biochar is ongoing, it is considered to be essential in soil regeneration especially in arid lands such as Qatar. The consequence is a significant increase in nutrient uptake and water use efficiency.

Figure 6 shows that the largest sources of GHG emissions originate from the food sub-system for all scenarios and operating modes. The source of which are the non-energy related emissions from the livestock sub-system which releases large amounts of CH_4 and N_2O, both of which have high GWP's. It is also clear that the total GWP for all three operating scenarios decrease with the introduction of the BIGCC. A comparison of the conventional nexus configuration with the BIGCC integrated system, shows a reduction in GWP for each of the three scenarios; baseline (20 %), PV integrated in the water system (45 %) and PV integrated for the water and food system (52 %). The total reduction of GWP with further utilization of the biochar is in the range of 33 %, 55 % and 62 % respectively in comparison to the conventional configuration.

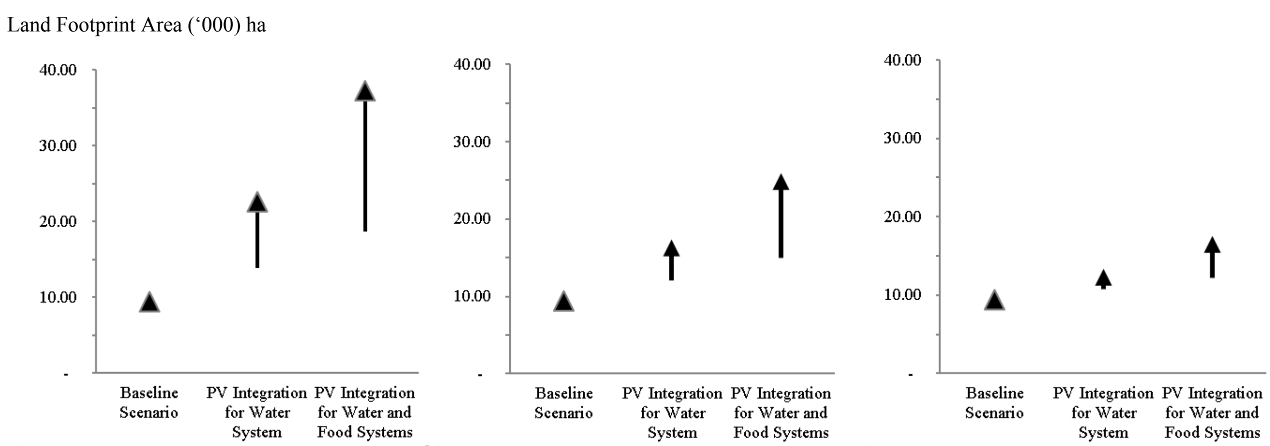


a) b) c)

Figure 6. Total GWP (kg CO_2 eq.) for the food production system for the three scenarios operating under different configurations a) conventional mode, b) BIGCC integration and c) BIGCC and biochar integration.

Evidently there is small improvement with the integration of biochar. This is because it is assumed that the biochar had no impact on the livestock management sub-system which is the largest emitter of GHG's. However, it is important to note that this study adopted a conservative 50 % improvement in WUE and 50 % improvement in nutrient uptake, whereas previous studies have recorded higher improvement. It is considered that further research is necessary to accurately quantify the improvements of biochar on the health of the soil, WUE and nutrient uptake.

The land footprint requirement rises with increased reliance on PV to power the nexus as illustrated on Figure 7. The largest PV land footprint is the upper limit of the conventional nexus configuration with a full PV deployment to power water and food systems requiring a total investment of 37,000 ha. This can be reduced by over 40 % with the integration of the BIGCC and the utilization of biochar. Within the nexus, natural gas is utilized in the CCGT and for ammonia production. In the conventional mode, the natural gas consumption required for the production of ammonia is insignificant in relation to the power generation. In the full deployment of PV to power the water and food system scenario, the natural gas consumption required to manufacture the PV aggregated over 30 years remains larger than the annual ammonia requirement with a 97 % of the total natural gas consumption.



a) b) c)

Figure 7. Total land footprint (thousand ha) requirement for the three scenarios operating under different configurations; a) conventional mode, b) BIGCC integration and c) BIGCC and biochar integration.

For the sub-systems considered, the integration of the BIGCC reduces the natural consumption required for energy amongst the three scenarios as illustrated on Figure 8. In fact, Figures 8b and 8c illustrate the natural gas credit which can be generated with the integration of PV and BIGCC with a further credit achievable with the integration of biochar.

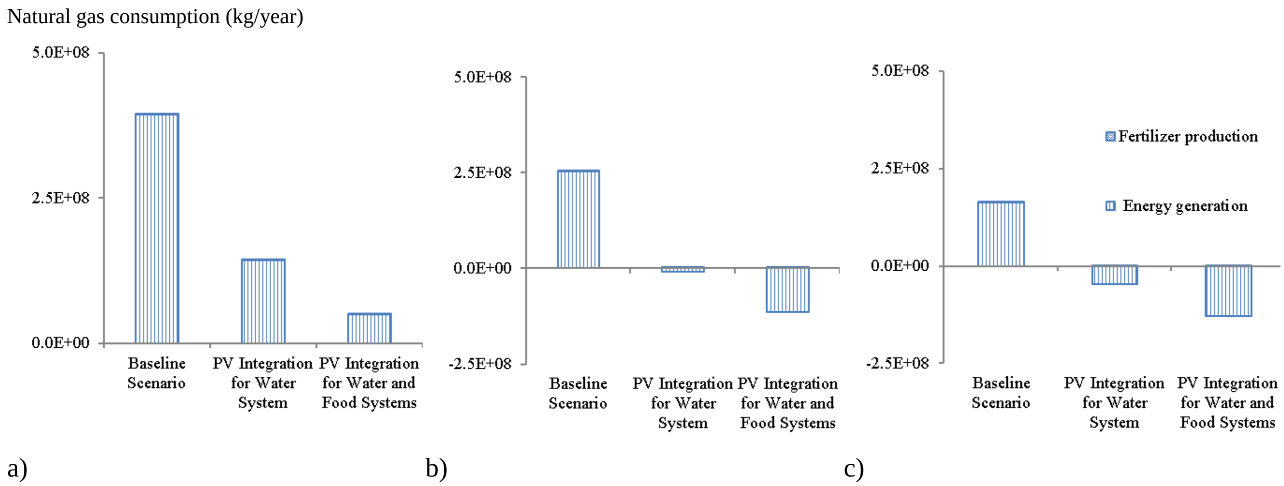


Figure 8. Total natural gas requirement (kg/year) for the three scenarios operating under different configurations; a) conventional mode, b) BIGCC integration and c) BIGCC and biochar integration.

4. Conclusions

The results of this study indicate that the BIGCC is a viable option to reduce environmental degradation with the quantity of waste generated in the livestock system. Further research is required to model the carbon fluxes within the system in order to accurately account for carbon emissions from the food sub-system and to the extent carbon neutrality is actually achieved. Furthermore, field scale experimental research is required in order to understand the true potential for agricultural productivity enhancement through the use of biochar. It is possible that this study may have underestimated the potential environmental benefits given the conservative 50 % improvement rate for WUE and nutrient uptake used in the analysis. The objective of such research would be to identify the optimum productivity increase that would need to be achieved in order to balance out the GHG emissions from the livestock sector. Additional onsite experimental research is necessary to gather the data required to adopt IPCC 2 and 3 analysis for livestock emissions as this study is based on the tier 1 approximation.

ABSTRACT

Life Cycle Assessment (LCA) is a helpful approach for a better understanding of the environmental impacts of apple orchard cropping systems. The application of LCA to perennial cropping systems raises methodological questions such as the consideration of non-productive stages. Two recent reviews give recommendations (Cerruti et al., 2011) and a methodological framework to deal with perennial crop cycles (Bessou et al., 2012). The objectives of our study were to test these recommendations and framework by comparing two contrasted apple fruit production systems (intensive and semi-extensive) and to assess the weight of the non-productive stages in the orchard life cycle impacts. Unproductive stages weighted up to 21% and 28% of the studied impact categories, in the semi-extensive and intensive orchard respectively, with little contribution of the nursery stage. The consideration of the unproductive stages is discussed and the necessity to explicit the approach used to account for the duration of perennial cropping systems is also outlined.

Keywords: LCA methodology, perennial crop, apple production, orchard conservative design, orchard management

1. Introduction

Life cycle assessment (LCA) is a comprehensive methodology, which considers the whole life cycle of the cropping systems. In the case of perennial crops such as orchards, unproductive then productive stages characterize the cropping system. This aspect raises methodological questions about the way to account for all orchard stages in the total impact assessment. Two recent reviews (Cerutti et al., 2011; Bessou et al., 2012) recommend integrating those non-productive stages in the impact assessment. Moreover Bessou et al. (2012) propose practical guidelines for perennial cropping systems according to data availability to describe and account for those stages in a LCA study. These guidelines propose to encompass every stage of the perennial cropping cycle, as well as different approaches to model it. Our main goal was to test the methodological recommendations of these authors, by analyzing the contribution of each life cycle stage in the total environmental impact of two contrasted apple orchard systems: one intensive and one semi-extensive. Intensive systems refer to orchards managed to maximize fruit production, usually including several of the following design traits and management practices: dense planting of short-lived trees on dwarfing rootstocks, high chemical inputs, intensive pruning to shape the trees in a restricted form, and frequent mowing the orchard groundcover (Dart, 2008). In contrast, orchards that are managed extensively request less use of pesticides and fertilizers with relatively long-lived trees that could reach the veteran stage. We expected these two orchard systems to affect the relative importance of the non-productive stages in the LCA and therefore, to be good case studies to use with this newly developed guidelines.

2. Methods

Two existing and contrasted apple orchards were compared following the methodological guidelines proposed by Bessou et al. (2012) and Cerutti et al. (2011) to analyze perennial cropping systems with LCA. To comply with current methodological frameworks for perennial crop LCA, the different stages of the orchard life cycle including non-productive stages, were accounted for. The non-productive stages included nursery, orchard creation (planting), orchard establishment and destruction.

2.1. The studied apple cropping systems and their modelling

The two studied orchard systems were described and modelled from on-farm surveys. The geographical origin, namely Northern (Picardy) and Southern (Rhone Valley) France, for the intensive and semi-extensive systems respectively, ensured the data consistency of each modelled apple production system (Bessou et al., 2012). The main characteristics of the studied orchards are summarized in Table 1. The two studied orchards differed in their lifetime, orchard height and associated machinery use, irrigation management (in relation with the climatic context) and planting distances. Moreover, the intensive orchard establishment stage lasted two years compared to one year in the semi-extensive orchard. Indeed, the semi-extensive orchard was harvested as soon as the annual production reaches around 3 to 4 tons/ha, i.e. in its second year after planting. In the intensive orchard, fruits were harvested only once the production has reached a yield of 20 tons/ha (namely in the 3rd year), in order to optimize the costs.

Table 1. Main characteristics of the two studied production systems.

Characteristics	Intensive orchard	Semi-extensive orchard
Cultivar	Jonagold	Golden
Planting density (number of trees/ha)	2500	1100
Tree height (m)	2.5	4.5
Pruning	Mechanical	Manual
Between-row management	Mowing and mulching	Mowing and mulching
Irrigation system	No irrigation	Buried irrigation system with localized drippers
Weed, pest and disease control	Mainly chemical	Mainly chemical
Harvest method	Manual	Manual with elevator
Lifespan (years):	15	26
- Orchard establishment	Year 1 and 2 (2 years)	Year 1 (1 year)
- Productive stage (commercialized apples)	Year 3 to 15 (13 years)	Year 2 to 26 (25 years)
Annual average yield over the productive stage (t/ha/year)	55.4	37.8
Cumulated commercialized yield over orchard whole life time (t/ha)	720	944.7

For both orchards, all cultural practices related to fertilization, plant protection, between-row management, tree training, fruit load management as well as harvest were collected. As recommended by the two reviews, the modelling of each orchard stage, namely the unproductive stages (i.e., nursery, orchard creation, establishment and destruction) and the productive stage (i.e., years with apple commercialization) was included in the analysis. During the nursery stage, grafted trees were produced, which were considered as inputs in the orchard creation stage. The orchard creation stage corresponded to the soil preparation before planting, planting and installation of orchard infrastructure such as poles, wires and the irrigation system if the orchard is watered. During the orchard establishment stage, fertilizer doses corresponded to one third of those of the full production years. The inputs of an average production year are listed in Table 2. The two studied orchards differed mainly in the fertilizer and pesticide doses, which were higher in the intensive orchard. The last stage of orchard destruction entailed the removal of trees and infrastructure.

Table 2. Input list for one average productive year for the two production systems, with N: Nitrogen and a.i.: active ingredient.

Input	Intensive orchard	Semi-extensive orchard
N fertilizer rate (kg N/ha)	114	47.3
Pesticide, active ingredient (kg a.i./ha)	74	28.5
Including copper and sulfur (kg a.i./ha)	44	15
Fuel consumption (L/ha), including harvest	289	234
Including self-driven elevator fuel consumption (L/ha)	-	67
Pesticide and fertilizer and growth regulator applications (runs/ha)	47.4	41
Other mechanical practices (pruning, mowing, mulching) (runs/ha)	5.7	4

Following Bessou et al. (2012), the data available for the two orchards implied to use two different approaches to describe the studied orchards during their whole lifetime. Indeed, a modular approach, with each stage independently modeled, was used for the intensive system: data were recorded for the different stages from one single year. A chronological approach, which consists in describing all the historical course of the crop development, was used for the first eight years of the semi-extensive system, while neighbor orchards were the basis to estimate the characteristics of the following seventeen years.

2.2. System boundaries and functional units

The two studied systems encompassed life cycle phases from cradle (namely the production of the inputs of all the modelled stages), to the gate of the apple storage place. To compare the two studied systems and follow the recommendations of Cerutti et al. (2011), two functional units (FU) were used. The mass-based FU was calculated for 1 ton of apples for the cumulated yield over the whole orchard lifetime. The area-related FU was 1 $ha^{-1}.year^{-1}$ of land used to produce apples over the whole orchard lifetime.

2.3. Inventory and characterization methods

The inventories needed for the manufacturing and supply of inputs and buildings were taken from Ecoinvent V2.2. Following the recommendations of Cerutti et al. (2011), a nitrogen balance based on the tree requirements was calculated for each year of the establishment and productive stage of the orchard.

Climate change, terrestrial acidification, freshwater and marine eutrophications and energy consumption were calculated with SimaPro V7.3.3 software using Recipe method (Goedkoop et al., 2009) and cumulative energy demand method V1.08 (Althaus et al., 2007). Despite the importance of pesticide applications (Table 2), emissions related to the use of sulfur- and copper-based pesticides could not be computed with the existing fate models (Villanueva-Rey et al., 2014). As a consequence, ecotoxicity and toxicity impacts were not assessed in the present study.

3. Results

3.1. Contribution of the non-productive stages to the total environmental impacts

The relative contribution of each stage (non-productive and productive) to the five calculated environmental impact categories is presented for both semi-extensive and intensive orchard systems (Figure 1). Whatever the impact category and the FU, the unproductive stages represented up to 21 % and 28 % in the semi-extensive and

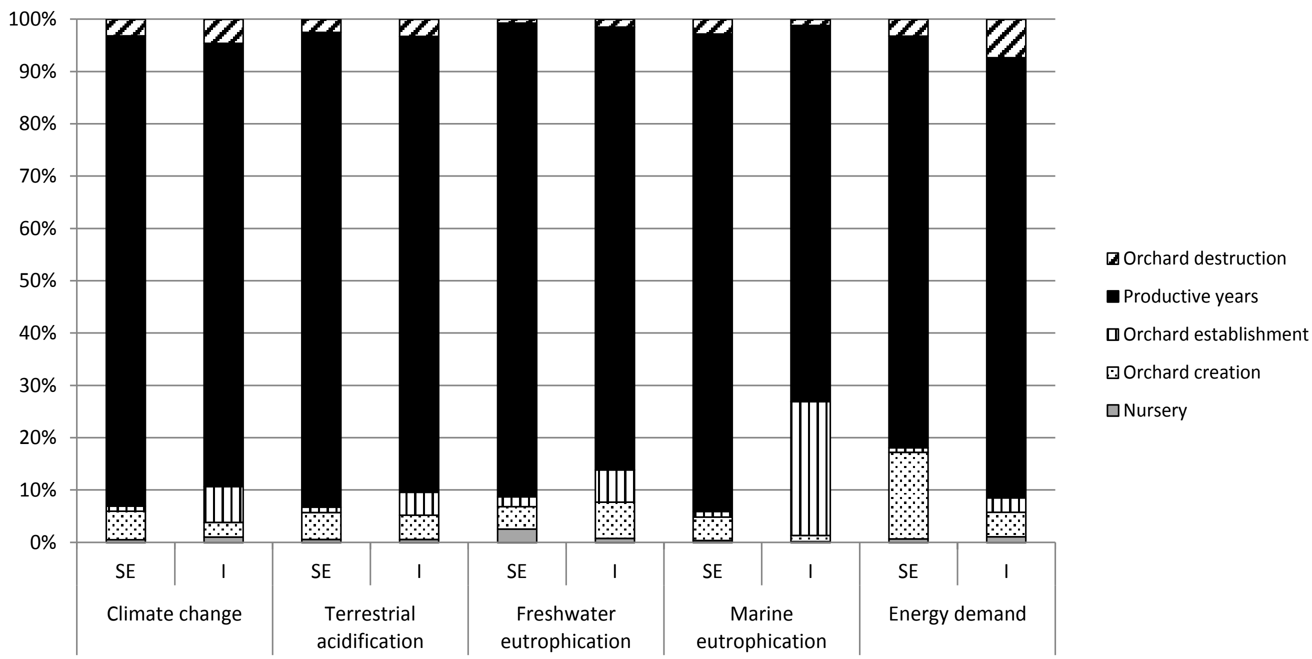

Figure 1. Relative contribution of each stage (productive years and non-productive stages) to five environmental impact categories in the semi-extensive (SE) and the intensive (I) orchard systems.

intensive orchards, respectively. The nursery itself accounted at maximum for 1% and 2.6% of the orchard whole life impact in the intensive and the semi-extensive orchards, respectively.

In the intensive orchard, the main contributor to climate change, terrestrial acidification, freshwater and marine eutrophication impacts among non-productive stages was the ‘orchard establishment’, while the ‘orchard creation’ stage accounted for 3% to 7% for climate change, terrestrial acidification and freshwater eutrophication impacts. In the semi-extensive orchard system, the main contributor to all calculated impact categories among the unproductive stages was the ‘orchard creation’ (i.e. soil preparation, planting and orchard infrastructure creation).

These differences among orchards can be explained by the duration of the ‘orchard establishment’ stage and the climatic constraint. Indeed, the establishment phase of the intensive orchard entailed two unproductive years, versus one in the semi-extensive orchard. Besides, as there was no irrigation system in the intensive orchard due to sufficient rainfall to fulfill the crop requirements, the relative weight of the creation stage was lowered.

The contribution of the non-productive stages to the total impacts was lower in the semi-extensive orchard compared to the intensive orchard for all the studied impact categories, except for energy demand with similar or higher value according to the FU. This result could be related to the energy consumption occurring during the ‘orchard creation’ in the semi-extensive orchard. Indeed, planting was mechanized and required heavy equipment, whereas it was manual in the intensive system. Moreover, the semi-extensive system was irrigated with a buried irrigation system, which also required heavy machinery use to install it. The energy demand for the non-productive stages mainly corresponded to the tree removal (orchard destruction) in the intensive orchard.

3.2. Environmental impact of the two orchard systems

The impact per (ha.year) of the intensive orchard was 1.5 to 11 times higher than the one of the semi-extensive orchard for climate change, terrestrial acidification, freshwater and marine eutrophication, except for energy demand with similar values. For the mass-based FU, the differences were less important, or opposite for freshwater eutrophication and energy demand (Table 3). Indeed the cumulated yield for both orchard types is relatively similar with 720 tons for the intensive orchard and 945 tons for the semi-extensive orchard, even though their lifetimes are different with 15 years for the intensive and 26 years for the semi-extensive orchard.

Table 3. Environmental impacts of the orchard systems as expressed per ton of fresh fruits and per (ha.year).

		ton^{-1}		**(ha.year)$^{-1}$**	
Impact categories	**Unit**	**Semi-extensive**	**Intensive**	**Semi-extensive**	**Intensive**
Climate change	kg CO_2 eq	75.24	89.79	2733.71	4309.94
Terrestrial acidification	kg SO_2 eq	0.710	0.985	25.789	47.269
Freshwater eutrophication	kg P eq	0.033	0.024	1.22	2.000
Marine eutrophication	kg N eq	0.037	0.155	1.33	15.005
Energy demand	MJ	1160	880	42143	42243

The higher environmental impact observed for most impact categories (except energy demand) in the intensive orchard was mainly related to fertilization, among which nitrogen applications. Indeed the production and in-field emissions of fertilizer inputs contributed to 55% and 28% of the climate change in the intensive and semi-extensive orchards, respectively. Terrestrial acidification and marine eutrophication were mainly explained by nitrogen fertilization in the intensive orchard (70 to 86% of the impact), whereas it was related to both fertilizers and pesticides production and use (50% of the total impact) in the semi-extensive orchard.

Regarding the energy demand, the mean annual fuel consumption during the productive years was lower in the semi-extensive than in the intensive orchard, but it was balanced by the mechanization of the semi-extensive system, which was higher over the whole orchard life cycle compared to the intensive orchard. Indeed, the machinery and the infrastructures used to plant and irrigate the orchard were more important and more energy-consuming in the semi-extensive than in the intensive orchard. Moreover, due to the tree height in the semi-extensive orchard, a self-driven elevator was used for each manual operation (pruning, thinning and harvest).

4. Discussion and conclusion

The present study confirms the environmental burden of unproductive stages with up to 28% of the total impact, although the nursery itself was of little importance (1 to 2.2% of the orchard whole life impact).

It is noticeable that the present comprehensive results about climate change impact and energy demand are similar to those published by Mouron et al. (2006) for the area-related FU, while they are two to threefold higher than those published by Milà i Canals et al. (2006) and Alaphilippe et al. (2013) on similar semi-extensive orchards. Only Mouron et al. (2006) included the unproductive and establishment stages in its calculation, which explain that the results are comparable to the present study. The use in the present work of a chronological approach, with the consideration of several years of full production, with annual adjustment in crop operations and alternate fruit bearing also contributes to explain the differences among studies.

Our work outlines the necessity of standardization to model the perennial crop life cycle and attests that the methodological frameworks proposed by Bessou et al. (2012), and Cerutti et al. (2011) are relevant to assess global environmental impacts in orchards.

In conclusion, aside from marine eutrophication and cumulative energy demand, the weight of the unproductive stages in all impact categories was only slightly changed between our two contrasted orchard designs and managements. An intensive establishment stage and a semi-extensive creation stage may noticeably contribute to marine eutrophication and cumulative energy demand, depending on their durations and intensification levels. So, based on our results, we recommend that, when identifying the hotspots of apple production systems, LCA has to focus on and privilege an accurate representation of the field stages, including the orchard establishment and the orchard creation.

Aknowledgement

The authors would like to thank Dominique Grasselly, who provided information on the nursery stage for the semi-extensive orchard assessment in the frame of the Agribalyse® program funded by French Environment and Energy Management Agency.

ABSTRACT

The aim of this work is to develop an organization, management and marketing model of Cantabria anchovy with environmental considerations in order to obtain environmental sustainability by improving the efficiency of use of raw materials, waste reduction and recycling, utilization and enhancement of products, energy efficiency and carbon and water footprint. This production and consumption model contribute to the Spanish Challenges according to the competitiveness of the fisheries sector in national and international markets.
The management model of Cantabrian anchovies allows to inform consumers about the environmental impacts associated with anchovy canning industry by means of Eco labels. In addition, the model allows transmission of knowledge about environmental and socio-economic impacts related to the life cycle of the product to those who make decisions on production, consumption and waste management product, in order to promote better management lifecycle for a sustainable production and consumption.

Keywords: Anchovy, Life Cycle Assessment, Canning Industry, Sustainable Production and Consumption

1. Introduction

The canning industry generates a lot of wastes. In this context, industrial waste management in the food industry is an important environmental problem that requires specific action draft through a comprehensive and coherent policy on the prevention and control of wastes. In addition, the European Thematic Strategy (SEC 2011 70 final) on the Prevention and Recycling of Waste and its relation to the life cycle approach, the Directive 2008/1/EC on Integrated Prevention and Pollution Control (IPPC), the Integrated Product Policy (IPP) (SEC (2009)1707 final) and the Strategy on the Sustainable Use of Natural Resources can help promote more sustainable production and consumption models based on the life cycle approach and the participation of stakeholders.

The fishing industry for Cantabrian anchovy (Engraulis Encrasicolus) is one of the main economic resources of the fleet of the Cantabria Region. According to CONSESA (Association of Manufacturers of Canned Fish of Cantabria Region), in 2,012 there was a production of 13,267 tons of canned anchovy, equivalent to more than 91 million euros.

The Anchovy caught in the Cantabrian Region is intended for direct human consumption either in the form of fresh fish, or to production of canned anchovies in oil. The usable of the fish for food is between 60% and approximately 70%. An important amount of waste streams occurs mainly in operations heading, gutting and packing. Taking into account that 40% of the weight anchovy captured just as waste, it is estimated that nearly 9,000 tons of this resource are wasted and also a lot of waste effluents (mainly water and oils) are obtained.

According to this, it is necessary a sustainable Cantabrian anchovy industry taking into account local considerations for global development. In this sense, it is necessary to design and implement strategies for sustainable management of Cantabria anchovy industry under a life cycle approach. These strategies will be focused mainly on increasing the utilization of wastes from anchovy production to obtain co-products with higher added value that can be allocated to new green markets. This new development is based on the application of tested methodologies (Life Cycle Analysis, Best Available Techniques and Eco-labels).

The canning industry uses a variety of types of packaging of different sizes and materials. Packaging the final product requires metallic packaging or glass packaging, with or without secondary packaging. After consuming the product, the packaging (which contain one part oil) should be managed appropriately. Directive 94/62/EC aims to limit the production of packaging waste and promote recycling, reuse and other forms of recovery of waste. In this context, it is very important the prevention and proper treatment of all waste generated in the lifecycle of the canned anchovy, including packaging.

The European Commission Joint Research Center developed a new method to calculate the environmental performance of a product based on LCA methodology. It has also developed the Single Market for Green Products to ensure that consumers are not confused by the environmental unclear information. In this sense, the presented methodology has as one of its main objectives developing a Product Category Rules (PCR) for the creation of an Environmental Product Declaration (EPD), which establishes the principles for communicating the environmental performance, such as transparency, reliability, completeness, comparability and clarity of the product. According to this, it is possible to promote the supply and demand for more sustainable products.

2. Proposed Model

The mode will be based on the concept of "with science and society". The methodology will be focused on the needs of society. In this sense, will be consider to governments and their representatives, businesses, social organizations and citizens. Figure 2 shows the diagram of the proposed model and the Life Cycle Approach on the proposed model.

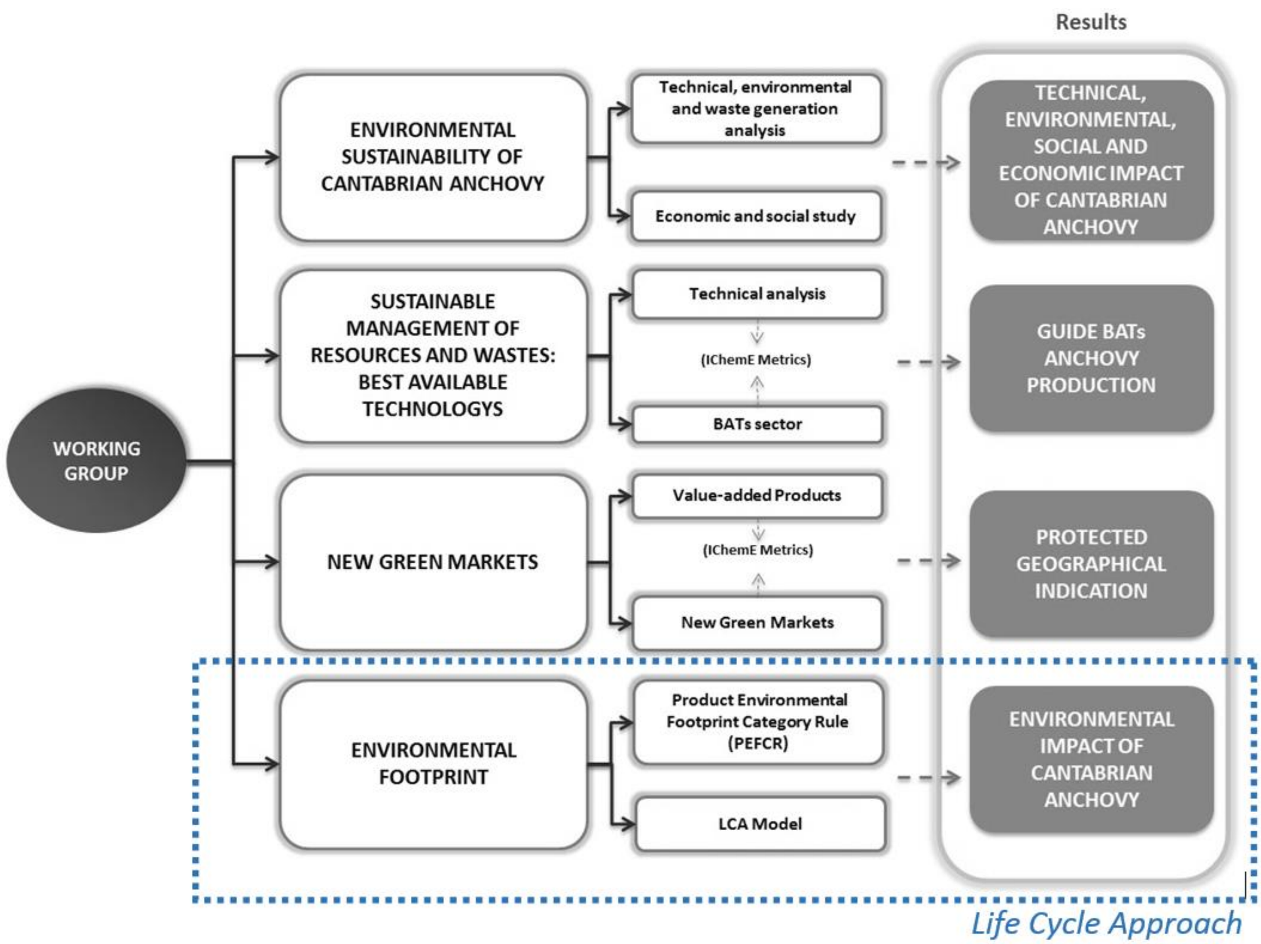

Figure 2. Diagram of the work methodology. Life Cycle Approach on the proposed model.

The main objective of the proposed model is to design and implement strategies for sustainable management sector of the Cantabrian anchovy under a vision of the life cycle. These strategies will mainly focus on increasing the use of generated waste effluents, in order to obtain co-products with higher added value that can be allocated to new green markets. The model will base on the application of tested methodologies (Life Cycle Analysis, Best Available Techniques, Ecodesign and Environmental Footprints) (Avadí and Fréon 2013; Ayer et all. 2007; Azapagic 1999; Pelletier et all. 2007). On the other hand, the methodology will base on the opinions and experience of industry representatives. This working method aims to apply the principles of the Integrated Product Policy (IPP) and the Politics of Sustainable Consumption and Production of the European Union, so that the conclusions reached in the process can be useful in a possible process to review these policies, both nationally and internationally.

The main objectives are:

- Contribute to the sustainable development of the canning industry of Cantabrian anchovy, by promoting the supply and demand for products that respect the environment throughout its life cycle.
- Promote the competitiveness of Cantabrian anchovy by promoting the efficient use of natural resources and exploitation of waste streams and using appropriate recovery systems for subvalue-added-products. This competition necessarily involves the application of Best Available Techniques in the fishing and processing of anchovy and proposed solutions to overcome barriers to implementation. The BAT's are necessary to evaluate in order to assess environmental, economic and social impacts. This work considered the environmental sustainability metrics developed by the Institution of Chemical Engineers (IChemE) that give a balanced view of the environmental impact of inputs-resource usage and outputs-emissions, effluents, and waste (Tallis et al. 2002).
- Disseminate to stakeholders (companies, government agencies, consumer organizations) valuable and updated information about the environmental impact and socio-economic development of fisheries and canned anchovy. In particular inform consumers about the environmental impacts associated with anchovy canning industry and its derivatives through the use of reliable eco-labels based on the methodology of Life Cycle Analysis (LCA).
- Optimize the final product packaging for marketing, analyzing the transformation process of the anchovy (sewage, oils, packaging waste and fish waste). It is necessary to develop the Product Environmental Footprint Category Rule (PEFCR) for the sector of anchovy, which would be used later to help consumers distinguish seafood and more respectful canners with the medium environment throughout their life cycle. Similarly, the development and dissemination of Footprint pursued.
- Monitoring and implementation of environmental legislation within a local and regional basis.

To achieve these broad objectives, will be held the following specific objectives:

- Coordination and Consultation Sector, including stakeholders.
- Environmental, economic and social Life Cycle Assessment of Cantabria anchovies. Updated and detailed analysis of environmental, social and economic sector.
- Sustainable management of resources and effluent canning Cantabrian anchovy: Analysis and Application of Best Available Techniques (BATs)
- New markets for canning Cantabrian anchovy.
- Environmental Footprint of Cantabrian anchovy.

3. Life Cycle Approach of the Proposed Model: Combining Type I and Type III Eco-Labels

Eco-labels are used by manufacturers and distributors to provide information about the environmental performance of their goods on a voluntary basis. When accurate and relevant, this information should help consumers to identify those products and services of the market with lower environmental impacts. In order to avoid impact shifts between different categories or life cycle stages, a life cycle approach should be applied when defining the rules for awarding eco-labels. Currently, only Type III eco-labels (or Environmental Product Declarations, EPDs) require that a LCA study of the product is undertaken following specific predefined calculation rules (named Product Category Rules, PCR). However, the technical and detailed contents of EPDs make them better suited for professional purchasers rather than final consumers, which may have the time and competence to understand their contents. On the other hand, Type I eco-labels are easier to understand, however the extent in which LCA methodology is followed in the definition of awarding criteria varies from one Type I scheme to another.

Within this context, the proposed model suggests that anchovies producers first develop an EPD of their products and then, by comparison to average market reference values of the different environmental impact categories (without aggregation), companies award an Eco-label Type I for their anchovies if they satisfy the threshold values. Such scheme, which may be applied to other product sectors, implies that the Eco-label Type I criteria should be based on LCA results of individual products. To this end, average environmental impacts of product categories should be known in advance. Therefore, LCA case studies will be developed for a number of anchovy's producers of the Spanish region of Cantabria in combination with scientific literature in order to define the thresholds values for the Type I eco-label.

Figure 3 shows conceptual scheme of Life Cycle Approach of the proposed model.

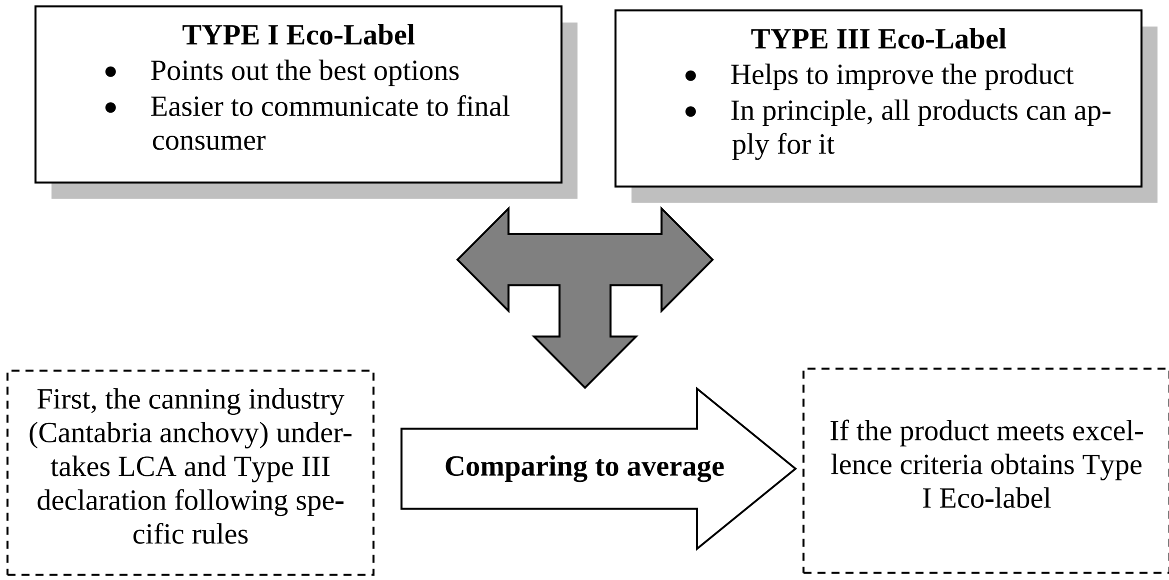

Figure 3. Conceptual scheme of Life Cycle Approach of the proposed model: Combining Type I and Type III Eco-Labels

3.1. Product Category Rules for development of Environmental Product Declarations of anchovy

The Type III environmental declarations, also known as "environmental product declarations" (EPDs), present relevant and quantitative environmental information about the life cycle of products. The information declared is based on an independently verified Life Cycle Assessment (LCA) study undertaken according to specific rules (i.e. Product Category Rules, PCR) developed in the framework of ISO 14040-44 and ISO 14025 standards. As stated in ISO 14025, the previous PCR document on fishery products will be taken into account, as well as previously published LCA studies on anchovies. In addition, we will be develop LCA studies of the products of local canning industries and the consultation with stakeholders of the Cantabria region that will allow gaining the required in-depth knowledge to develop a PCR document suitable for the Cantabria canned anchovies.

3.2. Definition of the environmental thresholds for the Type I eco-label

The Type I Eco-label requires a benchmark against which each applicant anchovy can be measured. For each impact category, average values can be defined based on the results declared through EPDs. These values should be updated periodically in order to foster the continuous reduction of the environ-mental footprint of anchovy.

Within the Project, pilot EPDs and LCA studies will be developed in collaboration with canning industries of the Cantabria Region. A comprehensive literature review of LCA studies of anchovies and related products in different parts of the world has been undertaken. Based on this available information, benchmarks will be identified for Cantabria canned anchovies for the following impact categories and indicators: global warming, water use and (fossil) primary energy consumption.

3.3. Expected Results

The development of the Product Category Rules and the definition of the environmental thresholds will be subject to external review by canning industries and other stakeholders belonging to the advisory group of the project. A number of seminars will be held with them to discuss key assumptions and methodological decisions, so as to achieve the widest possible agreement and contribute to the advancement of the state of the art in the LCA of canned anchovies.

Both the developed Product Category Rules and environmental thresholds for awarding the Type I eco-label will be tested for a reduced number of canning industries of the Cantabria Region. EPDs of Cantabria anchovies will be produced as pilot case studies within the Project. In addition, a PCR document will be available for its application in further cases.

With minor adaptations, the outcomes of the project could be transferred to other producing regions.

ABSTRACT

Global warming, viticulture progress and customer demand in aromatic wines have led to an international production of more and more alcoholized wines. More and more wine consumers complain about these high alcohol wines that are getting too heavy and strong to drink. Besides, this increase of alcohol content in wine is maybe not negligible from the viewpoints of individual alcohol intake and harmful effects of alcohol on health and behavior. The quest for techniques for wine partial dealcoholization allowing minimal aroma compound losses is yet currently ongoing. The currently most used techniques applicable at industrial scale are Reverse Osmosis and Spinning Cone Column. Both processes present high energy consumption and the sensory quality spoilage has not been overcome yet. Therefore, the main drawback of these technologies is the high energy consumption required, either to create vacuum conditions and slightly increase the working temperature or to pressurize the system. In order to reduce energy consumption, partial dealcoholization by Evaporative Pertraction (EP) technology is presented in this work as adequate technology to reduce energy consumption, and therefore, to reduce environmental impacts related to the dealcoholization process. In order to state the environmental benefits of obtaining the dealcoholized wines by the ecoinnovative process, the evaluation of the environmental impacts is necessary. Life Cycle Assessment (LCA) approach has been used in order to assess the environmental performance of the dealcoholized wines.

Keywords: Dealcoholization, Membrane contactors, Wine, Environmental Sustainability

1. Introduction

Wine is one of the most popular alcoholic drinks in the world. Mediterranean countries have a widespread culture of wine, being France, Italy and Spain the most important producers of this beverage in the world (Doering 2004).

Quality of wine is a key issue for the wine makers. Great effort is being done in optimizing the production of specific aromas and flavors (i.e. cherry, chocolate, vanilla), and minimize the formation of non-desired flavors (i.e. wet dog, plastic, rotten egg) (López et al. 2007). According to the European Commission (EC) regulations, wine is defined as an alcoholic beverage resulting from fermentation of grapes or grape must with ethanol content higher than 8.5% v/v (Commission Regulation, 2009). Generally, the wines are composed of 10–15% v/v alcohol, sugars, proteins, antioxidant agents and vitamins.

Alcoholic content has a strong impact on the quality of the wine affecting acidity, astringency and volatility of aroma compounds (Mermelstein 2000), altering the organoleptic properties of the product. The degree of ripeness of the grape conferring the optimum flavor characteristic matches normally the highest sugar content, and the resulting alcohol concentration. Therefore, a small adjustment in the alcohol content between 1 and 2% is currently and recently one of the most important objectives for the wine industry.

Nowadays, some methods to produce low alcohol-content wines or to adjust the ethanol content are employed by many wine makers in particular in the United States, for instance, spinning cone column (SCC) (Makarytchev 2004) and reverse osmosis (RO) (Ferrari 1991). Nevertheless, RO leads to a wine concentration (water and ethanol transfer through the RO membrane) which requires diluting further with water issued from wine itself. Though SCC is performed at mild operation temperatures (26–35 °C), this operation takes place in two steps: a first stage of aroma recovery and a second stage of ethanol removal. After ethanol separation, the aromatic fraction is added back to the wine, what results in a long and expensive operation.

Other technologies such as adsorption on zeolites and supercritical fluid extraction are being studied in the literature as possible alternatives to reduce the alcoholic content in beverages. Membrane technologies such as vacuum distillation, pervaporation and dialysis are also proposed to dealcoholize wine.

A membrane-based technology known as evaporative pertraction (EP), also named as osmotic distillation, shows promising results (Diban, el al. 2008) for partial dealcoholization of wine. During the EP process the feed phase (wine) is circulated through a hydrophobic hollow fiber membrane contactor while a second phase/stripping phase (water) flows through the other side of the membrane inside the hollow fiber contactor.

The partial pressure difference of the volatile components e.g. ethanol, between both phases creates the driving force of the process. The main advantages of the technology are: (i) the process can be conducted at room temperature, (ii) low energy consumption (no pressurization of the system is required) and (iii) a cheap and non-hazardous extractant, water, is normally used as stripping phase. The application of EP to get high dealcoholization degrees (> 2%, v/v) causes great sensory modifications on the wine. However, recently, the European Union (EU) regulation has fixed the maximum permitted dealcoholization level at 2% (v/v) (Commission Regulation 2009) for partially dealcoholized wines. Different red wine varieties partially dealcoholized (2%v/v) by EP were found to present an acceptable impact on the sensory properties (Diban et al. 2008). Moreover, the application of membrane contactors to the partial wine dealcoholization did not change significantly the presence of some of the main phenolic compounds and the color and total and volatile acidity of different red wine varieties studied (Gambuti et al. 2011).

In order to state the environmental benefits of obtaining the dealcoholized wine by the ecoinnovative process, the evaluation of the environmental impacts by the reference and by the alternative process is essential. Life Cycle Assessment (LCA) is a powerful tool used for assessing the environmental performance of a product, process, or activity that helps in identifying clean and sustainable alternatives in the process design activity. LCA also allows analysis at the different stages of the product life cycle. The present study focuses on the application of LCA for the evaluation of the dealcoholized wines by the different processes.

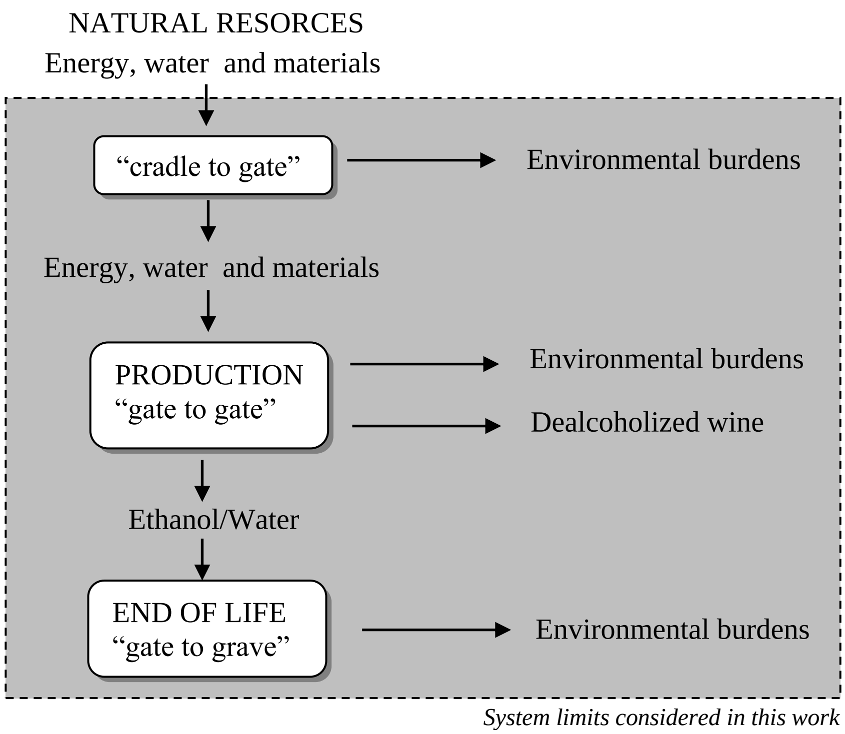

Figure 1. LCA for the environmental performance of dealcoholized wine using the reference and the alternative processes.

2. Methods

2.1. Goal and Scope

The main objective of the work is to quantify the environmental impacts of the conventional dealcoholization process (RO and SCC) and to evaluate the environmental benefits and drawbacks of EP process.

The scope of the assessment was based on the "cradle to grave" life cycle of a product and entailed resources usage and environmental impacts (Figure 1). The LCA started with the "cradle to gate" step where the natural resources water, energy, and materials needed for the manufacture of the resources used in the process were considered. The "gate to gate" step included traditional or the eco-innovative dealcoholization processes. The LCA ended with the "gate to grave" step that consisted of the transfer of the ethanol stream to valorization process or discharge.

2.2. Functional Unit

In this work, the functional unit (FU) was related to the dealcoholized wine, which is objective of the process under evaluation, the dealcoholization process. In order to compare the environmental performance of the traditional and eco-innovative process, the "cradle to grave" LCA of the different manufacture processes must be referred to the same quantity of the final product. The cubic meter of dealcoholized product was established as the most appropriate unit to describe the FU considering the available data. All the emission, consumption of materials, water, and energy during the scenarios are referred to this FU.

2.3. Description of Systems under Study.

In this work has been considered tree scenarios. Figure 1 illustrates the boundaries of the three scenarios under study.

Scenario 1: Evaporative pertraction (EP)

The evaporative pertraction (EP), also called osmotic distillation, is a membrane technology less energy demanding than Spinning Cone Column (SCC) and Reverse Osmosis (RO) as it operates at ambient temperature and atmospheric pressure. The gas transfer of volatile components (e.g. ethanol) is promoted from aqueous solutions through a micro-porous membrane. The wine is circulated through a hydrophobic hollow fiber membrane contactor while a second phase/stripping phase (water) flows through the other side of the membrane inside the hollow fiber contactor. The partial pressure difference of the components, between both phases creates the driving force of the process and permits the ethanol transfer. It has been determined that working under optimum operational conditions could minimize aroma compound losses below 20% during partial wine dealcoholization by EP. Therefore, the low energy consumption accompanied by the acceptable impact on sensory properties of wine make EP a promising technique to remove ethanol from wine at industrial scale (Diban et al., 2013, Lisanti et al., 2012 and Diban et al., 2008).

Scenario 2: Reverse osmosis (RO)

RO is the most used membrane separation process in wine industry for wine dealcoholization. However, the RO membranes allow the permeation of water and ethanol with high operation pressures (60 to 80 bar) which, in addition to considerable energy consumption, brings possible changes of the organoleptic properties of wine (Gonçalves et al., 2013). Two streams are obtained from the original wine: one of permeate containing water and ethanol, and one of retentate with the dealcoholized wine. The wine is slightly heated before the entrance to the membrane module from approximately 15ºC (wine storage temperature) to a temperature of 22-25ºC in order to facilitate the ethanol flux. The decrease in volume resulting from permeation is compensated by adding a large amount of water to the retentate. In this scenario, the water addition has been considered as an external income to simplify the calculations.

Scenario 3: Spinning Cone Column (SCC)

SCC is a two-stage distillation process used industrially for the production of wine with less 1% v/v of ethanol. In the first stage, the aroma compounds are removed at high vacuum conditions (0.04 atm), low temperature (26-28ºC) and collected in a high strength ethanol stream that represents approximately one percent of the original wine volume. The second stage in which ethanol is removed from the base wine is conducted at higher temperatures, usually around 38ºC. After ethanol reduction, the aroma fraction is added to the dealcoholized base wine. A number of ancillary devices are required for the SCC; heat exchangers to warm the product feed to operating temperatures, pumps and condensers to collect the gaseous vapor and collect the removed fraction. Therefore, this means a high capital outlay and operating costs (Belisario-Sánchez et al. 2009).

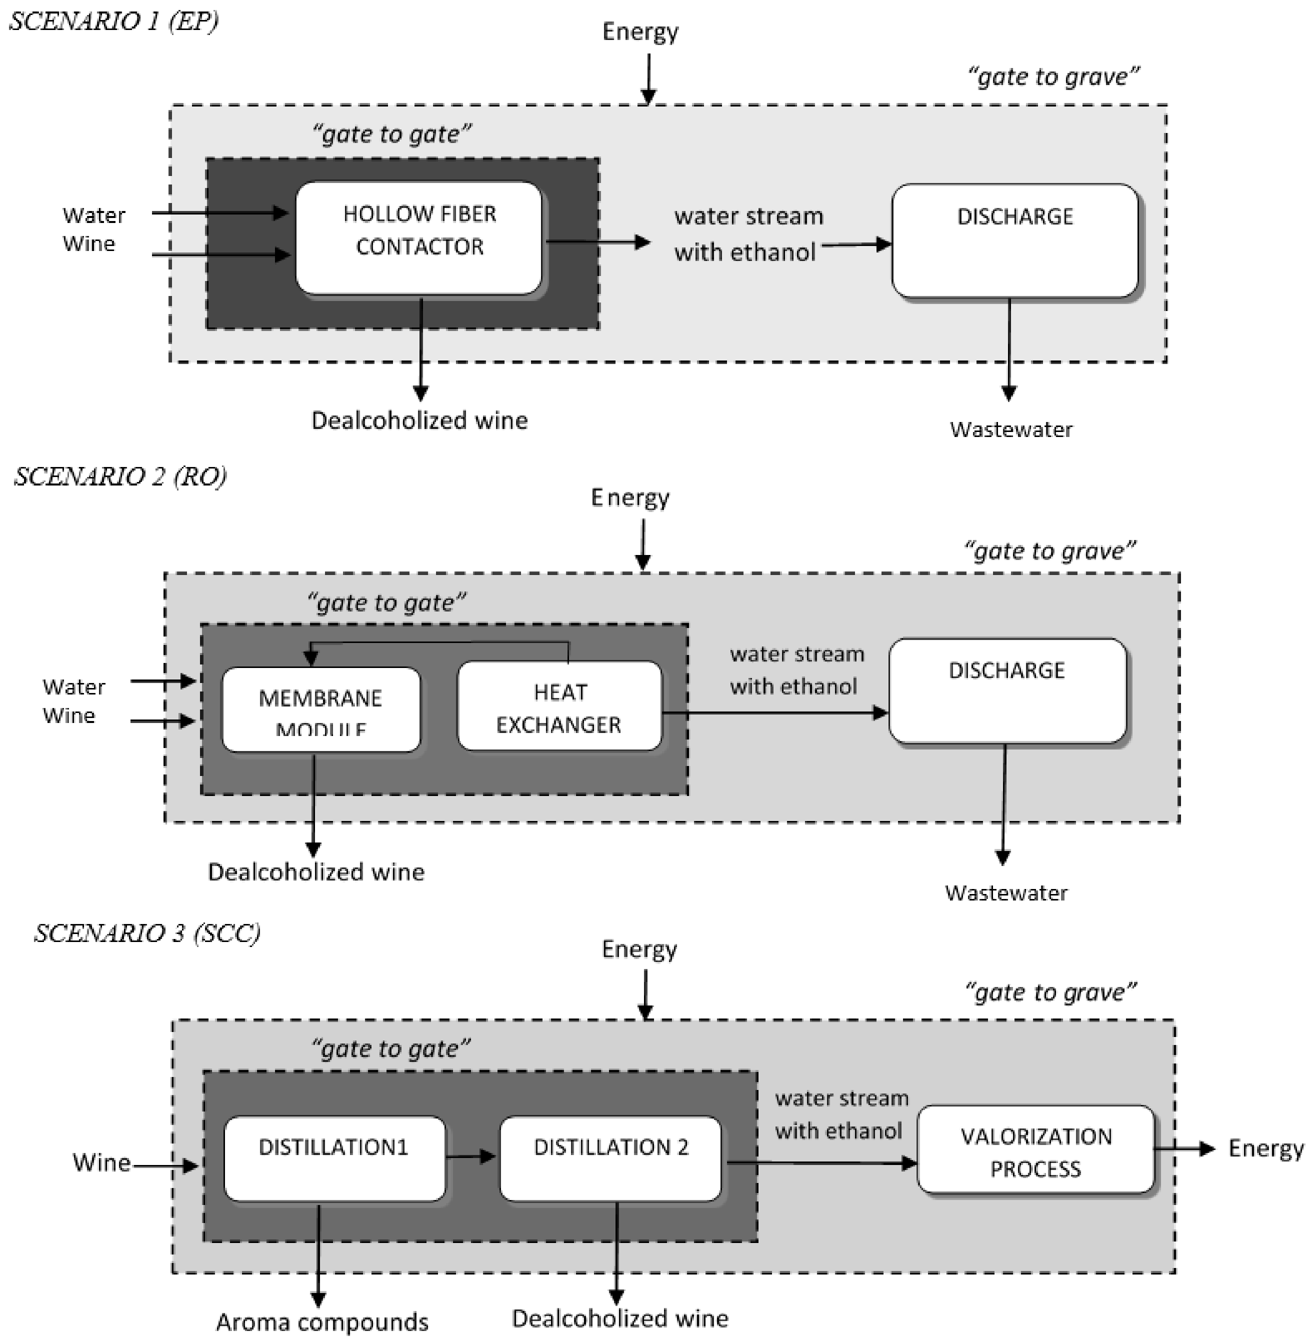

Figure 2. Flow diagrams of the "gate to gate" and "gate to grave" steps of the LCA: Scenario 1-Evaporative Pertraction (EP), Scenario 2-Reverse Osmosis (RO) and Scenario 3- Spinning Cone Column (SCC).

Table 1 collects a comparison of estimative energy and water consumption and the type of waste stream generated by the tree technologies (EP, RO and SCC). The waste generated in SCC is a stream rich in ethanol (<80%) that is usually valorized in waste to energy plants. The waste streams in RO and EP are poor amounts of ethanol (3-4%) that should be possible to recovery by distillation and pervaporation processes. However, these processes have low yields and high energy consumption, so the valorization process it is not technically and economically possible. The limits of BOD and COD established by the Spanish regulations for waste waters allow their discharge to the municipal sewage network.

2.4 Allocation

The total emissions and consumptions associated with dealcoholization process has been allocated to the wine stream. Additionally, waste incineration as valorisation process in the SCC process involves waste treatment and energy production, providing to the system an additional function. This situation was handled through system expansion. In this study the electric power mix of Spain included in the ELCD-PE GaBi database was selected as the technology in the system expansion (PE International 2011).

2.5. Life Cycle Inventory

The life cycle inventory (LCI) was developed using the data given by the dealcoholization unit supplier (AMTA, Alfa Laval), literature, regulation, ELCD-PE database (PE International. GaBi 4.4 Software and Databases for Life Cycle Assessment), chemical analysis, or was estimated by the authors using stoichiometric calculations. Further, Ecoinvent ELCD-PE database were mainly used for building the “cradle to gate” inventory. Table 1 encompasses the energy, water, and materials required in the scenarios, and Table 3 lists the generated outcome in the LCA steps.

Table 1. Comparison of estimative energy consumption, additional raw materials and waste generation between Scenario 1 (EP), scenario 2 (RO) and scenario 3 (SCC).

Dealcoholization process	**Scenario 1 (EP)**	**Scenario 2 (RO**	**SCC**
Energy consumption	Wine pump, water pump (<1 KWh/m3)	Wine pump, heat exchanger (approx. 1 KWh/m^3 for water desalination) (AMTA)	Vacuum pumps, heat exchangers, condensers (120 KWh/m^3) (Alfa Laval)
Raw materials	Water 0.5 m^3/m^3	Water 0.1 m^3/m^3 (Labanda et al., 2009)	-
Waste generation	Water stream with ethanol (<4% v/v) → discharge	Ethanol and water mixture (3.0-1.5% v/v) → discharge	Ethanol stream (80% v/v) → valorization

2.6. Life Cycle Impact Assessment

Most LCA studies apply the conventional impact assessment methods, such as CML 2001 (Guinée et al. 2001), EDIP 97 (Wenzel et al. 1997), or Eco-indicator 99 (Goedkoop et al. 2000). These methods use a set of metrics, which in some cases is hard to understand and makes difficult process comparison (Margallo 2014). In this sense, the use of novel indicators that reduce the LCA complexity and assist the decision making process, will improve the compression of LCA results. In this regard, this work propose a technical way to carry out the environmental sustainability assessment (ESA) of dealcoholization process based on a LCA approach using two main variables: natural resources sustainability (NRS) and environmental burdens sustainability (EBS) (Figure 3). NRS includes the consumption of the final useful resources, such as energy, materials, and water for the considered process and/or product. Land as a NR is currently excluded (Margallo et al. 2014). EBS is given by the environmental sustainability metrics developed by the Institution of Chemical Engineers (IChemE). This set of indicators can be used to measure the environmental sustainability performance of an operating unit, providing a balanced view of the environmental impact of inputs (resource usage), and outputs (emissions, effluents, and waste) (IChemE 2002). In relation to the outputs, a set of environmental impacts to the atmosphere, aquatic media, and land was chosen. The environmental burden (EB) approach was used to estimate and quantify the potential environmental impacts (Garcia et al. 2013). In particular, the environmental impacts were classified in 12 variables grouped into the release to each environmental compartment: air, water, and land. These environmental impact categories chosen are a sub-set of those used internationally in environmental management, selected to focus on areas where the activities of process industry are most significant.

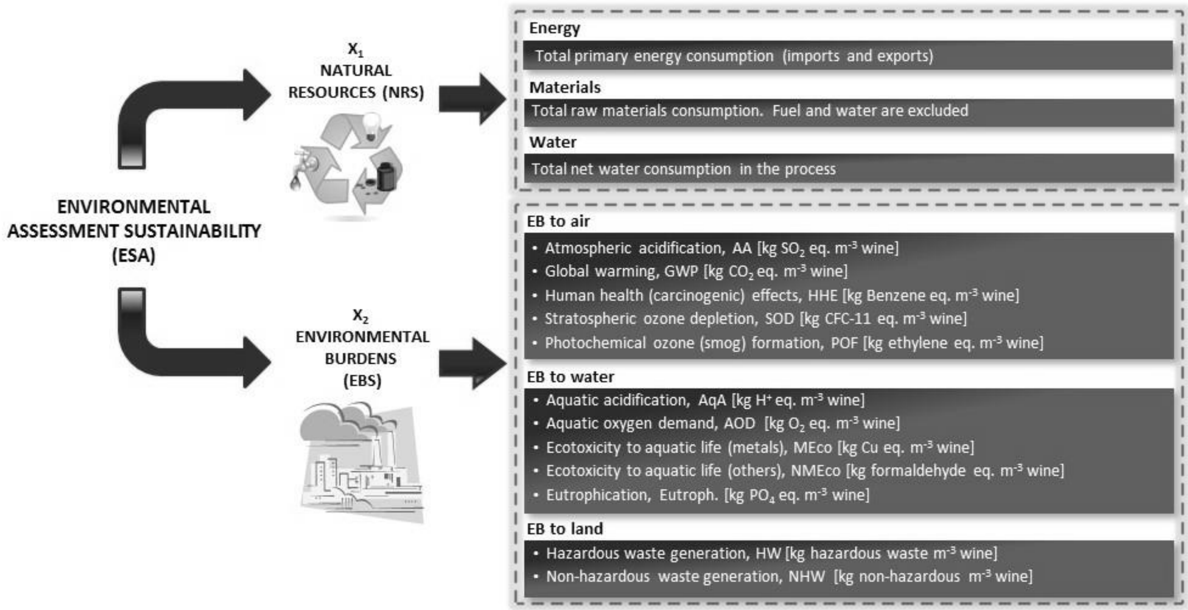

Figure 3. Life Cycle Impact Assessment methodology based on Natural Resources (NRS) and Environmental Burdens (EBS).

However, as natural resources (NR) and environmental burdens (EB) are rarely normalized, a normalization procedure is proposed. The normalization of EB is based on the threshold values of the European Pollutant Release and Transfer Register E-PRTR (E-PRTR Regulation 2006) leading to normalized variables, and a similar procedure based on the values given by Guide of Best Available Techniques of wine production (MTD Vi and Cava 2011) for the NR normalization. The E-PRTR regulation establishes the contaminants for which the European installations must provide notification to the authorities along with the threshold values of those pollutants. The threshold values can be used as an important aid in the normalization process because they provide an overview of the environmental performance of the installation at a European level (Margallo et al. 2014).

This normalization procedure reduces the complexity and allows the decision maker to track the progress towards environmental sustainability and to clarify the optimization procedure at least for the environmental pillar. As illustrated in Figure 1, the LCA considered the use of primary resources energy, water, and materials for obtaining the raw materials needed in the process or "gate to gate" cycle. This step generated some environmental burdens (EBs) caused by the substance upon the receiving environment. Further, the use of the resources needed in the process produced new EBs. The "gate to grave" step refers to the waste stream transfer to end of life process and also produced EBs, which refers to the discharge or energetic valorization. In this step, no materials as natural resources were considered. EBs for emissions to air and to water were estimated using GaBi 4.4. Related to the outputs, a set of environmental impacts to the atmosphere and aquatic media was chosen. The EBs approach was used to estimate and quantify the potential environmental impacts. The EB caused by the emission of a range of substance was calculated by adding the weighted emission of each substance. The weighting factor of the impact is known as the potency factor. In particular, the environmental impacts were classified into atmospheric and aquatic impacts. The EBs for emission to air were divided into atmospheric acidification (AA), global warming (GW), human health (carcinogenic) effects (HHE), stratospheric ozone depletion (SOD), and photochemical ozone (smog) formation (POF). The EBs for emission to water were defined by the aquatic oxygen demand (AOD), ecotoxicity to aquatic life (metals to seawater) (MEco), ecotoxicity to aquatic life (other substances) (NMEco), and eutrophication (Eutroph). The environmental sustainability indicators used in this study had different units depending on the environmental impact. In order to compare the EBs to air and water, the threshold values stated in the European regulation EC No 166/2006 for the main contributors to the environmental impacts were considered as weighting factors to obtain dimensionless impacts indicators. Table 2 shows threshold values from E-PRTR for Normalization and Impact Weighting purposes (Azapagic and Clift 1999, Regulation EC No 166/2006).

Table 2. Threshold Values from E-PRTR for Normalization and Impact Weighting purposes

Environmental Burden (EB)		Threshold Value (kg/year)	No. of substances
EB to air	AA (Kge SO_2)	150000	6
	GW (Kge CO_2)	100 million	23
	HHE (Kge benzene)	1000	52
	POF (Kge Ethylene)	1000	100
	SOD (Kge CFC-11)	1	60
EB to water	AOD (Kge H^+)	50000	14
	Meco (Kge Cu)	50	11
	NMEco (Kge formaldehyde)	50	18
	Eutroph (Kge phosphate)	5000	8

Abbrev: AA, atmospheric acidification; AOD, aquatic oxygen demand; EB, environmental burden; Eutroph, eutrophication; GW, global warming; HHE, human health effects; MEco, ecotoxicity to aquatic life (metals to seawater); NMEco, ecotoxicity to aquatic life (other substances); POF, photochemical ozone (smog) formation; SOD, stratospheric ozone depletion.

3. Results and discussion

The majority of the materials and energy used in scenario 1 (EP) are needed in the "cradle to gate" step to obtain water and primary energy: 100% of the materials and 64.7% of the energy as can be seem in Table 3. The energy used in the "gate to grave" step is neglected. Further, 78.0% of the water demand happens during the "cradle to gate" step. The "gate to gate" contributes to 20.0% of the water usage, mainly as second phase/stripping phase. It is important to note that the water footprint was out of the scope of this work, and only the use of natural resources has been considered when comparing the dealcoholization processes. Similar results has been obtained in scenario 2 (RO), where the natural resources to obtain water and primary energy (100% of the materials and 86.6% of the energy) has been mainly used in the life cycle or the process.

Table 3. Natural Resources Usage (NRS) in Scenario 1 (EP), Scenario 2 (RO), and Scenario 3 (SCC).

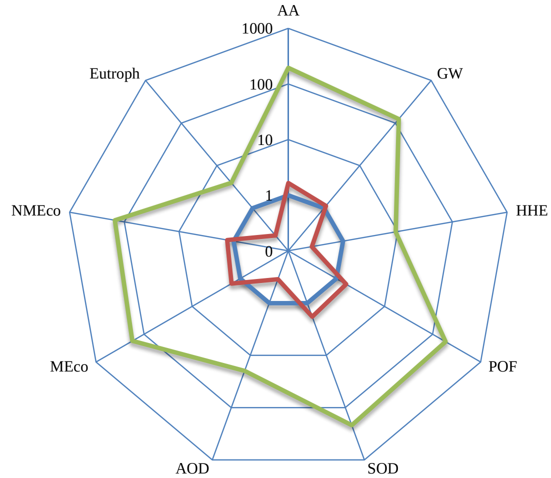
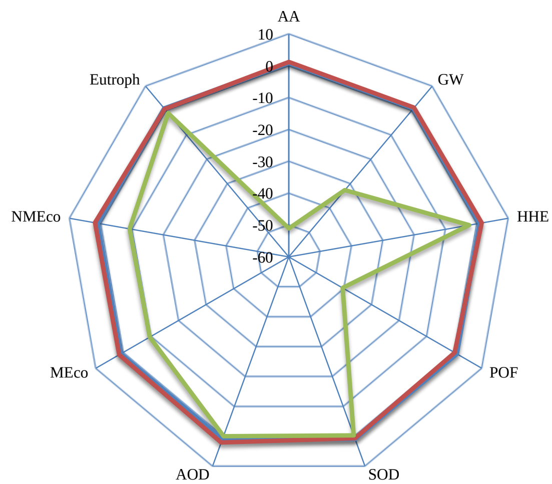
As can be seem in Table 3, energy in the “gate to grave” step of the scenario 3 (SCC) is negative related to the valorization process of the waste stream to energy. It is possible to check that scenario 3 (SCC) has a greater impact on energy consumption in the gate to gate step than RO and EP, but lacks of the necessity of any additional raw material, while RO and EP needs to supply water to perform the alcohol adjustment. Energy consumption appears as a key factor in the wine dealcoholization process. In this sense, energetic impact is environmental friendly when energetic valorization of the waste stream is possible.



(a) “cradle to gate” and “gate to gate”



(b) “cradle to gate”, “gate to gate” and “gate to grave”

Scenario 1 (EP) Scenario 2 (RO) Scenario 3 (SCC)

Figure 4. Weighted and normalized environmental impacts (EBS) of Scenario 1 (EP), Scenario 2 (RO), and Scenario 3 (SCC).

The weighted and normalized environmental impacts referred to the E-PRTR threshold are shown in Figure 4. Figure 4 (a) shows the environmental impact considering “cradle to gate” and “gate to gate” steps. From figure 4 (a) it is possible to check that the total environmental impact of scenario 1 (EP) is similar to scenario 2 (RO). However, the environmental impact of scenario 3 (SCC) increased significantly. The environmental impact to water and to air were mainly based on the contribution of the energy consumption of SCC technology.

From Figure 4 (b) it is possible to note that, when the valorization process of the water/ethanol stream is considered, environmental impacts of the scenario 3 (SCC) are drastically reduced. However, the actual energy valorization of ethanol should account on an additional evaporation of water that has not been considered in the present scenario. This should be further analyzed. According to this, AA, GW and POF impacts decrease about 130%. The environmental impacts of the scenario 3 (SCC) are negative, which is related to the avoided burdens on the generation of energy in the valorization process of the waste stream.

5. Conclusion

The LCA assessment of the dealcoholization practices demonstrated that the environmental profile of the “cradle to gate”, “gate to gate”, and “gate to grave” steps are directly related and that the “cradle to gate” and “gate to grave” (when valorization process in considered) steps of the scenarios contributed significantly more to the environmental impacts than the “gate to gate” step. The production of primary energy has the most important contribution to the environmental impact of the scenarios.

In this work, the reduction of the environmental impact of the partial dealcoholization of wines was obtained by reducing energy consumption. However, other measures may be implemented to the “cradle to gate” and “gate to grave” in order to further reduce the environmental impact of the overall LCA of the EP process. These measures may consist of some valorization process, avoiding the discharge of the waste stream. This work concludes that the eco-innovative dealcoholization EP process is positive in terms of resource usage and EB.

Finally, this work shows that future research should focus on evaluating the economic and social costs related to the eco-innovative dealcoholization process, in order to assess the sustainability of the process.

ABSTRACT

In this study, cheese produced in Switzerland was compared to imported cheese from the main countries of origin, France, Italy, and Germany. The environmental impacts of cheese production were dominated by milk production. The average Swiss milk production was characterized by a low input of concentrates and the lowest milk yield per cow. Despite this lower milk yield, the environmental impacts of Swiss milk were lower or similar to milk produced in the other countries, with the exception of land occupation. The good growing conditions for grassland and a high quality of roughage allow to produce milk at moderate intensity level in an efficient way. The study showed that there is no simple relationship between the amount of concentrates, milk yield and environmental impacts, instead the results depend on the whole production system, and site conditions can influence the environmental impacts significantly.

Keywords: milk, cheese, imports, concentrate feed, milk yield

1. Introduction

1.1. Background

Milk is the most important product of Swiss agriculture and also dominates its environmental impacts. In 2012, 21 % of the total agricultural production value in Switzerland was generated with milk (BLW 2013). Only 12 % of Swiss milk was directly consumed, whereas 42 % was transformed to cheese (BLW 2013). Since 2007, a free-trade agreement is effective between Switzerland and the EU, leading to increased imports and exports of cheese in Switzerland. In an effort to ensure the future ability of Swiss agricultural products to compete with those from abroad, the food industry, supported by the Federal Government, has developed a quality strategy aimed at setting the environmental and quality credentials of Swiss farm products apart from those of other countries. There is, however, a shortage of data which would allow a systematic and scientifically sound comparison of the environmental impact of foodstuffs from different countries of origin. Furthermore, production conditions as well as the production systems within a country vary widely. For a sound decision making on how to improve the environmental impacts of Swiss products, there is a need for reliable and comparable data on the environmental impacts of agricultural products originating from different countries.

1.2. Goal and scope definition

The aim of this study was to generate inventories of cheese produced in Switzerland and abroad, and to compare the environmental impacts of Swiss and imported cheese. Cheese produced in Switzerland was compared to cheese from the main countries of origin, France, Italy, and Germany. The Swiss production was differentiated according to the region (lowlands, hills, and mountains) and to the production system (grassland based with barn feeding, full grazing system and high-yielding system with higher concentrate input). To be able to distinguish between differences in the agricultural production and differences occurring in downstream stages (e.g. different transport distances), life-cycle-analyses were conducted both at the farm gate and at the point of sale. For the comparison at the farm gate and at the point of sale the functional units were 1 kg milk and 1 kg of cheese, respectively.

2. Methods

The environmental impact of the products investigated was determined using SALCA (Swiss Agricultural Life Cycle Assessment; Nemecek et al. 2010), the life cycle assessment method developed by Agroscope. SALCA comprises a life cycle inventory database for agriculture, models for direct field and farm emissions, a choice of methods for impact assessment, calculation tools for farming systems (farm and crop level), an evaluation concept, and a communication concept for the results.

The following environmental impacts were examined: non-renewable energy demand, global warming potential, ozone formation potential, demand for phosphorus and potassium resources, land competition, deforestation, water use WSI (water use in m^3 weighted with a "water stress index" which takes account of water scarcity in the different countries), eutrophication potential, acidification potential, terrestrial ecotoxicity potential, aquatic ecotoxicity potential and human toxicity potential. The impact assessment methods used as well as the models used to calculate direct emissions are described in Nemecek et al. (2010). A rating system was used to assess the differences in individual results. It was not possible to examine the environmental impact of soil quality or biodiversity due to a lack of the required data. The differences between the impacts were evaluated by assessment classes, which differed among the impact categories.

2.1. System boundaries

For the agricultural production, all on-farm activities and external inputs (e.g. feedstuff, diesel, mineral fertilizers) for milk production were considered, as well as the necessary infrastructure (buildings and machinery) and the usable agricultural area needed (Figure 1, A).

For cheese production, additionally to milk production transports to the cheese dairy, processing and transports to the point of sale in Switzerland were considered (Figure 1, B). Cheese processing generally took place in the country of origin and the finished cheese was transported to the point of sale in Switzerland.

2.2. Production inventories

The Swiss milk production systems were derived from model farms of a former project (Hersener et al., 2011) and refer to an average Swiss production. The foreign inventories were newly created on the basis of the Swiss systems, the most important key figures for livestock production being adapted to the specific country. If no data were available, Swiss data were extrapolated on the basis of the number of dairy cows. Table 1 shows an overview of the most important production inventories of the specific countries. The Swiss data represent a national average; the foreign systems refer to the most important production systems (typical) within the country under consideration.

An economic allocation was conducted between milk and meat. 87 % of the inputs were allocated to milk production and 13 % to meat production. In order to ensure comparability, Swiss data were used also for the foreign systems. Background data were derived from the SALCA database (Nemecek et al., 2010) and ecoinvent V2.2 (ecoinvent Centre, 2010).

Share of basic ration in total ration	%	89	72	76	62

2.3. Downstream processes

For all systems analyzed, data about cheese production were derived from Schmid et al. (2010). The cheese dairy in this study represents the average cheese production in artisanal dairies in Switzerland. Due to the lack of more country-specific data, this data was also used for the foreign systems; only the electricity mix was adapted to the country in question. An economic allocation between cheese and its by-products (whey) was carried out at which 85 % of the environmental impacts were allocated to cheese.

For the transports, average transport distances from the most important milk producing regions of each country (after Hemme et al., 2011) were considered. Table 2 shows an overview of the means of transport and transport distances assumed.

Table 2. Means of transport and transport distances for Swiss and imported cheese

Country of origin, route of transport	Means of transport	Distance (km)
Switzerland		
Farm – cheese dairy (milk)	lorry 3.5-20 t, fleet average Switzerland, refrigerated	20 [1)]
Cheese dairy – distribution center (cheese)	lorry 20-28 t, fleet average Switzerland, refrigerated	100 [2)]
Distribution center – point of sale (cheese)	lorry 3.5-20 t, fleet average Switzerland, refrigerated	25 [2)]
Germany		
Farm – cheese dairy (milk)	lorry >16 t, fleet average Europe, refrigerated	150 [3)]
Cheese dairy – distribution center (cheese)	lorry >16 t, fleet average Europe, refrigerated	650 [4)]
Distribution center – point of sale (cheese)	lorry 3.5-20 t, fleet average Switzerland, refrigerated	25 [2)]
France		
Farm – cheese dairy (milk)	lorry >16 t, fleet average Europe, refrigerated	150 [5)]
Cheese dairy – distribution center (cheese)	lorry >16 t, fleet average Europe, refrigerated	800 [4)]
Distribution center – point of sale (cheese)	lorry 3.5-20 t, fleet average Switzerland, refrigerated	25 [2)]
Italy		
Farm – cheese dairy (milk)	lorry >16 t, fleet average Europe, refrigerated	150 [5)]
Cheese dairy – distribution center (cheese)	lorry >16 t, fleet average Europe, refrigerated	400 [4)]
Distribution center – point of sale (cheese)	lorry 3.5-20 t, fleet average Switzerland, refrigerated	25 [2)]

3. Results

3.1. Agricultural production

At farm gate level Swiss milk production generally scored more favorably or was within the same range as milk production abroad. The only exception was land competition, where the Italian system was lower. Table 3 gives an overview of the environmental impacts of the different milk production systems analyzed.

The higher use of concentrates in the foreign systems led to a higher demand in phosphorus and potassium resources and to considerable higher values for deforestation, which was caused by the higher use of soya in the feed ration. Additionally, the foreign systems had a higher water use, which was a direct consequence of the higher irrigation during the cultivation of the concentrates used. Only for land competition one foreign system (Italy) achieved lower values than the Swiss system. This was due to its concentrate based ration with a very low share of grass, which leads to a high energy yield per hectare land occupied. For all other environmental impacts, the higher milk yield through increased use of concentrates in the foreign systems did not result in lower environmental impacts. On the contrary, the energy required to produce one kilogram of milk increased with the milk yield per cow due to the purchase of extra feed and the use of energy carriers on the farm, both of which were higher in foreign systems than in Switzerland (Figure 2). In addition, the higher restocking rates in the foreign systems lead to a higher impact of the purchased animals.

Regarding the global warming potential, the higher milk yields in the foreign systems led to lower methane emissions; however, for the total global warming potential there was no difference between the systems analyzed. The lower methane emissions in the foreign systems were compensated by higher CO_2-emissions caused by the higher energy demand (Figure 3). The same mechanism was found for ozone formation, where the lower methane emissions were compensated by higher nitrous oxide emissions.

Table 3. Overview of the environmental impacts per kg milk of milk production in Switzerland (Milk CH), Germany (Typ. Milk DE), France (Typ. Milk FR) and Italy (Typ. Milk IT). WSI: water stress index, N: nitrogen, P: phosphorus

Environmental impact	***Unit***	**Milk CH**	**Typ. Milk FR**	**Typ. Milk DE**	**Typ. Milk IT**

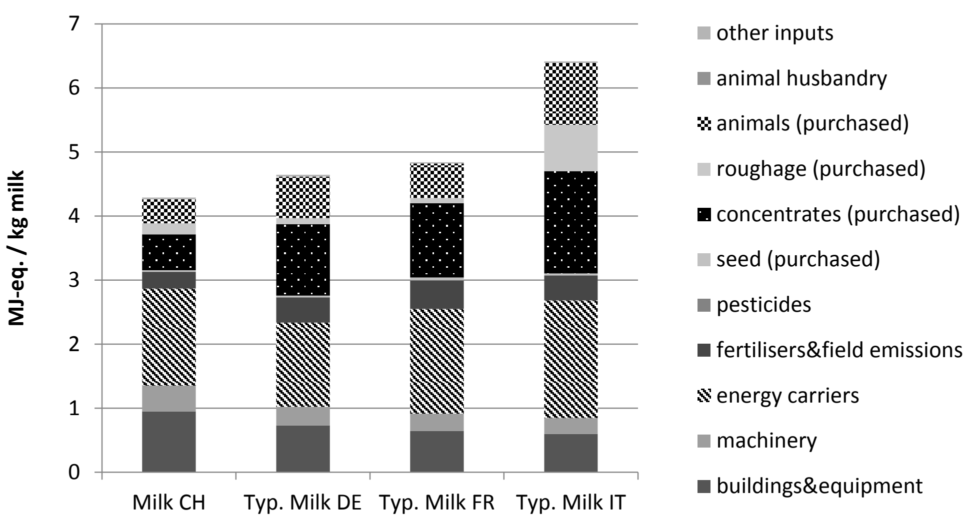

Figure 2. Energy demand of the different milk production systems analyzed.

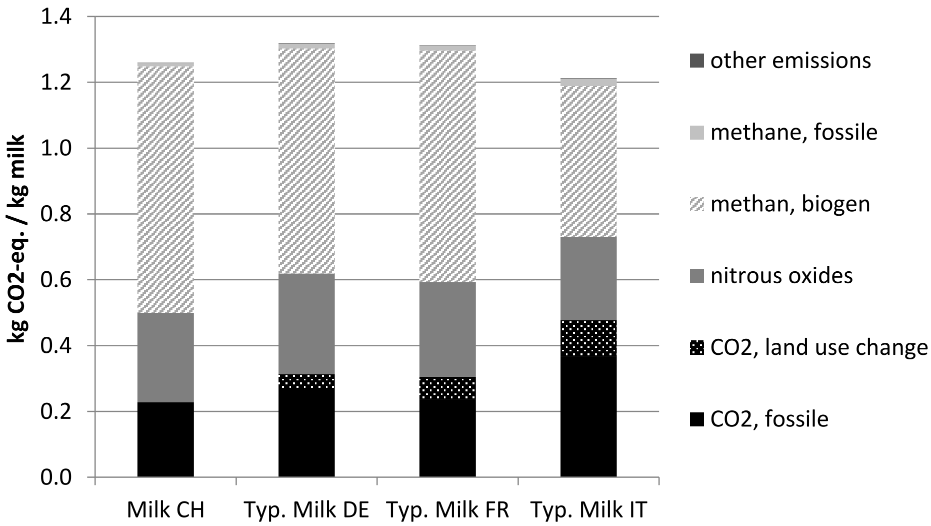

Figure 3. global warming potential of the different milk production systems analyzed

For the nutrient related impacts, the foreign systems had a higher aquatic eutrophication potential from phosphorus compounds. This was mainly due to higher field emissions during cultivation of the feedstuff used. The German system was also higher for the other nutrient related impacts (terrestrial eutrophication potential, aquatic eutrophication potential phosphorus and acidification potential). In Germany, the fertilization level on the agricultural area used was highest; in particular there was the highest amount of slurry applied per hectare, which lead to high emissions of ammonia.

For the toxicity related impacts, there were no relevant differences between the systems analyzed. This was also due to the high uncertainties in this field, so that relatively big differences are still not considered as being relevant. Only for the terrestrial ecotoxicity potential the German system had higher impacts than the Swiss system.

Comparing dairy systems within Switzerland showed that mountain production had generally higher impacts than lowland production due to less favorable conditions like lower yields, longer winter feeding periods and steep slopes in the mountains. Grassland based dairy systems with moderate milk yield had lower ecotoxicity impacts, lower use of mineral resources (P and K) and lower contribution to deforestation than the standard dairy system, but similar or higher impacts regarding the other categories.

3.2. Results at point of sale

The environmental impacts per kilogram of cheese followed the same pattern as the environmental impacts per kilogram of milk, since the agricultural phase dominated the environmental impact of cheese production up to the point of sale. The downstream process with the strongest influence was the cheese dairy, followed by the transports. The impact of the distribution center was negligible.

4. Discussion

The good growing conditions for grassland with abundant precipitation and a high quality of roughage in Switzerland allow to produce milk at moderate intensity levels with small amounts of concentrates in an efficient way. A higher use of concentrates with the resulting higher milk yield in the foreign systems did not lead to an improvement of the environmental performance of those systems. On the other hand, the analyses of modeled milk production systems with different share of grass in the feed ration within Switzerland showed a lower performance for the systems with a high share of grass in the diet.

This shows that when comparing different feeding strategies, not only the directly affected parameters such as feed intake and type of feed should be considered, but all relevant production parameters as well as site conditions must be included. The impact of a feeding strategy on health parameters and service life of dairy cows are particularly important. The foreign systems consistently exhibited a lower service life and a higher replacement rate than the Swiss systems, which significantly contributed to the higher energy requirement.

For the methane related impacts, this study revealed no difference between the Swiss and the foreign systems. However, methane emissions strongly depend on the equations used to calculate the emissions from enteric fermentation, as shown by Hagemann et al. (2011). According to the method of the Intergovernmental Panel on Climate Change (Eggleston et al. 2006) used in this study the methane emissions increase proportionally to the gross energy intake of dairy cows. The statistical analysis of a large number of published experimental data carried out by Ramin & Huhtanen (2013) confirms that gross energy intake is the main driving factor of methane emissions. However, the quality of the estimate could be improved by including several characteristics of the feed ration. Further studies are needed to estimate the methane emissions of grass based systems compared to concentrate based systems.

Two other essential parameters for the environmental effects of milk production are the manure management and manure spreading. While a high proportion of manure in the total fertilization has a positive impact on energy demand as well as on resource use phosphorus and potassium, there is a negative influence on the nutrient-related environmental impacts due to the slurry-related ammonia emissions. The modeling of the individual milk production systems revealed to be particularly difficult in this regard, as for the individual countries only few data on manure spreading on crop level was available and there was a complete lack of information about application dates. The management of the on-farm agricultural area for the production of roughage in the foreign systems is therefore partially modeled with Swiss data. Including country specific data on manure management and manure spreading could change the results in particular for the nutrient related impacts.

Another difficulty is the high variability in the milk production systems within a country. The Swiss results showed that the environmental impacts of different milk producing systems within a country can vary significantly. Guerci et al. (2013) compared twelve different milk producing farms in Denmark, Germany and Italy and analyzed their energy demand, global warming-, acidification- and eutrophication potential per kilogram of milk produced. He stated a significant positive effect of a high proportion of grassland on energy use, global warming potential and acidification. However, as only 12 farms were assessed, a more general analysis of the relation between the production and the environmental impact has to be handled with care, especially as the study revealed huge variability in environmental impact within the group of farms analyzed (Guerci et al. 2013).

To compare the milk production of a country with the one of another country, all milk production systems existing in a country would need to be modeled to form the respective national average. The milk producing systems in this study refer to a typical system and – except in the Swiss case – not to the average milk production of the country concerned. This must be considered when interpreting the results. Nevertheless, this study shows which parameters are important for the environmental impact of milk production and provides important information on existing differences between the countries studied.

5. Conclusion

The environmental impacts of cheese production are dominated by milk production. The study showed that there is no simple relationship between amount of concentrates, milk yield and environmental impacts; instead the results depend on the whole production system. Site conditions can influence the environmental impacts significantly: In Switzerland, the good growing conditions for grassland with abundant precipitation and a high quality of roughage allow to produce milk at moderate intensity level with small amounts of concentrates in an efficient way.

ABSTRACT
Water use is a hot topic worldwide in sustainability assessment. However, this issue is not well evaluated in traditional life cycle assessment (LCA). On the other hand, water footprint (WF) is a methodology that has been developed to give a more complete overview in the water use of particular products (Hoekstra et al. 2011). In this sense, this study evaluated the blue and green WF of three different milk production systems in the southern region of Brazil. To calculate the WF we based on primary data and several data from literature. The results showed that milk from confined feedlot, semi-confined feedlot, and pasture-based systems had blue WF of 19, 11, and 7 liters/kgECM, respectively, and green WF of 1478, 2209, and 1584 liters/kgECM, respectively. We could conclude that higher pasture productivities and/or feed conversion ratio should be sought in all systems, in order to reduce the green (and overall) WF.

Keywords: milk, water footprint, LCA, Brazil

1. Introduction

Water is a renewable resource, although its availability in good environmental quality is an important issue worldwide, especially in dry areas. In this sense, water use becomes an important issue for environmental sustainability. There are several ways to evaluate the environmental sustainability of products, and the most predominant is Life Cycle Assessment (LCA) (Dewulf and Van Langenhove 2006). Even though some efforts have been made in recent years regarding water use impacts in LCA (Bayart et al. 2010; Kounina et al. 2013; Pfister et al. 2009), in most traditional LCA studies it is not well evaluated (Milà i Canals et al. 2009), especially when dealing with food products.

Another environmental sustainability methodology, called water footprint (WF), is able to deal with water use in a more complete way. WF is a methodology that has been developed to give a more complete overview in the water use of particular products (Hoekstra et al. 2011). The combination of LCA and WF for sustainability assessment has already been discussed in literature (Boulay et al. 2013; Jefferies et al. 2012; Milà i Canals et al. 2010; Milà i Canals et al. 2009).

Milk is a product from the agricultural sector, which has (as any other product) a certain environmental footprint. In this sense, its environmental impacts have been studied in many reports and scientific publications, although not much has been done for milk in Brazil.

A LCA of milk produced in the southern region of Brazil has been recently studied (Léis 2013), but it did not consider water use and water use impacts. Therefore, the objective of this study is to account for the blue and green WF of three different production systems in the southern region of Brazil. In this sense, it can complement the aforementioned study, providing an additional report for a more complete environmental profile of that product.

2. Methods

This study evaluated three different milk production systems in the southern region of Brazil (Parana and Santa Catarina states).

The first system is a confined feedlot system, and it is located in the city of Mandaguari, north of Parana state. In this system the cows solely receive animal feed in the trough. The feed is composed by cottonseed, silage, commercial feed concentrate (cottonseeds, maize grains, wheat bran, soybean hulls, premix), hay, minerals, premix and other cattle foodstuffs.

The second system is a semi-confined feedlot system where the cows are fed in the trough and also through grazing. Apart from the grazed material, the feed is composed by silage, citrus pulp (byproduct of the orange juice industry), brewers spent grain (byproduct of the beer industry), commercial feed concentrate (cottonseeds, maize grains, wheat bran, soybean hulls, premix), minerals, premix, forage and other cattle foodstuffs. This system is located in the city of Porto Amazonas, east of Parana state.

In the third system the cows are mainly fed through grazing, but some feed is still provided in trough. This feed is composed by maize, soybean meal and mineral salts. This system is located in Campos Novos, central region of Santa Catarina state.

The functional unit was 1 kg of energy corrected milk (ECM) at the farm gate. The life cycle inventory was based on Léis (2013), in which a LCA was performed with focus on other environmental impact categories, as eutrophication and carbon footprint.

We calculated the WF based on Hoekstra et al. (2011). For blue water we considered estimations of animal water consumption, based on Araújo et al. (2011), which elaborated an equation of water consumption based on dry matter consumption, milk production, salt consumption, and minimum daily average temperature. We also accounted for the consumption of water from cleaning processes at dairy farms, based on Guerra et al. (2011), considered to be $25L/m^2$. With that, and knowing the area used for milk production in all three systems, we were able to calculate the direct use of blue water. For the indirect consumption of blue water, i.e., the blue water consumed to produce the feed ingredients, for instance, we used data based on literature (mainly the ecoinvent (2010)).

None of the ingredients consumed by the cows were considered to be produced in irrigated systems. According to IBGE (2006), in Brazil only 8% of cotton, 6% of maize, 4% of soybean, and 7% of barley are produced in irrigated systems. Therefore, due to representativeness, we assumed that those products were produced in non-irrigated systems.

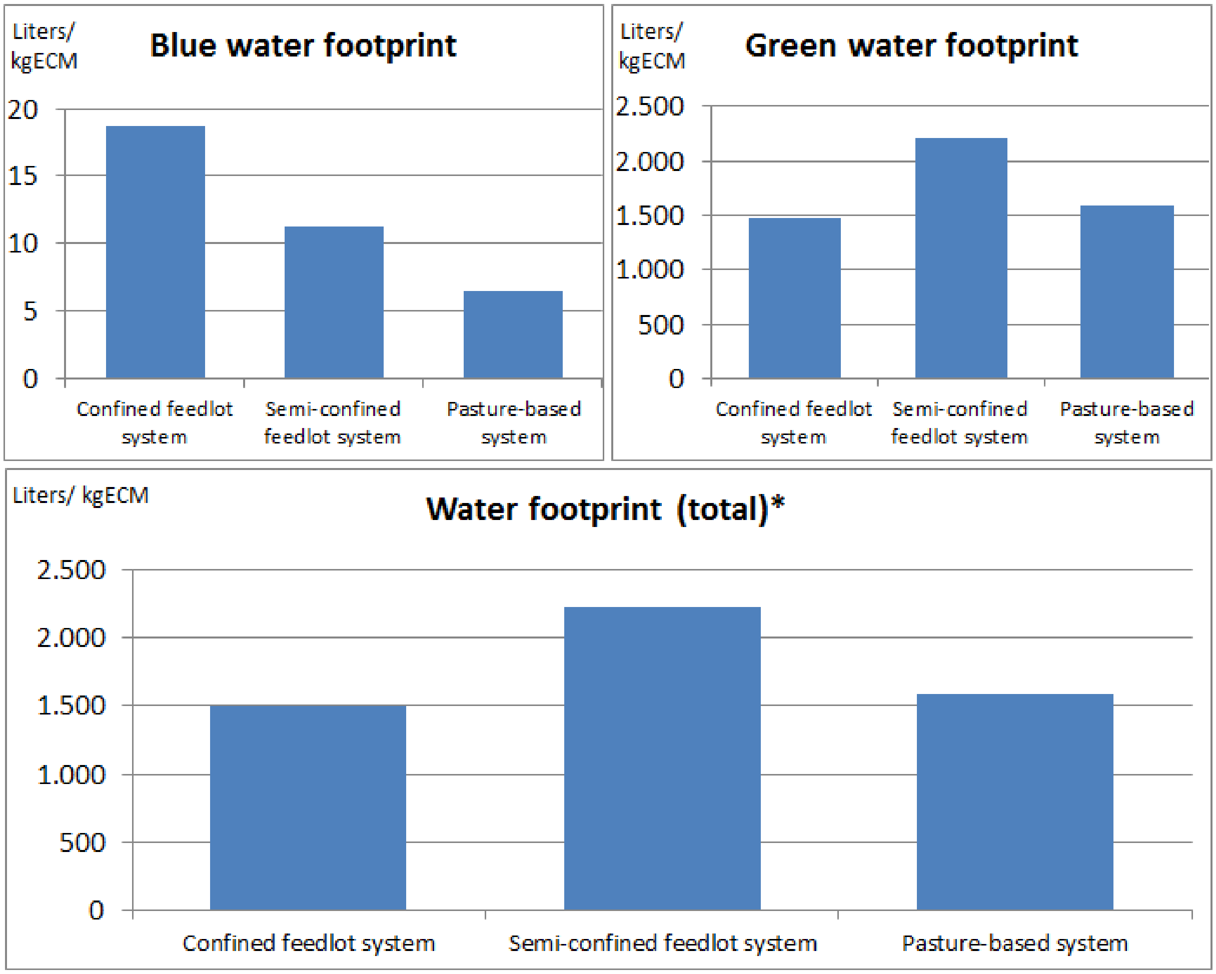
For green water we accounted the water content of the feed ingredients and grass (from grazing), based on data from literature (Brehmer 2008; Phyllis 2011). We also accounted for the water evapotranspired by these feed ingredients and grass (from grazing), also based the data on several other studies, which were from other areas of Brazil due to lack of available data and also lack of information on the origin of the feed ingredients: (1) For maize the evapotranspiration data was based on Albuquerque and Resende (2009); (2) for grazing the evapotranspiration data was based on Uda (2012); (3) for soybean the evapotranspiration data was based on Oliveira et al. (2011); for wheat the evapotranspiration data was based on Paiva et al. (2011); (4) for barley the data was based on Rodrigues et al. (2005); and for cotton the data was based on Pereira et al. (2013).

Even though the water footprint also considers gray water, we preferred to focus on green and blue water in this study, since the two latter represent the water consumed, the aspect that lacks on Léis (2013). Gray water represents rather an emission, and we think that other impact categories in the LCA study from Léis (2013) can better represent environmental impacts (e.g. eutrophication potential).

3. Results and Discussion

The results showed that milk from the confined feedlot, semi-confined feedlot, and pasture-based systems had blue WF of 19, 11, and 7 liters/kg ECM, respectively, and green WF of 1478, 2209, and 1584 liters/kg ECM, respectively (Figure 1). These results showed that semi-confined feedlot milk had the highest total WF, due to higher green WF results. This was mainly due to the high amount of brewers spent grain (byproduct of the beer industry) and maize in the feed composition.

Considering that blue WF is the traditional way to account for water use in LCA, it is interesting to note that even though confined feedlot milk had the highest blue WF, the bottleneck on (total) WF was found in the green water, with much higher results than blue WF. Therefore, a traditional LCA could have pointed out different conclusions from WF, as showed in this study (in traditional LCA confined feedlot milk would be the worst system for water use, while in WF system the semi-confined feedlot is the worst system).



* Except for gray water footprint

Figure 1. Blue water footprint, green water footprint, and the total water footprint for three milk production systems from southern region of Brazil.

Mekonnen and Hoekstra (2010) accounted for the green, blue and gray WF of several animal products from several countries. For milk produced in Brazil, the values ranged from 22-42 liters/kg of milk for blue WF, while for green WF the values ranged from 1046-1254 liters/kg of milk. It is possible to observe that the values for blue WF are similar to our system A, although it can be considered much higher when compared to our systems B and C. On the other hand, the green WF from our research (the three systems) are higher than from the values presented in Mekonnen and Hoekstra (2010). Our system A and C had values up to 51% higher, while system B had values up to 111% higher. The reasons for these discrepancies might be differences in amount of feed consumed (blue WF), percentages of feed consumed from irrigated systems (blue WF), amount of grazed land area (green WF), but also differences in evapotranspiration values, differences in the system boundaries considered, uncertainties on data collection, among others. The values presented in Mekonnen and Hoekstra (2012) and Mekonnen and Hoekstra (2010) for global average WF were between 790 and 1087 liters/kg of milk, for green WF, and between 49 and 82 for blue WF. Comparing our values with World average, we can see that blue WF were lower in our research, while our systems had higher values for green WF. The reasons for these differences can be the same as presented before, but for green WF it may also be due to climatic differences (e.g. higher temperatures in Brazil cause higher evapotranspirations).

The expansion of the system boundaries seems to be an important step on the WF methodology. For instance, the system boundaries for background blue WF can be exhaustive, if using life cycle inventory (LCI) databases (as ecoinvent database). On the other hand, the system boundaries have to be consistent among the different WF, and so far there is no LCI database that provides data on green or gray WF, most probably due to the complexity and local specificities of their calculations.

4. Conclusion

In this work we estimated the blue and green WF of three milk production systems in southern region of Brazil. Even though most of the data used to calculate the WF was based on secondary data, it was possible to observe possible hotspots (increase productivities of grains used in feed and/or feed conversion ratio), and to identify the systems with lower WF.

This was one of the first studies that published data on WF of milk production systems in Brazil. In comparison to other data from literature, we could observe that our values were higher for green WF, while blue WF had much lower results. These differences could be due to low amount of irrigated crop production systems considered, due to uncertainties on data collection, among other reasons.

ABSTRACT

In Life Cycle Assessment, agricultural fields have been defined as part of the technosphere. In order to cover environmental damage to fields during crop occupation and assess their reversibility, the different agricultural practices need to be covered by the land use impact category. The main goal of our contribution is to test the applicability of ongoing land use methods to assess agricultural practices, as well as provide recommendations for further research. Among existing complementary proposals of impact characterization models, we have chosen those, which could provide spatially explicit information on biodiversity damage expressed as species richness (relative or absolute number) and ecosystem services represented by net primary production depletion or biotic production potential. We have applied them in a case study of corn production comparing extensive and intensive management. Improvement of characterization factors for different land use intensity types and better definition of boundaries are main needs for further research.

Keywords: Biodiversity, Biotic Production Potential, Erosion, Organic matter, Technosphere

1. Introduction

In Life Cycle Assessment (LCA) agricultural studies, cropland is usually defined as part of the technosphere, and agricultural practices are assessed in relation to their effects on the surrounding environment (e.g. ecotoxicity, eutrophication). However, crop management affects the cropland itself as a natural resource. It can be argued that good management is reflected in the yields obtained, the quality of the crop and of subsequent ones. But a longer term vision, as well as the recognition of the importance of soil as provider of ecosystem services is necessary. Therefore, damage to the technosphere by the different agricultural practices needs to be covered by the land use impact category (or reconsider agricultural fields as part of ecosphere).

Land use impact assessment is a complex issue due to region specificities as well as the different nature of damages involved. The International Reference Life Cycle Data System Handbook (EU-JRC-IES 2011) and the ENVIFOOD Protocol (Food SCP-RT 2013) recommend cautiously (level III) the method that considers soil organic matter (SOM) (Milà i Canals et al. 2007a), because it is the most appropriate soil-quality indicator among the existing approaches to assess land-use impacts at midpoint level. No method was recommended for use at endpoint level; ReCiPe method can be used as an interim method.

Nowadays a lot of work is being developed in order to provide operational and globally-applicable methods to asses land use impacts in the framework of LCA. Milà i Canals et al (2007b), proposed that land use impact category should be assessed in terms of impact on biodiversity, impact of biotic production and impact on the regulating functions of natural environment. Within the framework of UNEP/SETAC Life Cycle Initiative a flagship project has been launched in 2012 to provide guidance and create consensus for assessing, among other LCIA indicators, land use impacts on biodiversity (Jolliet et al., 2014).

An updated version of the soil organic matter approach allows to use the change in soil organic carbon as an indicator for impacts on biotic production potential (BPP) (Brandão and Milà i Canals 2013), which in fact can also be considered as a measure of supporting services of ecosystems. Similarly Núñez et al (2013) developed a method using a growth-based value potential: net primary production depletion (NPPD) to assess the effect of soil erosion on ecosystem quality.

De Baan et al (2013) developed regional Characterization Factors (CFs) for land-use occupation and transformation using the species-area relationship model to assess the number of species that might be driven to extinction due to different land use types including agriculture.

More recently Elshout et al (2014) derived CFs based on findings of previous studies to assess agricultural land occupation on relative species richness. They provided midpoint CFs for different crops and differentiated between conventionally and low-input managed crops.

The main goal of our contribution is to test the applicability of ongoing methods to assess different agricultural practices focusing on endpoint damage, as well as provide recommendations for further research. We have applied them in a case study developed in the frame of a European LIFE project (F4F 2013-17), conducted in order to reduce the environmental consequences of manure livestock management.

2. Methods

2.1. Case Study

An LCA was carried out to compare intensive and extensive corn production. Crops were grown at the Mas Badia experimental station (La Tallada d'Empordà, Girona, north-east Spain) under different agricultural practices. Intensive corn production includes the use of chemical fertilizers and pesticides. Extensive corn production includes organic manure application and the use of catch crops as an intermediate crop to catch excess nitrogen and posterior treatment as a co-substrate in a biogas plant. In addition, growing catch crops are considered as a service to prevent erosion. We performed an attributional simplified LCA, where the functional unit was 1 ha. The life cycle stages included until farm-gate were: seeds production, manure, inorganic fertilizers, diesel consumption in labor operations and pesticide treatment. Livestock farming and posterior treatment for biogas plant are out of the scope of this study (they will be included in a subsequent step). In this paper we just focused on the land use assessment of foreground crops. A year period with one (intensive) or two annual crops, ryegrass and corn (extensive) are set as examples. Ryegrass was used as a catch crop previous to silage corn production. Table 1 shows relevant inventory flows of agricultural practices for each crop.

Table 1. Relevant inventory flows for ray-grass and corn.

LCI	**catch crop**	**corn extensive**	**corn intensive**
Seeds	26.70 kg·ha^{-1}	80000 u·ha^{-1}	80000 u·ha^{-1}
Date of sowing	Sept, 30th	Apr, 2nd	Apr, 2nd
Date of harvesting	Mar, 20th	Set,15th	Set,15th
Moisture content at harvesting	79.4%	78%	78%
Irrigation	--	2833 m^3·ha^{-1}	2833 m^3·ha^{-1}
Manure		170 kg·ha^{-1}	
N fertilizer	--		250 kg·ha^{-1}
P fertilizer	--		100 kg·ha^{-1}
K fertilizer	--		100 kg·ha^{-1}
Herbicide treatment	--		3.5 L·ha^{-1}
Tractor hours for different operations	7.7 h·ha^{-1}	12.6 h·ha^{-1}	12.6 h·ha^{-1}

2.2. Impact methods

Among existing complementary proposals of LCIA, we have chosen those for which inventory information was available and impact assessment provides information about agricultural impacts close to endpoint level for our specific area of study.

Following ILCD and Envifood protocol we used soil organic carbon (SOC), as a midpoint indicator and applied an updated approach (Brandao and Milà i Canals 2013) where the change in SOC is used as an indicator for impacts on BPP. Our area of study is located, according to this method, on the warm temperate dry climate region.

The effect of soil erosion on ecosystem quality is expressed using a growth-based value potential: net primary production depletion (NPPD). Indicator for soil erosion impacts was defined at the endpoint level for ecosystem quality in two steps: first relating soil loss to SOC loss and then relating SOC loss to ecosystem biomass productivity drop, NPPD. CFs are at a spatial resolution of 5 arcmin (Núñez et al 2013)

For biodiversity assessment the approach and CF for occupation and transformation provided by De Baan et al (2013) has been used. These authors calculated the total number of regional and non-endemic species lost per five different taxonomic groups (mammals, birds, plants, reptiles and amphibians) choosing biome units to derive CFs. This total regional damage was then allocated to the different land-use types according to the area share they occupied and their habitat quality. We applied the agricultural land use CFs for, Northeastern Spain and Southern France Mediterranean forest ecoregion, PA1215, (De Baan et al. 2013) for our case study.

In fact the area of study corresponds to. Climatically, the ecoregion experiences very hot and dry summers, and relatively temperate winters. Forests are mainly composed of mixed evergreen and deciduous broadleaf and conifer species. Endemism rate in the ecoregion ranges between 10-20% of the total vascular plants. Large mammals are not particularly prominent in this ecoregion. Most of the ecoregion has been intensively transformed into agricultural land or coastal urbanization for tourism.

Land use type according to Koellner et al (2013) corresponds to Arable Land, 5.1, differentiating between Arable, irrigated, intensive plus chemical–synthetic and organic fertilizer as well as pesticides use for corn (5.1.3.2) and Arable, irrigated extensive without use of chemical–synthetic or pesticides but indirect use of organic fertilizer and catch crop (5.1.3.1).

Table 2 shows main geographical characteristics of crop location relevant for the land use impact assessment methods applied.

Table 2. Geographical characteristics corresponding to location and each crop assessed.

Geographical characteristics	**Common to location**	**Extensive**	**Intensive**
Geographical coordinates	42º08' N; 2º99' E		
Climate region	Warm temperate		
Moisture regime	Dry		
Reference Ecoregion (De Baan et 2013)	Northeastern Spain and Southern France Mediterranean forests PA1215		
Land Use type (Koellner et al 2013)		5.1.3.1 Arable, irrigated, extensive	5.1.3.2 Arable, irrigated, intensive
Rainfall (mm y^{-1})	670.6	386.5	284.1
Sand (%)	64		
Silt (%)	23		
Clay (%)	13		
C org (%)		1.74	1.45
Land slope (%)	2		
Slope length (m)	100		
USLE ΔR-factor (MJ mm ha^{-1} h^{-1})	2360		
USLE K-factor (t ha h MJ^{-1} ha^{-1} mm^{-1})		0.026	0.027
USLE LS-factor (-)	0.285		
USLE C-factor (-)		0.475	0.755
USLE P-factor (-)	1		
Soil loss mass due to Erosion (t soil)		8.3	13.7

In addition, we provided the climate change impact for the same scope and reference period (one year of crop production to farm gate) expressed as kg CO_2 eq and in species·y following ReCiPe methodology to provide a reference to compare natural environment damage importance.

In order to have a detailed explanation of the methods, we invite readers to consult the corresponding references.

3. Results

The results shown in table 3 were calculated for the different approaches per ha and year. Despite the difficulties encountered to identify damage of the different land use intensity type, extensive production appeared to have lower impacts than their intensive counterparts. This is clear when applying BPP method, for which extensive practice did not report any impact. Considering uncertainty of results, none of the other methods can differentiate between different practices, regarding biodiversity damage (de Baan et al 2013), because there are common CFs for all agriculture types.

The use of catch crop helps to reduce soil loss in extensive systems and although the loss of organic matter is higher in intensive systems, there is not final difference in erosion ecosystem quality impact due to method applied to convert SOC loss in NPPD.

Transformation impacts are higher than occupation impacts. Land transformation impacts on BPP are one order of magnitude higher than land occupation impact on BPP. Biodiversity impacts due to land transformation were one or two orders of magnitude higher than occupation depending on the taxa.

Table 3. Results for the different impact categories are expressed in the respective units per ha and yr and show the geographical reference unit of CFs applied. Climate change is the full life cycle for an annual catch crop plus silage corn crops. Rest of the impact categories are related to one ha of land use for the foreground crops.

Damage Nature	**Units· $ha^{-1}·yr^{-1}$**	**Results Extensive**	**Intensive**	**Geographical unit**	**CF source**

NPPD: net primary production depletion; PLNE: potentially lost non-endemic species;

4. Discussion

The different methods provide CFs based on homogeneous areas such as climate region (BPP) or biome (biodiversity damage). However, they are still large areas, which, depending on final goals of LCA, application can make comparisons difficult. From an applicability point of view, it is clear that more site-specific CFs for land use offer a better approach to grasping the local specificities of crop production.

On the other hand, it is necessary to develop CFs for more specific agricultural practice types (e.g., extensive, intensive, irrigated, greenhouse, organic agriculture) instead of generic ones (agriculture).

Main differences between both agricultural systems, extensive and intensive management are found in BPP land use impact assessment, because this category is using management factors from IPCC (2006), which give special importance to the carbon sequestration through the incorporation of manure (management factor 1.37 with manure vs 1.04 without manure). The use of management land use factors similar to those included in land use change could be potentially a good approach to consider the different agricultural practices.

Similarly, current erosion impact are applying different management factors related to agricultural practices and can provide information on long-term effects on soil resources but the revision and inclusion of more soil archetypes and conversion to biodiversity damage units are recommended.

Regarding biodiversity damage, vascular plants were shown to be the most sensitive group, followed by birds. This makes sense because usually plants are considered competitors of crops and removed from agricultural fields. These results are in agreement with the CFs derived by Elshout et al (2014). These authors differentiated between conventionally and low-input managed crops giving the respective CFs of 0.42 and 0.05 expressed as relative value of potentially disappeared fractions. Despite these results agree with previous studies, they shows different ratios depending on crops and area of study, which can confirm a tendency of lower impact for extensive systems but also the need for more accurate assessment methods.

Also according to the study of Elshout et al (2014), arthropods do not appear to be significantly impacted upon; however, we presume that the different management practices especially those related to pesticides use may have a large effect on them and therefore arthropods may serve as a good indicator for the impacts of differentiate practices.

Although regeneration times applied according to SOC indicator are lower than for biodiversity indicators, differences in importance between methods for transformation related to occupation can be explained because while de Baan et al (2013) calculated the transformation impact as a multiplication of occupation CF with half the regeneration time, Brandão and Milà i Canals (2013) included in this impact, the deficit of SOC due to the postponed regeneration of the system.

In this paper we have focused on crops (foreground system), issues related to land use on background processes have already been established in Milà i Canals et al (2013) and De Baan et al (2013).

5. Conclusion

Although it seems that extensive agricultural practices should mean lower impact when compared to more intensive practices, currently we have not enough developed impact characterization methods to assess and compare different agriculture intensities.

Among the different needs for further research, from our case study in particular, and agriculture in general, special attention should be paid to developing CFs for different land use agricultural types, as well as a better knowledge of relevance of the different taxa affected.

Together with the development and improvement of methods we would like to highlight the importance of testing them in practical and different case studies.

And last but not least a clear definition of boundaries, not only between technosphere and ecosphere, especially important in agriculture, but also which level of detail could/need to be covered by LCA. That means assuming the degree of implicit uncertainty, or otherwise the need to advise that environmental damage may/should/shall be assessed by other tools.

Abstract

The United States Department of Agriculture (USDA) collects and releases a substantial amount of commodity crop production data to inform market activities. These data are frequently transformed into unit process data, which are used in life cycle assessments of agricultural production or agriculturally derived products. The USDA has recently transformed its Agricultural Resource Management Survey (ARMS) data into high quality and transparent unit processes that represent United States production for nine commodity crops in the USDA Life Cycle Assessment (LCA) Commons. However, neither high quality and transparent unit process data, nor complete input and yield data for specialty crops exist. State enterprise crop budgets are a consistent data source for specialty crop production and have been used in past agricultural LCAs (Adom et al. 2012, Matlock et al. 2008 and Eranki and Dale 2010). One of the major objectives of this project was to determine the reliability of "state enterprise crop budgets" as tools for collecting unit process data for crop production. This paper evaluates the applicability of state cost of production (COP) estimates, which underlie state enterprise crop budgets, to LCA.

State extension agricultural economists compile enterprise crop budgets from surveys of horticultural scientists, agricultural suppliers, marketers, crop consultants, and other local and regional stakeholders. The crop budgets define a range of management practices that vary based on local conditions and estimate the costs and revenues associated with production. Crop budgets are pragmatic and based on survey results from industry experts. However, crop budget survey methods are not necessarily standardized and may not be a reliable sampling of the industry. They can have a varying level of technological, temporal, and geographic specificity and vary across states such that state comparisons or multi-state aggregations may not be reliable. Therefore, indiscriminately transforming enterprise crop budget data into unit process data may not be scientifically defensible. Life cycle inventories calculated from corn production unit processes developed from the 2005 Iowa state enterprise crop budget for corn will be analyzed and compared to unit processes developed from USDA crop production surveys.

1. Introduction

The first objective of this work is to determine if "state enterprise crop budgets" and the "cost of production (COP) estimates," upon which they are based, can be reliably transformed into "unit process" data for strawberry crop production. We refer to gate-to-gate crop production as a unit process here, with a functional unit of a unit of crop produced, which is a part of larger product systems not treated in this paper.

In 2012, USDA-National Agricultural Library (NAL) released the *Life-Cycle Assessment Commons,* an open source, life-cycle inventory database for nine (9) commodity crops. The main data source used for developing unit processes for commodity crops is the annual USDA Agricultural Resource Management Survey (ARMS) (U.S. Department of Agriculture, Economic Research Service 2013). ARMS data are derived from an annual, national, statistical survey of field-level farm practices sponsored jointly by USDA Economic Research Service (ERS) and the USDA National Agricultural Statistics Service (NASS). USDA-NAL has transformed ARMS and NASS Quick Stats data into high quality and transparent unit process data that represent United States commodity crop production and can be used in life cycle assessment of agriculturally derived products. Crop production survey data represented in ARMS covers land occupation and transformation from previous crops, seed use, irrigation, tillage, crop residue management, and the use of nutrients, manure, and pesticides. When these data are combined with NASS Quick Stats data representing field crop production for each ARMS crop-state-year combination, the basis for an LCA unit process data flow is created.

A comprehensive federal survey of production practices or cost of production does not exist for specialty crops. USDA-NAL is investigating the transformation of crop production practices data that underpin the variable cost estimates of state enterprise crop budgets into unit process data that can be used for life cycle assessment of specialty crops. However, when analysts transform existing data for unintended uses, they must fully understand how the intended use and collection methods relate to the new questions they are asking. ARMS data were appropriate for transformation into commodity crop unit process data that represent U.S. agriculture because they were developed from a statistical sampling that represented historical activities. Their state level resolution and historical perspective make these data suited for policy analysis more so than producer planning purposes. Conversely, state cost of production estimates are not necessarily statistical samples and are developed for planning purposes. Therefore, they may not be representative of typical production practices and may not be adequate for policy analysis.

2. Methods

The basis for this work is a qualitative literature review and meta-analysis of the methods behind state and federal COP data. Our hypothesis is that the state COP data that underpin crop enterprise budgets are representative of state level management practices. This hypothesis is being tested with a two phased approach. The first phase, documented here, is a qualitative review of COP estimate methods and their applicability to LCA. The second phase is a quantitative meta-analysis that will compare life cycle inventory results from unit process for corn production developed from USDA ARMS data that reside in the USDA LCA Commons and corn production unit processes developed from state COP data collected by varying methods. Phase two results will be documented in a separate paper and presented at LCA Food 2014.

3. Results

Inconsistencies between the methods used by land grant universities developing state level COP estimates and USDA's Farm Cost and Returns Survey (FCRS) methods surfaced during congressional deliberations on the 1990 Farm Bill. Policy makers and researchers found that the variety of methods used in collecting, calculating, and analyzing state and national cost of production estimates yielded inconsistent analytical results. Essentially, using COP data gathered on a local or regional level with the intended use of improving farm management were not necessarily transferrable for federal policy making. Libbin and Torrel compared data collected in the 1986 crop and livestock budgets for New Mexico with data collected through the FCRS in that year. They found tremendous discrepancies among the state and federal data mainly due to methodological differences in data collection (Libbin and Torell 1990). An exploration of the discrepancies in state and federal cost of production estimates were formalized in a volume of Costs and Returns for Agricultural Commodities (Ahearn and Vasavada 1992), with the over- arching recommendation that states and the USDA must collaborate to coordinate state and federal cost of production estimation methods. As a result, the Commodity Costs and Returns Estimation Handbook was developed and is hosted on the web by the USDA Natural Resource Conservation Service (NRCS). The "handbook's purpose is to gather in one place information on estimating costs of and returns to agricultural enterprises (American Agricultural Economics Association 2000). In addition to publishing the Handbook, these activities culminated in the evolution of FCRS into the Agricultural Resource Management Survey in 1996. Presumably, the Handbook produced by this process helped align the methods used in state and federal cost of production estimates for commodity crops to support more consistent analyses.

3.1. Transforming COP Data into Unit Process Data

Transforming state COP data into unit process data requires an understanding of both the intended uses and data collection methods of COP data. In the Costs and Returns for Agricultural Commodities (Ahearn and Vasavada 1992), House (1992) and Guedry caution that the intended use of the COP data should determine the data collection methods. Alternatively stated, data collection methods must support their ultimate use. Guedry asserts that the purpose for which COP estimates are used influences the manner in which they are collected and that [if they are going to be used for research] analysts should focus on the differences that exist in the data and the procedures used in developing the estimates, rather than the formats in which they are presented (Guedry 1992). This statement is particularly pertinent for analysts using data for purposes other than their intended purpose. In this case, cost data are not being collected and used for economic analysis, but rather existing cost data are being used for environmental analysis. Klonsky asserts that in developing COP estimates each institution's methods are constructed following an internally standardized set of methods, but the methods used to estimate cost vary from state to state (Klonsky 1992). These variable methods may include both the intended uses of the COP estimates and the sampling methods.

3.2. Intended Use of COP Estimate

COP estimates are generally used for three purposes 1) assisting farmers in planning and improving their management performance 2) policy analysis (Morehart, Johnson, and Shapouri 1992) and 3) research activities (Guedry 1992). Therefore, cost of production information is of interest to farmers, farm management specialists, policy makers and researchers (Ikerd 1992). Subsequently, the first question that should be asked when using these data for analytical purposes is, "what does the economic [or life cycle] analyst need from a cost and returns data set? (House 1992)." It is proposed here that the material and energy input and output data be used to model field scale environmental emissions. Because results could inform both growers in improving production practices and/or commercial and government policy decisions, it must be determined if state strawberry crop production estimates provide an adequate representation of state-wide production. Indeed, many state enterprise crop budgets include a disclaimer that production practices and their associated costs may not be representative of production practices and costs throughout the state. Furthermore, "one fundamental difference among enterprise budgets is that some are intended to reflect historical events and are summary for the current year. Others are intended to be projections of costs for the coming year (Klonsky 1992)." The strawberry state enterprise crop budgets used in this study indicate that they represent "typical" state level production.

Extension economists may want to develop Cost and Return (CAR) estimates that are representative of progressive, well-managed farms (rather than all farms) engaged in the selected enterprise because those estimates may be more useful in guiding potential producers. On the other hand, the United States Department of Agriculture (USDA) and others producing historical estimates generally want to include a broader geographic area and to target all farms engaged in the enterprise regardless of whether they are progressive or not (American Agricultural Economics Association 2000) Therefore, state enterprise crop budgets may represent "target yields" or "safety first" estimates that may not necessarily be representative of typical production (Schoney 1992). However, enterprise cost budgets are usually part of on-going and even long-term programs in which production practice and cost estimation methods have been refined over time. The data quality conferred by the longevity and expertise of the stakeholders involved in developing state cost of production estimates is certainly implicit, if difficult to measure.

3.3. Data Collection Methods

If the intended uses of the COP data collection yield data that are representative of crop production practices, the methods by which COP data are collected must also yield representative estimates. The most important factor in assuring data quality is statistical inference. Statistical inference determines whether, and to what extent, results from the analysis and estimation can be generalized to a broader set of farming operations. Statistical inference is largely determined by two activities: precisely defining the group (or target population) the analyst wants to investigate, project for, or draw conclusions about; and selecting representative data from that population for the analysis. There are two sampling methods that allow analysts to select a representative sample of data from the target population in such a way that valid inferences can be maintained: a statistical sample and a judgment sample (American Agricultural Economics Association 2000).

A statistical/probability sample is considered superior to a judgment/non-probability sample. A statistical/probability sample is one in which each farm in a targeted population has a positive and knowable chance of being included and produce data that are representative of the entire target population. Judgment samples, on the other hand, are selected through some method other than statistical sampling, usually the subjective decision of one or more individuals. Consequently, at least some members of the target population did not have a chance to be selected. Judgment surveys are not necessarily inaccurate, but it is also not possible to determine if they are accurate either. The accuracy of the sample depends on the expertise of the individual selecting the sample (Williams 1978). State COP estimates are usually derived from judgment samples of the local and regional industry. In rare cases, state COP estimates are derived from statistical samples for commodity crops. However, statistical sampling is cost prohibitive and it is not realistic to accomplish for each specialty crop or even each commodity crop in each state in every year.

In fact, statistical sampling may not be appropriate for specialty crop COP data collection. Judgment samples may produce more reliable data when the sample size is very small. Also, depending on the specialty crop and state, judgment samples may be more effective in terms of cost and reliability. Another disadvantage of probability surveys is that they are not collected longitudinally and lack richness over time. State COP estimates, on the other hand, “are designed to provide usable estimates within the resource constraints of those preparing the estimates. Information that is developed annually is, in general, part of an ongoing educational program that has been developed over a period of years. Such programs have an advantage of being validated annually by users (Guedry 1992).” The veracity of the data gathered through long-term judgment sampling is likely to continue to be improved over time and may be more representative of reality than statistical sampling.

4. Discussion

The results of this review indicate that transforming state enterprise crop budgets into reliable unit processes for life cycle assessment is feasible. The “static snapshot” of COP estimates for an agricultural enterprise is aligned with the nature of a unit process. However, several subtle issues with respect to the use of crop budget derived unit processes in life cycle assessment became apparent. Primarily, cost estimates cannot be categorically transformed into flow data and data collection methods vary among states and unit processes developed from state COP data must be used with caution in LCA. COP data collection methods must be understood, reconciled across states, and fully documented if the unit processes are used as part of an aggregation or comparative LCA. Aggregations or comparisons across states cannot be reliably made based on state COP estimates. Second, the data used to build state enterprise crop budgets do not necessarily produce “representative” production practice data. Before using an enterprise crop budget, the life cycle analyst must endeavor to understand how the data were collected and for what purpose. Unit processes for a single state is reliable if the crop budget states that production practices and costs are representative of state-wide production. A statistical sample is not essential for collecting reliable data, but the survey must be deemed to be representative of current activities.

Most state COP estimates for commodity crops are based on judgment samples because the cost of ongoing statistical sampling is cost prohibitive. State specialty crop markets cannot bear the costs of ongoing statistical sampling either. However, statistical sampling may not be appropriate for state specialty crop markets due to small sample sizes of producers in each market. The ongoing, annual sampling of the industry and continuous improvement of methods and estimates provides confidence in the quality of COP data collection methods. State economists sample the local and regional industry over a period of years and continuously endeavor to improve their methods and estimates. The institutional knowledge and continuous improvement developed over a period of years in these programs provides confidence that state COP estimates and their underlying production practices do, indeed, represent state production. These data may be more reliable than a statistical sample of the same market.

5. Conclusion

While data collection methods for state enterprise crop budgets are reliable and internally consistent within a state from year to year, survey methods vary among states. Therefore, budgets must be individually evaluated to determine if they are reliable for comparative LCA. Unit processes can be reliably developed for individual states, but differences in data collection methods among states must be reconciled before the unit processes are used in LCA. If state enterprise crop budgets as a whole are to be reliable data sources for LCA, data collection methods must be standardized beyond format. State enterprise crop budgets are designed for field-level micro-economic planning and may not provide the resolution of input/output data necessary for a detailed field-level LCA. For example, a budget may estimate an aggregated cost for pesticides required for a crop in that year, but may not define which specific pesticides or the quantity of those pesticides used. Crop budgets may be more appropriate for developing background unit process data for more complex agriculturally derived products rather than higher resolution data required to inform field level activities. In the absence of standard methods across states, the analyst must understand and reconcile variability among states before making comparisons and the intended use of the budget. The variability among state budgets and their intended application must be fully transparent in the LCA documentation.

ABSTRACT

System analysis was performed to gain an overview of key environmental challenges and pinpoint hotspots causing environmental impacts in three European food supply chains. An overview was obtained based on a review on LCA studies for beef, dairy, orange juice and aquaculture food supply chains. Similarities of the main environmental impacts were identified to rationalize and justify the selection of key performance indicators chosen for a simplified web based LCA tool developed within the EC funded project SENSE (FP7). Life Cycle Assessment methodology covered many of the key challenges identified but will not be sufficient to address all environmental impacts generated from the food supply chains. Especially for aquaculture impacts that are not taken into account with LCA are i.e. nutrient and organic matter releases, impacts associated with feed provision, diseases introduction, escapes, and changed usage of coastal areas. In agriculture land use and biodiversity are issues not well covered.

Keywords: Environmental challenges, agriculture, aquaculture, LCA, key environmental performance indicators

1. Introduction

The food and drink sector is the largest manufacturing sector in the European Union (15%) which directly employs 4.1 million people but it is a highly fragmented sector consisting of 99% of SME's and microenterprises (FoodDrink Europe, 2011) which makes the supply chain from "farm to fork" complex with a multitude of actors involved. This sector is also associated with high environmental impact; a study commissioned by the European commission showed that three areas of consumption – food and drink, private transportation, and housing – are together responsible for 70-80 % of the environmental impacts of private consumption. Food and drink consumption was responsible for 20- 30% of the various environmental impacts of total consumption, and in the case of eutrophication for even more than 50% (Tukker, 2005). Meat products have generally a higher environmental impact than vegetables and fruit (Mogensen *et al.*, 2009; Figure 1) but variations within product groups can be highly depending on production system. Geographical region also influences the environmental sustainability.

Life cycle assessment (LCA) according to an ISO standardized method (ISO 14040, 2006) is generally applied to quantify the environmental impact for a product or service from cradle to grave. LCA is a valuable method but it is difficult to compare one food product to another due to differences in the goals and scopes of the different studies. Defra recently reviewed over 180 LCA studies on food and found that most studies end at the farm gate of the food supply chain, and very few extend as far as the consumer and that there is a shortage of studies which include information on distribution, retail and consumption and waste (Defra, 2011). Due to differences in goals and scopes, methodological approaches, setting of boundaries and assumptions as well as data quality and availability it is often not possible to compare the environmental impact of food products within the same product category and even less so between different product groups.

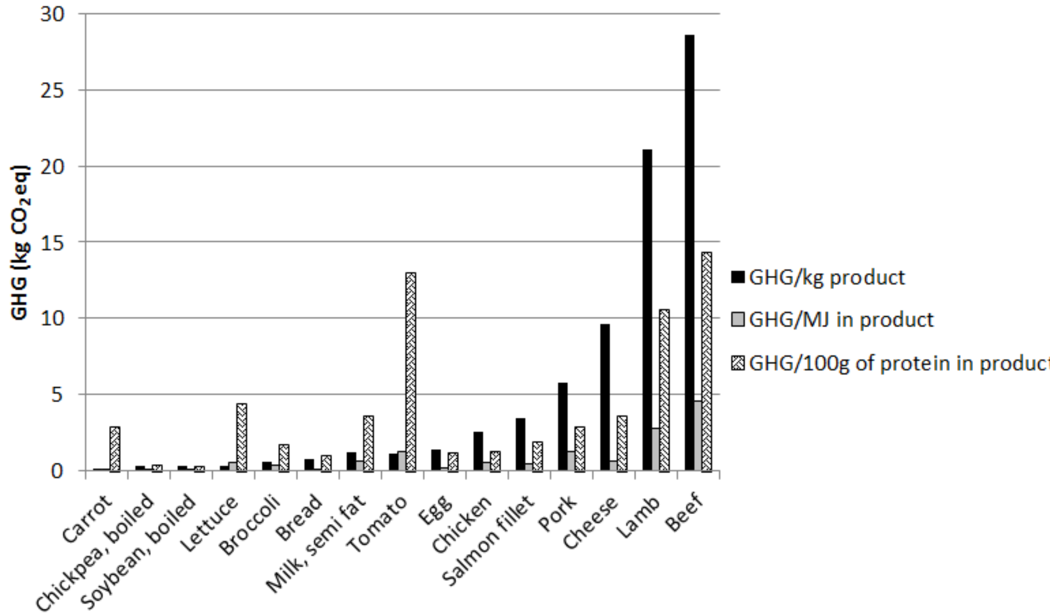

Figure 1. Greenhouse gas emissions of a range of food products per kg of product, per energy content and protein content from farm to retail. The figure is based on the following references: vegetables- Sonesson *et al*. 2010 except chickpea from Gan *et al*. (2011) and soybean from Prudencio da Silva *et al*. (2010); meats (bone free) Cederberg *et al.* (2009) and dairy products Flysjö, (2012). Data on protein content is from the Swedish Food Agency (www.slv.se).

In the SENSE project the aim is to obtain a simplified impact assessment, thus the most relevant impacts that are common in all food supply chains are chosen in order to design a simple LCA based tool, the SENSE-tool. As a first step to gain an overview of challenges in food supply chains in Europe a literature review of existing LCA studies was performed to identify the key environmental impacts as a basis to select key performance indicators that can be used in a simple life cycle assessment tool.

2. Methods

Key environmental challenges in food supply chains were identified based on literature review by selecting as case studies the following food sectors to represent a range of variation of food supplied to the European market:

- Orange juice (Esturo *et al.*, 2013)
- Beef meat and milk (Aronsson *et al*., 2013)
- Aquaculture (salmon) (Olafsdóttir *et al*., 2013)

Published life cycle assessments (LCAs) were chosen as the preferred source of evidence for quantifying environmental attributes of the selected food chains. This is not an exhaustive literature study but key references have been chosen to gain an overview and to compare the impacts in the different food supply chains. The main aim is to demonstrate the similarity and variability of the environmental impacts by giving a range of values reported for the most common environmental impacts assessed by LCA in the respective food supply chains.

3. Results- Environmental challenges

In general supply chain of food products share similarities where food moves from producer to consumer via the processes of production, processing, distribution, retailing and consumption. Each step of the supply chain results in an environmental impact on local, regional or global level (Figure 2 and Table 1). If the environmental hot spots or a key environmental challenge for each step in the chain is known, efforts can be used to focus on these problems and effectively minimize the environmental impact.

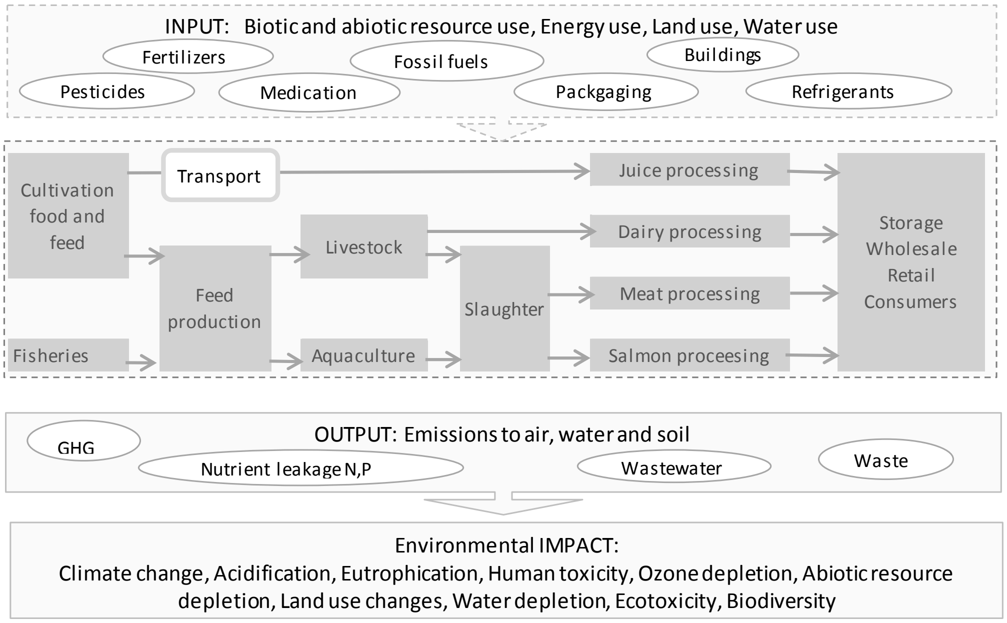

Figure 2. A simplified overview of the common steps in three food supply chain systems (orange juice, meat/dairy and aquaculture) and examples of input resources and output emissions causing environmental impacts.

The environmental challenges of food supply chain systems are typically caused by the use of fossil fuels, water, fertilizers, pesticides and land in the primary production as well as the accumulation of discards from the farm animals i.e. manure and excessive feed in aquaculture. Other challenges in farming are related to the use of feed, medication, the occurrence of escapees and the impacts of the farming on the wild flora and fauna. In the processing steps of food the use of resources, energy, water, packaging and refrigerants, waste and wastewater generation, and the type of facilities like buildings and infrastructure will influence the overall environmental impacts. The choice of technologies is often a key influential factor and the yield, full utilization of resources including the use of by-products is of importance in the overall estimation of the environmental load both in production and processing. In the transport phase the use of diesel is a challenge where the mode of transport can influence the severity of environmental impacts.

Table 1. Identified key environmental categories for the food chain, relevant production steps and challenges.

Impact category	Production step	Challenges
Climate change	Cultivation of biomass, Fishing (feed fish), Feed industry, Animal rearing, Food industry, Transport	Nitrogen fertilizer production, Use of N fertilizer and manure, Enteric fermentation, Manure handling, Use of fossil fuel, Refrigerant leakage
Acidification	Cultivation of biomass, Fishing (feed fish), Feed industry, Animal rearing, Food industry, Transport	Use of N fertilizer and manure, Use of fossil fuels
Eutrophication	Cultivation of biomass, Fishing (feed fish), Feed industry, Animal rearing, Food industry, Transport	Use of N and P fertilizer and manure, Manure handling, Nutrient release from aquaculture, Waste water
Human toxicity	Cultivation of biomass	Use of pesticides
Ecotoxicity	Cultivation of biomass, Feed industry (fishing), Animal rearing, Aquaculture	Heavy metals from fertilizers, Use of pesticides, Use of medicines, Use of antifouling paint
Land use	Cultivation of biomass, Animal rearing (Aquaculture sea surface/floor use)	Land use efficiency
Abiotic resource depletion	Cultivation of biomass, Fishing (feed fish), Feed industry, Food industry, Transport	Use of fossil fuels, Use of P fertilizer
Water depletion	Feed industry, Food industry, Transport	Irrigation, water use
Biodiversity	Cultivation of biomass, Animal rearing	Land use, Use of pesticides, Escapes and diseases in aquaculture

3.1. The beef and milk supply chain

The farm stage is generally the main contributor to the total environmental impact of a food product and for beef and dairy chain the farm stage contributes approximately 80 to 95% percent to the total emissions (e.g. FAO, 2010), with grassland systems having higher emissions than mixed systems (FAO, 2010). Methane is the main contributor with an average of 52 percent of the total emissions. CH_4 emissions from ruminant livestock systems come from enteric fermentation that ruminants produce as a by-product of their metabolism (Crosson et al., 2011) and approximately 6 percent of the energy intake converts to CH_4 but can vary between 2-12 percent depending on the diet. The second largest contributor to environmental impact from beef and dairy systems is N_2O emissions (approx. 27%; FAO, 2010) which can arise as direct emissions from organic manures or inorganic fertilizers applied to soil. In addition, indirect N_2O emissions associated with agriculture arise from volatilization of land applied manures and/or N based fertilizers, and N lost via runoff and leaching from agricultural soils (IPCC, 2006). N_2O emissions also occur upstream when mineral fertilizers are produced. Besides being a potent GHG, N_2O also contributes to ozone depletion. Carbon dioxide emissions contributing to climate change potential and acidification are caused by energy use from operations using fossil fuels and also from production of mineral fertilizers.

There are many LCA studies on beef and dairy production up to farm gate but it is rare with studies that follow the beef and milk to the consumer or grave. Post farm stages for milk and beef production has been estimated to 5-20% of the total environmental impact depending on what life cycle stages are included (Sevenster and de Jong, 2008). Energy use during the processing of milk and the packaging have major influence post farm. Transport often has minor influence but it depends on mode of transport and distances. The processing in the dairy plant results in the highest environmental impact. The separation, homogenization and pasteurization use the most energy (Nilsson and Lorentzon, 1999). However, the cleaning operations have also been identified as a major source of environmental impact (Hogaas Eide, 2003).

Packaging material is important for the environmental impact. Carton packs for UHT milk have been shown to have a significantly better environmental profile compared to HDPE and PET bottles with respect to CO_2 emission, use of fossil resources and consumption of primary energy. Recycling beverage packaging materials as a lower environmental impact than disposal in landfills or incineration plants (Meneses *et al.,* 2012). Up to 17 percent of the total life cycle emissions for energy and 18 percent for global warming potential can be contributed to the manufacturing and distribution of milk packaging consisting of paperboard carton (Hogaas Eide, 2003). The waste management of packaging can contribute significantly to the environmental impact. Packaging design is also an important factor when it comes to product loss in the consumer phase.

No information has been obtained when it comes to the environmental impact of beef and dairy at retail.

At the consumer stage the energy used to refrigerate milk and meat will result in the major environmental impact. There can be large variations in energy consumption of household refrigerators with up to 11.27 MJ/liter and year difference between the lowest and highest energy consuming refrigerator (Sonesson *et al*., 2003). To prepare the meat also demands energy. When it comes to waste in the household there are different kind of losses of milk and meat. In the milk and dairy chain approximately 11 percent of the milk is lost due to wastage (Gustavsson *et al*., 2011). For the meat chain (note, all meats) the wastage is around 20 percent. The consumer stage is the main stage were wastage occur for milk, dairy and meat products (Gustavsson *et al*., 2011).

3.2. The orange juice supply chain

During the cultivation of orange trees high fertilizer rates and large applications of manure concentrated in specific geographical areas lead to significant emissions of ammonia and nitrate, which creates eutrophication and acidification in sensitive aquatic and terrestrial environments and pollution of ground and surface water (EEA, 2009). The use of pesticides affects toxicity both for humans and the ecosystems. Eutrophication caused by agricultural practices has been identified as a serious problem in several Mediterranean countries. Specifically, Comunidad Valenciana region, which is the main orange production area in Spain, is included in the vulnerable zones to nitrate pollution from agricultural sources. Nevertheless, Murcia region and the West of Andalucía are also important orange producing areas. Moreover water depletion effect may be severe in Mediterranean area, where water scarcity is a particularly significant problem. The loss of biodiversity, changes to biotic interactions, and resource depletion in ecosystems are possible impacts of water scarcity.

The main contributor to atmospheric emissions at the processing stage is the energy consumption, mainly for thermal treatments (i.e. pasteurization, evaporation) which is usually related to the combustion in boilers of fossil fuels. Cooling and refrigerated storage of juice have also electricity requirements that implies indirect environmental impacts. Additionally, leakage of refrigerants fluids can be a direct source of GHG emissions contributing to climate change and ozone layer depletion potential. Carton based packaging dominates with 60% of total volume consumed and this type of packaging has been shown to have the lowest environmental impact concerning climate change, energy use and eutrophication when compared to glass and plastic (PET) packaging (Labouze, *et al*, 2008). For the retail and consumption steps of the orange juice value chain very little environmental information exists but it may be concluded that the impact of these steps are small. The main contributors to the environmental impact from the orange juice supply chain are fuel consumption during transport or distribution, followed by the use of fertilisers, herbicides and pesticides and consumption of fossil fuels in agriculture (Beccali *et al*, 2009). Regarding eutrophication potential more than 80% of the total impact is due to the use and production of fertilizers, pesticides and herbicides. The transport and agricultural inputs are the most influential stages of the orange juice value chain.

3.3. The salmon aquaculture supply chain

Environmental challenges in aquaculture which have been in focus are related to the potential loss of biodiversity due to the use of medicine for control of diseases and the salmon lice, and the effect of escapees on the wild salmon. The efficiency of feed and farming systems can have an impact e.g. excess feeding causes eutrophication which influences the benthic ecosystem because of nutrient enrichment of sediments and the water column. Exploitation of forage fish for feed has been a controversial issue, since this puts pressure on fish stocks and may have an impact on the seafloor. The use of soya and other crops for feed has also a considerable environmental impact because of land use changes caused by cultivation and the use of fertilizers, pesticides and water for irrigation. These issues have influenced public opinion and their perception towards aquaculture, which is sometimes a priori negative image.

The salmon production industry is concentrated in Northern Europe, Canada, and Chile and studies on LCA of aquaculture of salmon have focused on the effects of different composition of feed in these countries. While net-pen systems are most common for salmon LCA studies are also available for other rearing technologies like closed system aquaculture and other species farmed in Europe like trout, and arctic charr, as well as turbot and seabass.

Feed production is most often the major contributor to environmental impacts in conventional aquaculture systems (Ellingsen and Aanondsen, 2006; Ziegler *et al.*, 2012), while the impact of energy use is dominating in recirculation systems (Ayer and Tyedmers, 2009). Feed producers source raw materials from diverse fish, crop, and livestock sources globally, each with characteristic resource dependencies and environmental impacts. Fuel use in fishing, and feed production in aquaculture are key contributors to greenhouse gas emission (Ziegler *et al.*, 2012) and the impact of fuel use for global transport involved in sourcing feed is also of concern.

Water use is of importance especially in water scarce areas and land based systems and water use for irrigation in production of crop for feed.

Processing, packaging, transport, sale, consumption and waste management have not been commonly included in life cycle stages in seafood LCAs. This is particularly the case in aquaculture studies, while fisheries studies have often followed products through the transport stage (Ziegler *et al.*, 2012). Results from recent studies which have focused on environmental impacts of the processing and transport steps have shown that they are not significant in the overall impacts for the products when the transport is a short distance to the market within Europe. However, when considering the product type (whole fish or fillets), long distance transport and mode of transport (air or ship) the transport was found to have a large impact on the energy use and GWP and trucking is also an important contributor to GWP. LCAs that have focused on the transportation phase of chilled fish supply chains agree that sea freight is by far more environmentally friendly transportation mode than air freight and therefore it is very important to consider how food is produced and transported to the market and not only where it is produced in terms of environmental performance of products (e.g. Tyedmers *et al.,* 2010; Ingólfsdóttir *et al.*, 2010).

The impacts of packaging material and chilling in transportation were the main contributors to environmental impact potentials in a seafood supply chain systems (not including the fisheries) when comparison was made between chilled and superchilled fillets (Claussen *et al.*, 2011). The environmental impact of EPS packaging has been shown to be considerable, where the main contribution is energy use in the production of EPS granulates (Ingólfsdóttir *et al*., 2010).

The impact category ozone depletion is related to the use of refrigerants. However, new refrigerants are being developed where replacement of the HCFC R22 with environmentally harmless refrigerants like ammonia is in progress. According to Ziegler *et al.*, (2012) this change would reduce the carbon footprint of fish products by up to 30% if the right substitutes were chosen.

The aquaculture sector has made considerable efforts to mitigate the environmental effects for example by changing the composition of feed and development of aqua feed, as well as improved aquaculture technologies and good practices. Governmental monitoring and legal requirements in many countries require that aquaculture farms report occurrences of sea lice, escapees, the use of medication and water quality and sediment monitoring in the areas close to the farms. This implies that data on these aspects may be readily available and currently there is an increasing awareness that monitoring data should be accessible in the public domain to enhance the transparency and help building an image of responsibility for the sector.

Table 3 shows reported values from LCA studies for four of the most common impact categories for milk, beef orange juice and salmon aquaculture. Much of the variation in the values is due to differences in goal and scope, if the studies were attributional or consequential or how the metrics were reported (especially for energy use).

Table 3. Examples of reported key values for four impact categories for milk, beef, orange juice and salmon aquaculture.

Impact category	Milk[a]	Beef[b]	Orange juice[c]	Salmon Aquaculture[d]
Climate change (kgCO_2e/kg)	0.5-1.8	20-27	84-112	1.8 – 3.3
Acidification (g SO_2e/kg)	4-7.5	101-510	0,.5-5.5	10.3 -29.7
Eutrophication (g PO^{4-}/kg)	4.8-19	59.2-169	2.5-11.3	31.8 – 74.9
Energy use (MJ/kg)	1-6.9	325-1650	764-952	26,2 – 32,1

4. Discussion

4.1. Issues not covered by LCA

There are other aspects that so far are not adequately included in LCA's studies due to lack of consensus methodology (e.g. soil carbon dynamics) and data availability (e.g. waste percentages). As LCA is a method for assessing the environmental sustainability, socio-economic indicators (e.g. animal welfare) are typically not analyzed in LCA. The inclusion of social impacts will be considered in the SENSE project but these are typically associated with the performance of the enterprises, working conditions and employee rights.

Many of the aquaculture-related environmental impacts are not incorporated in appropriate impact categories in LCA and therefore, LCA methodology for environmental assessment will not to be sufficient to address all of the key global challenges generated from aquaculture i.e. nutrient and organic matter releases, impacts associated with provision of feed, introduction of diseases, introduction of exotic species, escapes, and changed usage of coastal areas (Samuel-Fitwi *et al*., 2012). The indicators and methods applied for chemical discharges and assessment of ecotoxicity are not well developed and their use for environmental impact assessment of aquaculture have been questioned (Ford *et al.*, 2012). Land use for crop production for feed and sea primary production - required to sustain the fish used for salmon feed and the benthic area influenced by fishing gear and methodologies have been suggested to calculate these effects to assess the impacts of feed for salmon (Ytrestöyl *et al.*, 2011). Therefore, when developing a simple tool for environmental assessment like the SENSE tool the limitation and justification for the LCA approach and the methodologies applied need to be addressed.

Some of those aspects that could be addressed in addition to using the LCA methodology are listed here:

- Amount of wastage could be used to measure efficiency in the supply chain. Food wastage reduction has been identified as an important part of EU policies over the last years.
- Feed efficiency in animal rearing can be a relevant indicator to evaluate several environmental impacts. For example, higher feed efficiency results in increased daily weight gain of cattle which means that rearing times can be reduced. This in turn can lower environmental impacts.
- The use of fish for feed is a biotic resource use for which no validated LCIA method yet exists. However, the use of forage fish and the FIFO (Fish in – Fish out ratio) could be used as a basis for an indicator.
- Carbon sequestration can be a positive effect from some systems, e.g. pasture based cattle production, while on the other hand annual cropping can lead to soil carbon emissions. Methods to measure carbon sequestration form different rearing system should be developed.
- Animal welfare is of concern and different opinions exist depending on culture and history in different countries. A production system for animals can be very efficient for the environment but result in poorer animal welfare.
- In some countries esthetical values in the countryside are discussed. Without any grazing animals the biotope will change from agricultural landscape to forests or larger monocultures of arable farming. This can have an impact on the rural communities both for inhabitants and visitors. In this case indicators for eco system services are being developed and could be considered.
- Use of antibiotics versus preventive actions to improve the animal health is very much discussed. Antibiotics can give higher and more efficient production as well as there is a risk for releases to the environment that can introduce resistance to the antibiotics. This is not integrated in LCA.
- How to assess the effects of land use change (LUC) and indirect land use change (ILUC) is very much discussed in the LCA community. There is not yet any consensus on how this should be integrated in LCA.
- Effects on biodiversity are often included in the land use impact assessment methods. It is widely recognized that it is important to assess the land use impact on biodiversity but because of the complexity of the issue there is no widely accepted methodology to use.

5. Conclusion

From the review of LCA studies the main environmental challenges for the three food supply chains have been highlighted and the most important issues can be assessed by LCA based methodologies and included in a simplified LCA web based tool. There are however environmental challenges that LCA methodology does not cover which are important to consider when assessing the environmental sustainability of a food supply chain, especially related to effects on biodiversity. Additionally there are other aspects and challenges that are not environmental, e.g. animal welfare and release of antibiotics to the environment, which are not possible to address with LCA methodology.

Environmental impacts of producing bouchot mussels in Mont-Saint-Michel Bay (France) using LCA with emphasis on potential climate change and eutrophication

ABSTRACT

LCA of bouchot blue mussel culture in Mont Saint-Michel Bay (France) was performed to identify impact hotspots of the activity. To better characterize potential positive effects on eutrophication and climate change, the chemical composition of the flesh and shell was analyzed. A small but potential mitigating effect on eutrophication was observed, reaching 1 kg PO_4-eq. per tonne of "ready-to-cook" mussels. The potential carbon sink effect is influenced by hypotheses about the wooden stakes of the bouchots and about the fate of the shells, associated to the management of discarded mussel and of the household waste. This effect barely compensates the climate change due to the use of fuel for on-site transportation. In addition, environmental impacts of blue mussel culture depend on its production location, as a function of mussel yields due to the marine currents combined with the distance to on-shore infrastructure.

Keywords: LCA, Mussel, Carbon sink, Eutrophication, Climate change

1. Introduction

Blue mussel (*Mytilus edulis*) culture yielded 207,918 tonnes of shellfish worldwide in 2010 (FAO 2012). Blue mussel culture in France represents about 35% of world production (CNC 2012) and is performed using two different techniques: long-line rafts and bouchots. Bouchot culture is currently the only type of mussel culture in Mont Saint-Michel Bay, which produces 10,000 tonnes of blue mussels annually. Bouchot culture consists of using wooden stakes sunk into the foreshore as a culture support for the mussels.

In the scientific literature, interactions between mussel culture and the environment have been studied mainly from a nutrient-cycling perspective (Brigolin et al. 2009, Jansen 2012, Nizzoli et al. 2011, Richard et al. 2006) or one assessing biodeposition and benthic effects (Chamberlain et al. 2000, Christenssen et al. 2003, Grant et al. 2012). Few authors have assessed environmental impacts of mussel culture with a broader viewpoint using holistic approaches. Thrane (2004) assessed energy consumption of mussel production in Denmark, Fry (2012) estimated a carbon footprint of longline mussel production in Scotland, and Iribarren et al. (2010a,b,c) performed Life Cycle Assessment (LCA) of the longline mussel supply chain in Spain. Among these studies, the methodology used to establish an inventory differs and the inclusion of effects of mussels on nutrient and carbon cycling in the marine environment varies.

Mont Saint-Michel Bay is located between Brittany and Normandy, two regions of high livestock production, where water quality is regularly called into question due to overloading of nitrogen (N) and phosphorus (P) caused by agricultural activities. Our study aimed to evaluate environmental impacts of bouchot mussel production in this context. In particular, we investigated its potential role in mitigating climate change by stocking carbon in mussel shells and potential eutrophication by extracting nutrients from the bay.

2. Methods

2.1. Goal and scope

LCA was performed to assess environmental impacts of Mont Saint-Michel mussels produced according to the Appellation d'Origine Contrôlée (AOC) label, with the double objective of establishing an environmental profile of the activity and highlighting potential impact hotspots. The LCA followed the main guidelines of the ILCD handbook (JRC 2011), with a cradle-to-gate approach. Boundaries of the production system included spat collection and transportation, the culture stage (including equipment use), and the processing and packaging stage at the producer organization's plant (Fig. 1). The distribution, marketing and consumption stages are not included in the study. The functional unit was 1 tonne of packed, “ready-to-cook” mussels at the producers’ plant.

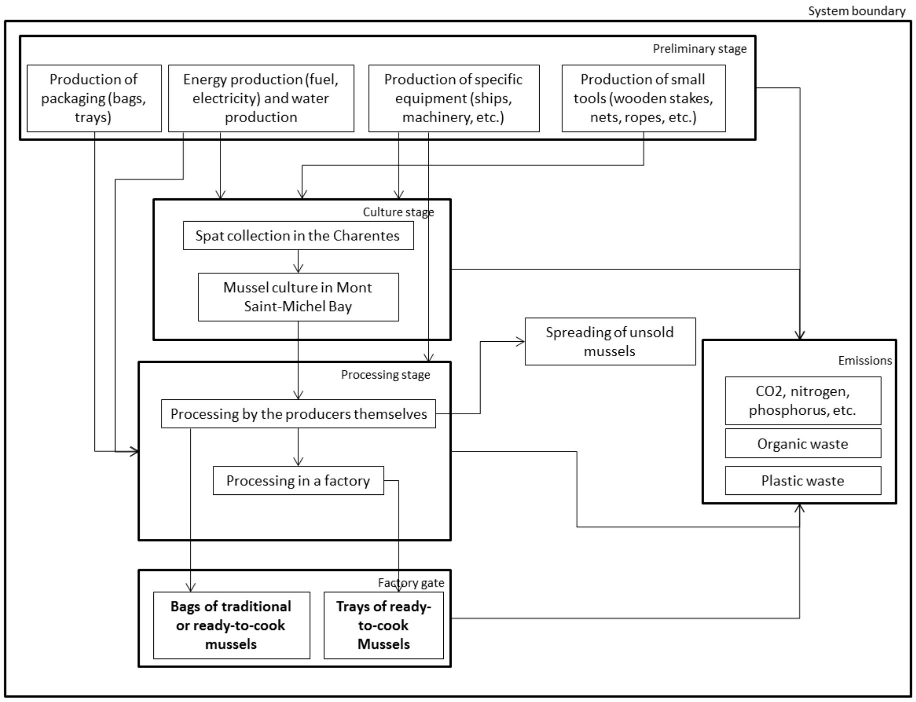

Figure 1. Stages of the mussel-production system included in the LCA

2.2. Life cycle inventory

Six of the main producers, operating in two or three subareas of the bay (Center, East, Far East), were interviewed from spring to summer 2012. They produced 300-450 tonnes of mussels per year. Their practices are regulated according to AOC specifications, which restrict the percentage of bouchots in use at the same time (55-65% according to the area) and the maximum mean annual yield to 60 kg of mussels per bouchot. These rules aim to preserve the productivity of the bay, and some producers have chosen to use only 50% of their bouchots at the same time. Bouchots are square wooden stakes, 5-6 m long and 10 cm wide, sunk 1 m deep in the foreshore. The stakes are made of exotic woods, most often *Lophira alata* and *Dinizia excelsa*, and are expected to last over 15 years. Bouchots are arranged in pairs of lines 100 m long and 25 m apart. The mussels must remain a minimum of 8 months on the bouchots. The beginning of harvest season occurs once the mussels have reached 4 centimeters in length and meet criteria of condition index and taste. This usually occurs in the first half of July. Mussels are harvested using hydraulic arms supported by amphibious boats, which scrape the whole mussel assemblage off, leaving the bouchots clean.

Water conditions in Mont Saint-Michel Bay are not suitable for natural reproduction of the blue mussel. Therefore, spat collection starts in March in the Bay of Biscay, mostly in the Charentes region. We described this stage using data provided by one producer, who is responsible for producing 300 km of seeded ropes each year. Producers construct temporary wooden structures on the lowest parts of chosen beaches and then extend ropes made from hemp or coconut fibers on these structures. The ropes remain in place for about two months before being brought to Mont Saint-Michel Bay by road.

Upon arrival, seeded ropes are coiled around free bouchots or laid out on temporary horizontal structures built on the foreshore until new bouchots are available. Once mussels start growing, producers stabilize the structure of the bouchot by progressively encasing each in 3-7 polypropylene nets, depending on the exposure of their sites. To reach the culture sites, producers use tractors, small aluminum boats or amphibious boats. Specific data collection on amphibious boats was performed at the main shipbuilding company.

After harvest, mussels are placed for at least 24 hours in an oxygenated purification pool. Water is pumped from the bay into a lagoon shared by all shellfish producers in the area. Afterwards, mussels go through a declumper, which separates the mussels from each other and shreds the ropes and nets. They are then cleaned in a brushing machine and calibrated, first mechanically, then by hand, to remove any other kind of waste (crabs, algae, broken mussels, etc.).

At this point, 20-30% of the production is discarded, mostly due to undersized mussels. These mussels are currently spread over the tractor roads in the bay. This practice serves two goals: stabilizing the roads in the sand and driving mussel predators away from the bouchots by giving them an easily available food source. Mussel spreading is currently under heavy debate and may soon be discontinued.

Mussels may then be put in 5, 10 or 15 kg polypropylene bags of "traditional" mussels and put up for sale. They may also pass through another machine that removes the byssus threads and be sold in 5, 10 or 15 kg polypropylene bags of "ready-to-cook" mussels, or 1 kg polypropylene trays of "ready-to-cook" mussels. LCA was performed on each type of packaging. However, this paper shows the LCA results for "ready-to-cook" mussel's bags only. Organic waste from cleaning and processing stages and all other types of waste are buried at the local landfill. Wastewater is returned to the ocean without any kind of treatment. All back ground data was extracted from the ecoinvent v2.2 database (Swiss Centre for Life Cycle Inventories 2010).

Mussel shells are composed of $CaCO_3$ and may be considered a carbon (C) sink if they are degraded slowly. According to Fry (2012) and considering that coastal seawater is saturated in $CaCO_3$ and that the Mont Saint-Michel Bay is shallow, we treated spread mussel shells as C sinks. Since other shells are expected to join ordinary household waste, we examined common waste-management options in France. Since 44.4% of French household waste ends up in landfills (ADEME 2008), we assumed that the shells of 44.4% of all mussels sold in France would be buried and act as a C sink.

Spread mussel flesh was excluded from our calculations since it belongs to a short cycle and did not influence overall nutrient balance of the bay. We calculated N and P exports based on the amount of mussel flesh present in marketed mussels. We also assumed increased biochemical oxygen demand of the water released into the bay due to organic-matter processing and bacterial decomposition of discarded mussels.

We estimated amounts of C, N and P in mussels (Table 1) based on Brigolin et al. (2009) and Chairattana et al. (2012). With data from the former, we excluded mussel respiration, considered as a short cycle in the bay, and calculated the amount of C sequestrated in mussel shells based on the balance of the remaining C flows. We supplemented this analysis with data from Chairattana et al. (2012), who showed that part of mussel shells is formed from dissolved CO_2, (not included in Brigolin et al.(2009)).

Table 1. Estimated C content in the shell, and N and P contents in the flesh, per tonne of blue mussels in the life cycle inventory.

Element in shell or flesh	Per tonne of harvested mussels
C in shell from ingested C (Brigolin et al. 2009)	198 kg C
C in shell from dissolved C (Chairattana et al. 2012)	18 kg C
N in flesh (Brigolin et al. 2009)	4.17 kg N
P in flesh (Brigolin et al. 2009)	0.38 kg P

2.3. Life cycle impact assessment

Impact categories were selected based on previous studies and guidelines in aquacultural LCA (Aubin et al. 2013; Pelletier et al. 2007): climate change (kg CO_2-eq), acidification (kg SO_2-eq) and eutrophication (kg PO_4-eq) were calculated using characterization factors of CML2 Baseline 2000 version 2.03 (Guinée et al. 2002). Energy use (MJ) was calculated according to the Total Cumulative Energy Demand (TCED) method, version 1.03 (Frischknecht et al. 2004). Water dependence (m^3) refers to freshwater use and was calculated according to Aubin et al. (2009). Calculations were performed with Simapro® 7.0 software.

2.4. Interpretation of results

Impacts of mussels at each production site for each producer were calculated independently (13 observations) and then aggregated. Variability in impacts was considered but not uncertainty due to foreground and background data. Contributions of different production stages of the system to the impacts were studied.

3. Results

Impacts of one tonne of ready-to-cook mussels varied according to production area and producer: acidification from 1.47-2.65 kg SO_2-eq, eutrophication from -1.69 to -0.85 kg PO_4-eq, climate change from -44.7 to 125.5 kg CO_2-eq, TCED from 7666-12,866 MJ, and water dependence from 92-98 m^3 (Table 2).

Table 2. Means and standard deviations (SD) of impacts calculated for 1 tonne of “ready-to-cook” mussels, depending on their location of culture within Mont Saint-Michel Bay.

	Center		**East**		**Far East**	
Impact	**Mean**	**SD**	**Mean**	**SD**	**Mean**	**SD**
Acidification (kg SO_2-eq)	2.24	0.25	2.29	0.26	1.59	0.15
Eutrophication (kg PO_4-eq)	-1.09	0.27	-0.98	0.14	-1.24	0.32
Climate change (kg CO_2-eq)	37.49	70.37	77.45	64.68	-6.56	34.81
Total cumulative energy demand (MJ)	11,360	1132	11,237	1599	8285	1069
Water dependence (m^3)	96.9	18.4	96.7	18.7	94.0	18.2

On-site transport was the main contributor to acidification and climate change impacts and a major one to TCED (Fig. 2). The culture stage greatly decreased eutrophication and slightly decreased climate change. Wooden stakes decreased climate change as much as on-site transport increased it. Wooden stakes were also an important contributor to TCED. The cleaning and packing stage was the main contributor to water dependence and a major one to TCED and eutrophication. The spreading of discarded mussels contributed markedly to eutrophication but slightly decreased climate change.

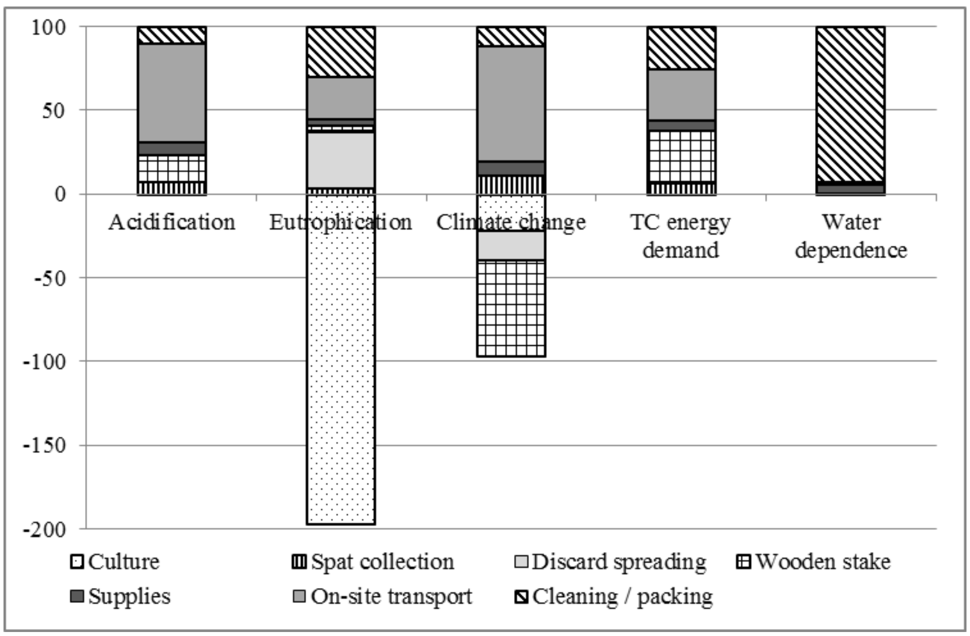

Figure 2. Contribution to environmental impacts of different stages of the production system of ready-to-cook mussels in Mont Saint-Michel Bay

4. Discussion

Assuming the uptake of N and P by mussel production induces a negative value for eutrophication impact, indicating a potential mitigating effect on water quality of the bay. Nevertheless, this favorable effect is low, around 1 kg PO_4-eq per tonne of “ready-to-cook” mussels, which should be compared to eutrophication impacts of other agricultural products produced in the Mont Saint-Michel region (e.g. 14 kg PO_4-eq per 1 tonne of pig live weight (ADEME 2013)). This result indicates a small but potential ability of mussel production to decrease eutrophication impacts due to livestock production at the territory level. This type of complementarity activity is also developed, for example, in integrated multi-trophic aquaculture for salmon production (Barrington et al. 2009).

Estimated climate change impact in this study showed high variability. On average, climate change impact is decreased first by the sequestered C in wooden stakes, then the spreading of discarded mussels, and then the burial of sequestered C in mussel shells in landfills. All of these processes, however, have high levels of uncertainty. Inventories from the ecoinvent database used to model exotic wood production are standard ones, and estimates of the wood's C sink effect are debatable. From this ecoinvent methodology, CO_2 assimilation is based on 49.4% of woods' C content. The percentage of household waste put into landfills may vary greatly depending on region and time period. Finally, the spreading of discarded mussels is about to be forbidden in Mont Saint-Michel Bay. In our case study, mitigation of climate change impact mainly compensates CO_2 emissions due to on-site transportation. At best, the bouchot blue mussel culture of Mont Saint-Michel Bay can be considered to produce little or no climate change impact but not as a C sink. Uncertainty analysis needs to be performed to assess the robustness of this conclusion.

In our study, impacts varied greatly according to the geographic location of bouchot sites. Two competing factors may explain this: mussel yield is higher in the Far East of the bay (due to ocean currents) than in the two other sites, but the Far East is further from on-shore infrastructure, and fuel consumption due to on-site transportation is a major contributor to impacts. As a consequence, we can observe negative values in eutrophication and climate change in the Far East area, where the production yields are the highest, inducing the highest nutrient uptake, and where the C fixing in shell over-compensate the CO_2 emissions of the rolling stock. This result has led the mussel producers' organization to revise their transportation strategy and the location of infrastructure.

5. Conclusion

Considering the chemical composition of mollusk flesh and shells to better describe their extractive capacity in the environment influences estimates of eutrophication and climate change impacts calculated with LCA. Results show a potential mitigating effect of blue mussel culture on water quality. A C sink effect due to mussel shell calcification was not confirmed, but a methodology that includes the composition and fate of shells during production processes and after consumption was developed. A similar approach should be performed on other production systems, other mollusks, and in other regions.

The bouchot culture of mussel is a low-impact activity, but fuel consumption to transport workers and mussels is a key point to analyze. Different environmental impacts in different locations suggest that efforts to render LCA increasingly spatially-explicit should be continued.

ABSTRACT

A comparative Life Cycle Assessment (LCA) of different management strategies in the pork industry was performed to evaluate the impact on global warming potential (GWP) and energy and water use. The management strategies included immunocastration, production without ractopamine, production without antimicrobials, and use of gestation pens. Impacts of each management practice were compared to a common baseline production strategy that represents current production practices. Scope of this study was from cradle through farm gate with a functional unit of 1 kg of live weight at the farm gate. Each scenario was simulated using the Pork Production Environmental Footprint Model, to populate life cycle inventory inputs for SimaPro V7.3 (Pre' Consultants, The Netherlands). The results showed that compared to the baseline, use of gestation pens and production of immunocastrated pigs had lower GWP, energy use and water use. Production without ractopamine and antimicrobials increased GWP, energy use, and water use.

Keywords: Swine management practices, Life cycle assessment,

1. Introduction

There is a demand for changes to some of the management practices prevalent in the swine industry Florida, in 2002, banned use of sow gestation crates and similar ban was imposed on the swine industry in Arizona in 2006 (Mench 2008). A survey conducted by the Rutgers University in 2003 revealed that between 74 and 83% of the participants disagreed with practices such as tail docking of cows and pigs without analgesics and confining gestating sows (Mench 2008). Heeding its consumers, (Smithfield Foods) decided in 2007 to phase out gestation stalls on company-owned farms over next 10 years and replace them with pens.

Life Cycle Assessment (LCA) is an effective tool for performing trade-offs associated with alternate management strategies. This project supports the goal of the National Pork Board environment committee to: optimize management practices to enable producers to make informed management practice decisions to continually improve their farms; provide pork producers with the information and education they need to evaluate and implement appropriate management practices on their farms; and educate customers about the environmental and sustainability consequences of their purchase decisions.

The objective of this study was to quantify differences or establish the absence of differences in the global warming potential (GWP), cumulative energy demand, and water consumption between current practices and proposed alternates. All the scenarios were simulated for Wright County, Iowa and a typical meteorological year was used as the simulated climate.

2. Methods

This study analyzed the cradle to farm gate impacts for 5 different management practices (Table 1) with a functional unit of 1 kg live weight at the farm gate was chosen for this study.

Table 1. Proposed alternate management practices

Management strategy	Description
Immunocastration	Use of inmmune-castration methods/product(s)- Improvest®
No ractopamine	Removal of ractopamine (RAC) as a tool to improve growth and production
No GP antimicrobials	Removal of antimicrobials as growth promoters (GP)
No Prev. antimicrobials	Removal of antimicrobials to prevent emergence of herd infection in addition to removal of GP antimicrobials
Pen gestation	Use of pen gestation housing

2.1. Description of Models

Assessment and comparison of different management practices in terms of greenhouse gas emissions, water use and electricity use involved a two-step process. In the first step nursery, grow-finish and sow barns were simulated using Pig Environmental Footprint model (University of Arkansas). The outputs of these simulations were used in the second step for LCA analysis using SimaPro V7.3 (Pre' Consultant, the Netherlands).

2.2. Pig Environmental Footprint model

The growth and feed conversion performance of pigs, resource consumption, and emissions to the environment were simulated using the PPEF model. The model simulates pig growth, feed intake and water consumption, electricity and natural gas use, manure handling, and greenhouse gas emissions over an annual cycle. The PPEF model uses a growth performance model developed by the National Resources Council (NRC) to predict growth and feed consumption of pigs (National Research Council 2012).

2.3. SimaPro LCA model

The SimaPro software platform was used to compare each management scenario to the baseline and for uncertainty analysis. The Ecoinvent database, corrected for US electricity, was used for background processes, and feed production data for the US developed at UA was used for constructing the animal's rations.

2.4. Scenario Description

Each test scenario evaluated only one management practice, where only the key element was changed. A single, typical ration was used for all scenarios to prevent confounding effects of the ration with the practice under evaluation. The last dietary phase in grow-finish barn was formulated to accommodate use of ractopamine by adding 0.05% Paylean 9 (Rikard-Bell et al. 2009, See et al. 2004). It was assumed that pigs have ad libitum access to the water and drinking water consumption, along with cooling and wash water, were simulated in the PPEF model.

2.4.1. Baseline scenario

Each scenario was compared pairwise with the baseline scenario. The baseline scenario included male (barrows) and female pigs in equal numbers and assumed growth promoting antimicrobial (AGP) use in the nursery, preventive antimicrobial use as required, ractopamine use in grow-finish barn, with tail docking and surgical castration of male pigs performed in the lactation barn. The NRC growth model for growing pigs assumes that the maximum protein deposition value (Pdmax) in pig decreases after a certain weight is reached (National Research Council 2012). Paylean-9 was added to the diet in the last phase of feed formulation and at a pig body weight of 96 kg to simulate 28 days on the ractopamine. The average market weight of 125 kg (approx. 275 lbs) (National Pork Board , USDA , USEPA) was chosen for fair study.

2.4.2. Removal of ractopamine (RAC)

Ractopamine is a dietary supplement which improves average daily gain (ADG) and feed efficiency (FE) in finishing pigs (Armstrong et al. 2004, Barbosa et al. 2012, Dunshea et al. 1993, Hinson et al. 2011) and is usually added to the diet during last 28 days in the finishing phase (Hostetler et al. 2012). The final ration phase, without ractopamine, was also altered to include more corn based on recommendations from swine nutritionists. No changes were made to the nursery and sow barn that provided feeder pigs to the grow barn for this scenario.

2.4.3. Antimicrobial use

Antimicrobials are used in animal industry for disease prevention, animal health improvement (Romina Ross et al. 2010), and as growth stimulants (Kiarie et al. 2011). However, antimicrobial use in animal industry has come under scrutiny due to the concerns about development of antimicrobial resistant strains that could affect human health (Holt et al. 2011). We constructed scenarios to evaluate the impacts associated with reduced use of antimicrobials in pig production. The first scenario assessed impact of eliminating growth promoting antimicrobials (AGP), while the second scenario assessed impacts of eliminating both growth promoting and preventive antimicrobial (NoPrev) use.

2.4.4. No growth promoting antimicrobials

Williams et al. (1997) estimated 12.7% increase in the metabolic maintenance energy requirement (MMER) when pigs have poor health. To simulate elimination of AGP from the production in the nursery phase, the MMER in the NRC growth equations for pigs between 5 and 23 kg was increased by 12.7%. The grow-finish phase of the production was assumed to be unaffected by elimination of AGP, as far as pig performance is concerned.

The National Pork Board Taskforce suggested not using AGP could mean fewer pigs would reach the expected weight and size requirements in the production facility, which was estimated to increase voluntary cull rate in the nursery and grow-finish barn to 0.25% for median health facilities. Without AGP, the mortality rate was expected to increase by 0.2% in the nursery phase. Because AGP is used mostly in the nursery phase, production without use of AGP was expected to have no impact on mortality rates in grow-finish barn.

2.4.5. No growth promoting and preventive antimicrobials

In this scenario, the effects of production without use of either AGP or preventive antimicrobial use on performance parameters were estimated. When herd health is trending downward, antimicrobials are used prophylactically to reduce the chance of herd-wide infection. Animals which become sick are treated therapeutically and will recover or die. Without preventive use, more animals are likely to need therapeutic doses. Whittemore et al. (2001) reported that chronic diseases in pigs increase the maintenance energy requirements by up to 1.3 times the normal predicted value. However, in the current scenario it was assumed that not using preventive antimicrobials in the grow-finish barn does not necessarily mean the pigs fall sick. It was assumed that without AGP and preventive antimicrobials in the production, the performance of pigs would be poor compared to the baseline. Therefore, MMER of pigs in the nursery and grow-finish barns was increased by 12.7% (Williams et al. 1997) and 15% respectively.

Without AGP and preventive antimicrobial use in the production the voluntary cull rates and mortality was expected to increase by 4% in the nursery and 5 and 5.5% respectively in grow-finish barn.

2.4.6. Immunocastration

Surgical castration of male pigs without anesthesia within first 1 to 2 weeks of age is a standard industry practice (FAO , Thun et al. 2006). Besides preventing boar taint in the meat, which is a result of skatole levels higher than 0.2 $\mu g\ g^{-1}$ of fat, surgical castration also improves meat quality and suppresses aggressive behavior in pigs (Dunshea et al. 2001, Morales et al. 2010, Thun et al. 2006). However, surgical castration is under scrutiny of animal welfare groups because the procedure is painful and distresses pigs (Millet et al. 2011, Morales et al. 2010).

An alternative to the surgical castration that is being studied is immunocastration, which involves administering male pigs a dose of gonadotropin-releasing hormone (GnRH) which creates antibodies against GnRH and reduce skatole production. Dunshea et al. (2001) reported that immunocastration also reduces size of testes in male pigs suppressing sexual aggressive behavior. This compound is administered at about 9 weeks of age and then again between 3 and 10 weeks prior to slaughter. Because male pigs perform like boars, which means they gain leaner muscle mass, until the second dose of GnRH compound, immunocastration offers improved ADG and FE in male pigs compared to surgically castrated pigs (Batorek et al. 2012).

The performance of immunocastrated (IC) pigs was modeled as a split sex barn with half males and half gilts. The NRC growth model for growing-finishing pigs assumes not effect of pig sex on the MMER (National Research Council 2012). However, it is assumed in the model that entire males have lower metabolizable energy intake (MEI) compared to the barrows.

Effects of immunocastration after second injection were captured in the model by increasing estimated MEI by 21% and reducing MMER and Pd by 12 and 8% respectively. No changes to the diet formulation were made for the immunocastration scenario.

2.4.7. Gestation stalls

Gestation stalls offer benefits such as maximum barn space utilization and controlled feeding, but the management practice has criticized by animal welfare groups because the stalls offer sow minimum or no free movement (Lammers et al. 2007). Group housing reduces the stocking density and thus requires additional housing to maintain animal production. Due to the difference in barn infrastructure necessary for the alternate management using gestation pens, the LCA scenarios have included the effect of changes in the infrastructure. A 10 year life for the barn facility, including the stalls and pens was assumed for this scenario. A bill of materials for construction of sow, nursery and grow-finish barns from plans published by Iowa State University Midwest Plan Service was created (data not published).

This scenario was designed to evaluate environmental impact of production management using gestation pens. Data for comparison between gestation stalls and group pen housing were obtained from published articles. This scenario evaluated the option of using gestation stalls for the entire gestation period only. It was assumed that farrowing stalls were used for both group pen and individual stall scenarios. The differences between sows housed in gestation stalls and in group pens were observed in number live births, litter size, pre-weaning mortality, and piglet weights at birth. An analysis of data obtained from peer-reviewed articles was performed to prepare scenarios for group and gestation housing (Table 2). These numbers were close to the results reported by (McGlone et al. 2004).

Bates et al., (2003) reported that 72% of sows housed in group returned to estrus within 7 days compared to 68.4% of sows in gestation stalls. In addition, 94.3% of group housed sows remained pregnant after initial service compared to 89.4% of sows in stalls. These differences were capture in the PPEF model by adjusting the average number of days between piglet weaning and insemination.

Table 2. Production parameters for gestation stalls and group housing

	Gestation stalls	**Group pens**
Litter size	10.5	10.34
No born alive	9.55	9.41
Preweaning mortality	15.4%	16.3%
Pigs weaned	8.08	7.88
Weight per piglet	1.5	1.53
Backfat thickness (mm)	19.6	20

Averages of data obtained from Anil et al. (2005), Bates et al. (2003), Harris et al. (2006), Lammers et al. (2007), SCHMIDT et al. (1985), Wang et al. (2011)

3. Results and discussion

Results of the LCA for the baseline and five pork production management strategies are presented in Analysis of the changes in environmental impact category metrics as a result of changed inventory from the PPEF for each management strategy showed that some strategies increased impacts, while others decreased impacts (Figure 1, 2 and 3). These analyses represent simulated estimates of impacts and should be interpreted as potential trends rather than absolute estimators.

3.1. Ractopamine

Not using ractopamine resulted in 6.5% increase in global warming potential, 4.6% increase in fossil fuel increase, and 5.6% increase in water use. The driving factor for the increase in GWP from removal of ractopamine was lowered productivity during the last month of finishing. The model simulations showed that days in the barn are increased when RAC is not used in the production. This directly affects the quantity of feed consumed, manure produced, and requires a small increase in necessary barn infrastructure to support the same annual lean pork production (i.e., a decrease in the number of turns per barn per year).

3.2. Antimicrobials

Not using antimicrobials as a growth promoting strategy resulted in 1.6% increase in global warming potential, 1.8% increase in energy use, and 3% increase in water use. The increased GWP was driven by two factors: lowered daily gain and feed efficiency leading to increased feed consumption and time required to reach market weight, and thus additional manure production as well. If preventive use of antimicrobials is avoided, there will be additional mortality, as well as further decrease in daily gain and feed efficiency compounding the effect. Finally, additional barn infrastructure will be needed due to lengthened time to reach market weight.

Coupling removal of AGP with not using antimicrobials for disease prevention resulted in 17.4% increase in global warming potential, 18.6% increase in energy use, and 18.9% increase in water use, the largest changes in this assessment. The effects of not using antimicrobials for disease prevention were driven by the same process impacts as not using them for growth promotion, compounded by increased mortality across the entire herd.

3.3. Immunocastration

This management alternative resulted in 2.3% decrease in global warming potential, 2.5% decrease in energy use, and 1.9% decrease in water use. This alternative approach to controlling boar taint resulted in increased average daily gain and reduced daily feed intake compared to baseline. In the grow barn, using immunocastration also resulted in increased cycles per year. This resulted in less overall feed consumption and manure production as well as a small reduction in the necessary barn infrastructure associated with the faster average turn-around for the barns.

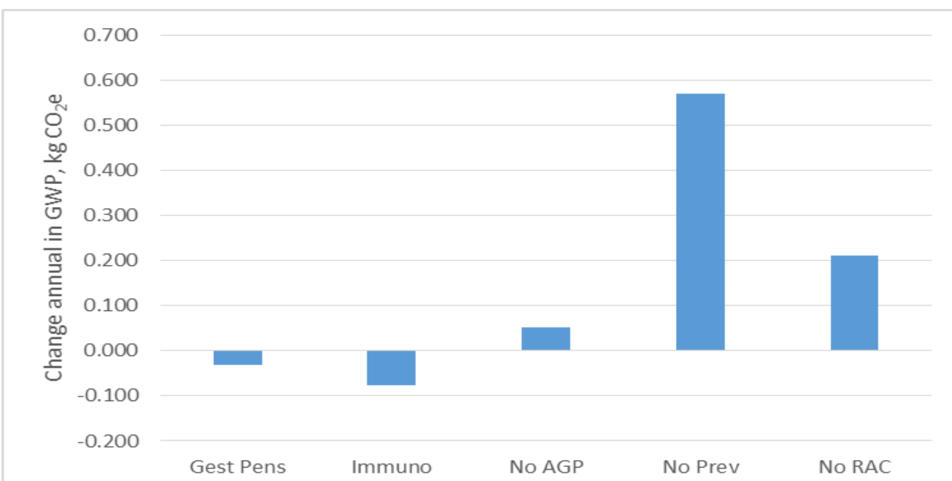

Figure 1. Estimated potential change in annual global warming potential (kg CO_2e) resulting from US production strategies for 1 kg live weight at farm gate

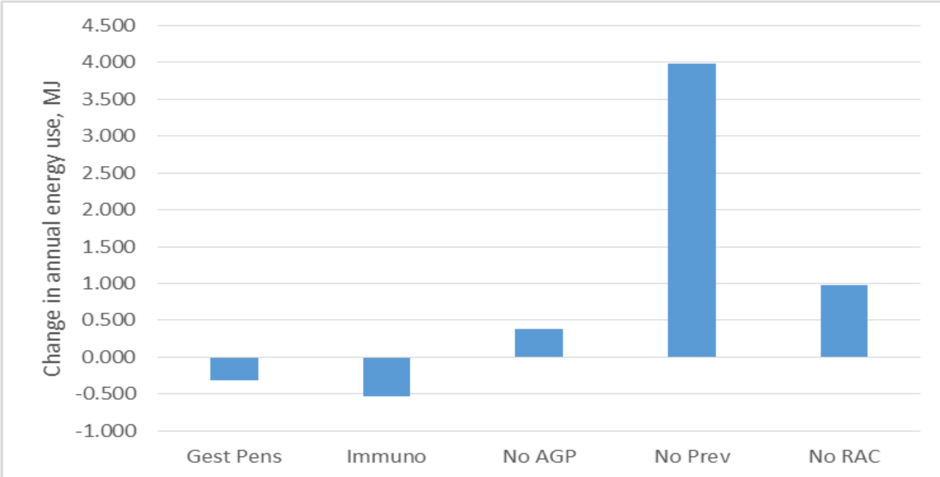

Figure 2. Estimated potential change in annual energy use (MJ) resulting from US production strategies for 1 kg live weight at farm gate

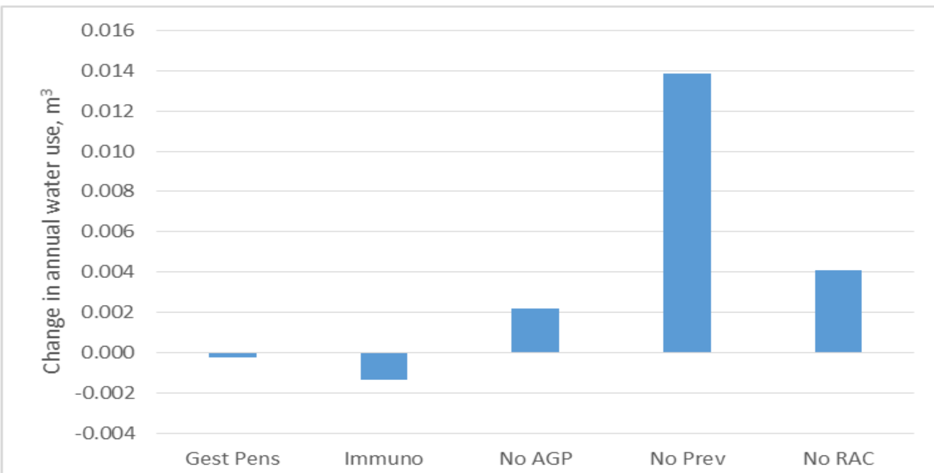

Figure 3. Estimated potential change in annual water use (m^3) resulting from US production strategies for 1 kg live weight at farm gate

3.4. Gestation pens

Using pen gestation structures rather than stall gestation structures resulted in 1% decrease in global warming potential, 1.5% decrease in energy use and 0.3% decrease in water use. Lower GWP observed in this scenario was a result of lower feed consumption and lower manure emissions. However, the barn infrastructure requirements for pens are 65% larger, based on our modeling of the space requirements for sow in stalls compared to pens. This increase the GWP, which is amortized over the expected life of the barn, and essentially offsets the lower GWP observed for this scenario. The lower energy demand appears to be a result of lower electricity use for fans observed for gestation pens.

4. Conclusion

Life cycle analyses of five pork production strategies for three environmental impact categories for yielded a range of results, from 17% increase in global warming potential (removing AGP and preventive antimicrobials) to approximately 2.5% reduction in energy use (immunocastration). Based on LCA results, the following pork production strategies increased environmental impact metrics across all three impact categories: not using antimicrobials for growth promotion or disease prevention and not using ractopamine for growth promotion. Conversely, using immunocastration and pen gestation production strategies decreased global warming potential and energy use, and water use. The results of this study indicate that changes made to production practices in the swine industry, could affect sustainability metrics and therefore need cautious evaluation. These results however, are the product of simulation of pork production strategies combined with unit process LCAs; these models are very sensitive to time in the barn at each growth stage, temperature inside the barn, and mortality rates and therefore should be interpreted cautiously.

ABSTRACT

As part of the AGRIBALYSE® project, apple and peach from France, small citrus from Morocco and mango from Brazil were evaluated. Representative systems for each fruit were designed relying mostly on expert knowledge for apple, peach and small citrus and on a detailed survey of 8 commercial orchards for mango from the Rio San Francisco Valley in Brazil. For most impact categories, apple showed the least impacts, small citrus the greatest. Beyond the classical yield effect, this was mostly linked to lower fertilizer rates for apple and to fossil energy share in the electricity. For marine eutrophication, mango and small-citrus had the least impact, followed by apple and peach far above. For ecotoxicity, mango had the least impact followed by apple, peach and small citrus far above. Ecotoxicity results revealed the most uncertain due to the difficulty to determine representative crop protection practices for perennial crops. Complementary research is needed to better model crop protection practices, field emissions and water use impacts.

Keywords: Fruits; environmental impacts; crop protection practices; uncertainty; representative systems

1. Introduction

As all other food products traded globally, fruits are under growing scrutiny regarding their environmental impacts. In France, the Agribalyse® program was launched by the French environment agency (ADEME) in 2009 to support environmental labeling as planned by the "Grenelle de l'environnement" roundtables. Based on the life cycle assessment (LCA) methodology, the objective of Agribalyse® was the development of a homogenous and consensual LCI database for French agricultural products and a few imported products. In France, 50% of fruits are produced locally and 50% are imported often from distant and warm countries. As part of the Agribalyse® program, two locally-produced fruits: apple and peach, and two imported from overseas: small citrus from Morocco and mango from Brazil were evaluated. The evaluation of fruits with LCA is quite recent, the most studied fruits being citrus (Sanjuan et al. 2005; Beccali et al. 2009; Trydeman Knudsen et al. 2011; Pergola et al. 2013; Lo Giudice et al. 2013) and apple (Mila i Canals et al. 2006; Mouron et al. 2006; Alaphilippe et al. 2013). Ingwersen (2012) recently published a full LCA study on pineapple from Costa-Rica, but tropical fruits have been seldom studied with complete LCA studies. The application of LCA to fruit cropping systems has revealed specific challenges related mostly to their variable and perennial cropping systems, frequent pesticide treatments and use of irrigation water (Mouron et al. 2006; Bessou et al., 2012; Cerutti et al., 2011 and 2013). Although most LCA studies do not account for the perennial cycle of fruit cropping systems, certain authors have recommended the inclusion of all phases of fruit orchards in the LCA modeling of fruits including nursery, orchard installation, growing of trees, full production phase and possibly decreasing-yield phase and dismantling of plantation (Mila i Canals et al. 2006; Cerutti et al. 2011; Bessou et al. 2012; Cerutti et al. 2013). Bessou et al. (2012) proposed a formalization of the different possibilities to account for the perennial cropping systems depending on the objective of the study and data availability. One can either use a spatial assessment, a chronological assessment or a modular assessment, presented as the minimum requirement to account for the perennial cropping cycle. A modular assessment in which each phase is modeled independently with different sources of data can be used when neither complete spatial data nor chronological data are available on the studied system. Bessou et al. (2012) also highlighted the inadequacy of usual methods for estimating field emissions for perennial cropping systems especially under tropical, sub-tropical or semi-arid conditions. For instance, tropical and sub-tropical systems remain clearly underrepresented in IPCC Tier 1 data sets. Bessou et al. (2012) concluded on the need for producing specific data sets on perennial cropping systems to improve existing operational models and the prediction of their field emissions. Finally, several authors also raised the issue of the choice of functional unit and allocation procedures for fruit products, insisting on the various qualities of fruits including their edible content. Ingwersen (2012) used the serving of fruit (165 g fresh fruit according to USDA 2009 definition) to express his results and compare with other LCA studies. Cerutti et al. (2013) recommended indicating the edible content of fruits when a mass-based functional unit is chosen. Regarding the comparison of imported fruits with locally-grown equivalent, the question of allocation may be crucial since the fruits exported correspond to the highest quality fruits, the lower quality fruits being usually sold locally.

In a context of recent application of LCA to the fruit sector, the objective of the Agribalyse® program was not to develop new research but to properly apply the consensual and up-to-date methodology for all agricultural products including fruits.

The objectives of this paper are:

- To present the methods and data used to design and assess fruit cropping systems in each situation
- To present and discuss the LCA results for the 4 fruits in relation to existing literature, methodological choices, data availability and studied function
- To identify some margins of improvement and research perspectives

2. Materials and methods

2.1. Goal and scope

The main objectives of this study were:

- Comparing a panel of major fruits produced with conventional rules and consumed in France, two locally-grown: apple and peach and two imported: mango from Brazil and small citrus from Morocco.
- Applying the consensual methodology of the AGRIBALYSE® project (Koch and Salou, 2013).
- Designing most representative systems as possible for each situation given the data availability.

In line with the Agribalyse® method, the functional unit used was 1 kg of fruit at farm-gate. Representative systems for each fruit were designed relying mostly on expert knowledge for apple, peach and small citrus and on a detailed survey of 8 commercial orchards for mango from the Rio San Francisco Valley in Brazil. The reference period defined in the Agribalyse® report is 5 years from 2005 to 2009 but must reach 10 years for strongly alternating productions such as fruits. This was formally possible for mango where data were collected over more than 20 years on real orchards but relied on expert advice for other fruits supposed to include seasonal and regional variability over the orchards' life. For crop protection practices, data were based on a large sample survey (349 field surveys) for apple, on expert advice for peach and small citrus and on average data for the 8 surveyed orchards for mango. For all fruits, the full orchards' life was modeled according to recent practice (2000-2010) as presented in section 2.2.1 using either real data or expert advice.

2.2. Studied systems

In agreement with the AGRIBALYSE® method, the system boundaries were set from cradle-to-farm-gate including the production, transport and use on the farm of all inputs except very minor tools and inputs, e.g. pruners, and non-agricultural buildings (Figure 1).

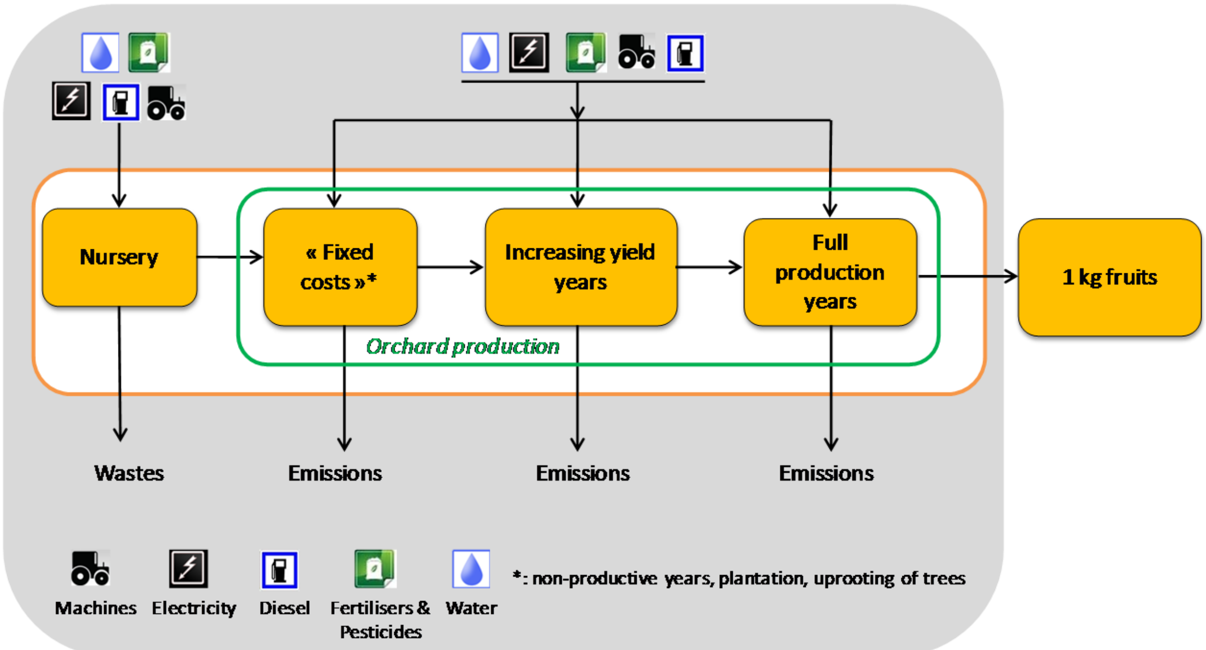

Figure 1. Cradle-to-farm-gate fruit systems for apple and peach from France, mango from Brazil and small citrus from Morocco

2.2.1. Modelling of perennial cropping systems

According to the AGRIBALYSE® methodology, the perennial cropping system was modeled in four phases: nursery (or plant production), fixed costs (including plantation, non-productive years and uprooting of trees at the end of the orchard life), increasing yield years and full production years. This implied to collect or estimate representative data for all four phases in terms of agronomic practices and duration. An important assumption for perennial cropping systems is the life time of the orchard. It was assumed to be 20 years for apple, 15 for peach, and 25 years for mango and small citrus.

2.2.2. Apple from France

Apple is mainly produced in the South-East, the South-West and the Loire Valley regions in France, according to 38%, 31% and 23% surface-wise, respectively (Agreste, 2008). In each region, experts of apple production from technical extension services and farmers' associations participated in the design of most representative apple production systems for the recent period. The average conventional system was a combination of non-scab and scab resistant (or tolerant) varieties across all regions weighted by their respective share. Crop protection practices were based on a survey from a large sample of orchards (349 field surveys) for the period 2005-2008. These data for the full production phase (years 5 to 20) were extrapolated to the entire life cycle of the orchard ignoring the constant evolution of active molecules certification. For the first (non-productive) years, crop protection practices were assumed to be one third of that for full production years while they were assumed to be two thirds for increasing yield years (from 2 to 4). Only the most common molecules were selected from the survey. Data for the nursery phase was based on the survey of two nurseries, one in the Loire Valley region the other in the South-East region. Key agronomic data for the full production phase of apple production and other fruits are presented in Table 1.

2.2.3. Peach from France

The production of peach is mainly located in the South of France. Similarly to the apple inventory, experts of peach production from technical extension services and farmers' associations were involved in the design of the most representative peach production systems for France for the recent period. Based on national statistics from Agreste (2008), the national average system was the weighted (surface-wise) combination of early, median and late productions, influencing the yield, mechanization requirements, crop protection and irrigation practices (see table 1 for full production phase). Two commercial nurseries representing more than 25% of the production of peach scions and grafted plants were surveyed to design the nursery phase. Crop protection practices were based on expert knowledge for the full production phase (years 5 to 15) and extrapolated to other phases of the orchard assuming one third of pesticide inputs from the full production was applied for the first non-productive years (years 1 and 2) and two thirds for increasing yield years (years 3 and 4).

Table 1. Main agronomic data for the full production phase of apple (France), peach (France), mango (Brazil) and small citrus (Morocco). Values are given per annum.

Intervention	Unit	Apple	Peach	Mango	Small citrus
Country		France	France	Brazil	Morocco
Orchard age	Years	20	15	25	25
Density	Trees/ha	1730	640	280	500
Yield	t/ha	53,7	28	33	28
Fertilisation					
N	kg/ha	50	110	165	180
P_2O_5	kg/ha	30	100	100	45
K_2O	kg/ha	125	220	273	180
Irrigation					
Water	m^3/ha	2767	7000	7999	8000
Energy	MJ/ha	2,988	7,560	2,946	22,830
Plant protection products					
Total herbicides	kg/ha	3.4	4.4	0	10.2
Total insecticides	kg/ha	5.1	0.7	0.301	9.58
Total fongicides	kg/ha	38.4	24.2	5.66	16.5
TOTAL pesticides	kg/ha	48.9	29.3	5.961	36.3
Growth regulators	kg/ha	0.2	0	4.03	0.02
Petroleum oils	kg/ha	12.3	16.3	0	0

2.2.4. Mango from Brazil

Brazil is the leading supplier of fresh mangoes to the EU. In the Rio San Francisco Valley which concentrates more than 90% of Brazilian mango exports, modern and intensive production systems have developed. These systems feature year-round production thanks to well-controlled floral induction and abundant dam water access. In this region, a sample of eight contrasted Kent and Tommy Atkins mango orchards was surveyed in 2012. Data over the complete crop cycle of mango trees was collected, over more than 20 years for elder orchards. Despite this detailed and very time consuming survey, many input and yield data were missing over the 25 years of mango orchards. Annual average for all input and yield data available across the eight orchards were first calculated and aggregated into average data for each phase (see table 1 for full production phase). No nursery was included since grafted plants are produced on farm.

2.2.5. Small citrus from Morocco

In Morocco, small citrus for export to France are produced in two main regions of production: the Souss region and the Oriental region (Berkane area) with, for the 2009-2010 season, 55.6% of small citrus exported and 32.8%, respectively (EACCE, 2010). Until recently in each region, specific varieties and cropping system management were used. In the Oriental region, traditional practices included mainly Clementine varieties such as Cadoux, low density orchards (270 trees.ha^{-1}) and gravity irrigation, while in the Souss region the management was more modern and intensive using mostly the Nour variety, high density orchards (500 trees.ha^{-1}) and drip irrigation. According to local experts, the Oriental system is rapidly evolving toward a more modern management very similar to the Souss system. For this reason, we chose the Souss system using Nour variety, high density orchards and drip irrigation as the most representative for the Moroccan small citrus for export to France.

Key input and yield data for the representative Souss-Nour system were based on expert knowledge of the small citrus production in Morocco for each phase of the citrus orchard (see table 1 for full production phase). Other more specific operations and data were based on a detailed survey over the whole orchards' life of one commercial orchard of small citrus from the Beni Mellal region. Regarding crop protection practices, the main pests were inventoried and the most common practices and active molecules used for each pest defined. Other practices may exist. A detailed survey was conducted in a commercial nursery to design the nursery phase.

2.3. Environmental inventory

2.3.1. Emissions from orchards

To estimate field emissions, the AGRIBALYSE® recommendations were applied (Koch and Salou, 2013). Phosphates and pesticides emissions were calculated according to Nemecek and Kägi (2007), assuming that 100% of the pesticides applied would be emitted to the soil (Nemecek and Kägi 2007). Nitrous oxide, carbon dioxide from urea and lime and nitrate leaching were estimated according to IPCC (2006). Ammonia emissions were based on emission factors from EMEP/CORINAIR 2006 and nitrogen oxides according to EMEP/EEA (2009). According to IPCC (2006), nitrate leaching was considered nil for mango and small citrus because localized irrigation is used and rainfall is reduced in both regions (daily irrigation (or rainfall) volume was constantly below the soil field capacity) while for apple and peach it was assumed to be 30% of the nitrogen inputs. The SALCA-SM method was used for trace elements but only for French products since data was missing for imported fruits (Freiermuth, 2006 and SOGREAH, 2007). For land transformation, the Ecoinvent v2 reference was used (Frischknecht et al., 2007).

2.3.2. Indirect inventory data

Indirect inventory data were based on Ecoinvent Life Cycle Inventories (LCI) database available in the SIMAPRO software and on processes developed specifically for the studied production system and the country.

2.4. Characterization of environmental impacts

The impact assessment was performed using the ReCiPe Midpoint life cycle impact assessment method (Goedkoop et al., 2009), adopting the Hierarchist perspective. The following environmental impact categories were considered: climate change (100 years; kg CO_2eq), terrestrial acidification (g SO_2eq), freshwater and marine eutrophication (g P-eq and g N-eq respectively, based on the nutrient-limiting factor of the aquatic environment), terrestrial and freshwater ecotoxicity (g 1,4-DB-eq: 1,4-dichlorobenzene), agricultural land occupation (m^2.year), fossil depletion (kg oil-eq). The non-renewable energy consumption (fossil and nuclear; MJ-eq) was assessed using the Cumulative Energy Demand method (Hischier et al. 2009). To facilitate comparison with published LCA studies, we also calculated LCIA results using the CML 2001 methodology (Guinée et al., 2002) (see section 2.5).

2.5. Comparison with published LCA studies

We compared our cradle-to-farm-gate LCA results with cradle-to-farm-gate LCA results from 9 published studies on fruits using the CML 2001 methodology (Guinée et al., 2002) (Table 2). Incomplete LCA studies were discarded. Among all studies, GWP and Non-renewable energy demand were the most consistently evaluated and could be systematically reported. Apart from Pergola et al (2013) who evaluated both non-renewable and renewable energy sources based on Namdari et al. (2011), all other authors used different versions of the Ecoinvent method for cumulative energy demand in MJ (Frishknecht et al., 1996; Frishknecht et al., 2003; Hischier et al., 2009). For eutrophication and acidification potentials, most studies used CML 2001 or EDIP97 which are identical for eutrophication and slightly different for acidification (Dreyer et al., 2003). Several studies did not include toxicity impacts due to methodological limitations (Beccali et al., 2009; Trydeman Knudsen et al., 2011; Pergola et al., 2013). In other studies a range of approaches was used for toxicity impacts. We only selected results from studies using the CML methodology: Sanjuan et al. (2005), Alaphilippe et al. (2013).

3. Results

3.1. Cradle-to-farm-gate LCA results for apple, peach, mango and small citrus

Except for marine eutrophication, terrestrial ecotoxicity and freshwater ecotoxicity, apple revealed the least impacting per kg of raw fruit at-farm-gate, followed by mango, peach and small citrus showing the greatest impacts (from twice to four times apple's impacts) (Table 2; Figure 2). This was firstly due to the yield of raw fruits ranging from 54 t/ha at full production for apple, to 33 t/ha for mango and 28 t/ha for peach and small citrus. A second important aspect was the fertilizer rates on orchards increasing from apple, peach, mango and small citrus. Overall, the two imported fruits showed higher fertilizer rates than the French ones. Another reason for this ranking was the share of fossil energy in the mix electric in each country, increasing from France (less than 10%), Brazil (10%) and Morocco (50%).

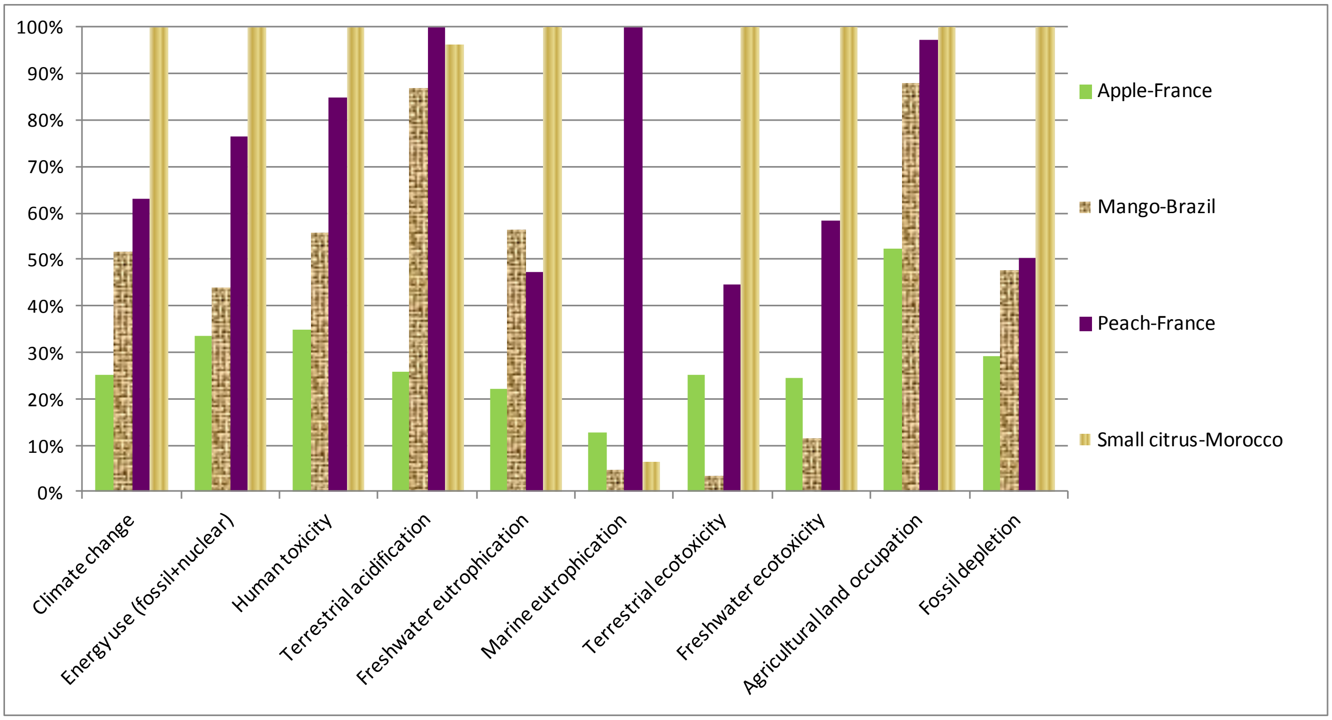

Figure 2. Cradle-to-farm-gate LCA results per kg of raw fruit for a selection of environmental indicators (ReCiPe Midpoint (H)) for apple, mango, peach and small citrus. Results are expressed as a percentage of the greatest result.

Table 2. Cradle-to-farm-gate LCA results per kg of raw fruit for a selection of environmental indicators (ReCiPe Midpoint (H); Cumulative Energy Demand) for apple, mango, peach and small citrus.

	Apple France	Mango Brazil	Peach France	Small citrus Morocco
Climate change (kg CO_2-eq)	0.0678	0.139	0.170	0.269
Non-renewable energy (MJ)	1.12	1.46	2.54	3.32
Human toxicity (kg 1,4 DB-eq)	0.0273	0.0436	0.0664	0.0783
Terrestrial acidification (g SO_2-eq)	0.610	2.05	2.36	2.27
Freshwater eutrophication (g P-eq)	0.0283	0.0715	0.0602	0.127
Marine eutrophication (g N-eq)	0.233	0.0842	1.83	0.116
Terrestrial ecotoxicity (kg 1,4 DB-eq)	0.00177	0.000230	0.00312	0.00699
Freshwater ecotoxicity (kg 1,4 DB-eq)	0.00151	0.00071	0.00359	0.00616
Agricultural land occupation (m^2.a)	0.239	0.402	0.445	0.458
Fossil depletion (kg oil-eq)	0.0195	0.0317	0.0334	0.0667

Mango and small citrus had both lower marine eutrophication (around 0.1 g N-eq), compared to apple (above 0.2) and peach (1.8). This was explained by the use of IPCC nitrate emission factors: being nil under drip-irrigated crops in semi-arid climate as mango from Brazil and small citrus from Morocco but reaching 30% of nitrogen inputs for crops under temperate climate as apple and peach from France.

Regarding terrestrial and freshwater ecotoxicity, mango showed for both the least impact followed by apple and then by peach and finally by small citrus far above. The great ecotoxicty impact for small citrus was essentially due to the use of Chlorpyrifos-ethyl for controlling California red scale in small citrus orchards in Morocco. This molecule has a very high toxicity potential and does not have efficient alternative up-to-date. The low ecotoxicity impact for mango was probably also the most uncertain of all since it relied on a small sample of farms. Furthermore, although the use of highly toxic molecules, such as Cypermethrin, in mango orchards had been orally reported we could not find evidence of such treatment in our sample of farms. This would definitely warrant further confirmation through survey across a wider sample of farms.

3.2. Comparison with published references

We could not find complete LCA studies for peach and mango. For apple and small citrus, our results were in the same range as results from the literature for GWP, Energy use, eutrophication and acidification (Table 3). For toxicity impacts, we only had one reference for each product to compare with. Overall, results were of the same order. Overall, the literature references confirm the least impacts of apple compared to citrus at farm-gate. This can be explained by higher nitrogen inputs and energy use for irrigation in citrus production associated to lower yields compared to apple.

4. Discussion

4.1. Farm-gate environmental impacts for 4 fruits consumed in France calculated with the Agribalyse® methodology

Until recently, fruits consumed in France had never been assessed with the LCA methodology. LCA references were therefore crucially needed to feed the eco-labeling program and debate on food products. Two locally-grown and two imported fruits were evaluated with the LCA methodology following a consensual method as dozens of other French agricultural products. This constituted an important step forward. At farm-gate these studies confirmed the greater impacts of citrus compared to apple mainly due to intensive practices associated to lower yield. It also produced novel references for peach and mango for which no LCA studies could be found worldwide. Contrary to most LCA studies on perennial products, in the Agribalyse® methodology the whole perennial crop cycle was modeled which represented an important and systematic progress. Beyond these important achievements, one should remind that in the Agribalyse® program the system boundaries were set at farm-gate which represents a limitation to properly compare imported with local fruits. The first reason relates to the exclusion of the transport of imported fruits to their final market which can represent important impacts. The second limitation is the non-inclusion at that stage of the quality requirements on fruits for export. From the total yield at farm-gate, only a fraction will have the required quality and should be allocated most of the impacts due to its higher economic value compared to the local quality fruits. Locally-grown (French here) fruits also show different qualities but will all end up on the local market. Moreover, in Agribalyse® the functional unit used was the kg of raw fruit while another important aspect for comparing fruits is the actual number of servings per kilogram of fruits also corresponding to their edible part (Ingwersen 2012; Cerutti et al. 2013). Thus, the rules for a proper comparison of imported versus locally-grown fruits need to be analyzed and formalized. At least the system

a: based on Namdari et al (2011), these figures include both renewable and non-renewable energy sources but Pergola et al (2013) explained that the renewable energy share is reduced to 5% in conventional systems. b: presented figures correspond to EDIP97 for Mila i Canals et al. (2006) and Trydeman Knudsen et al (2011) and to Heijungs et al. (1992) for Mouron et al. (2006) being probably overestimated compared to CML 2001 acidification results.

boundaries should be extended beyond the farm-gate to include transportation phases, fruit quality (including edible part) and allocation issues between the different fruit qualities. Regarding the method used for estimating field emissions, the most consensual and up-to-date ones were chosen which represented an important progress. However, the very generic emission factors used (such as IPCC or EMEP-CORINAIR ones) are not particularly valid for perennial crops under semi-arid climate. This represents definitely an important margin of progress and perspective for research. Finally, although water deprivation can represent a key environmental problem for fruit production, this indicator could not be included in the Agribalyse® program and this should be completed in upcoming studies.

4.2. Design of representative systems

One key difficulty of the Agribalyse® objectives was the design of representative systems in terms of technology, time and space. Important discrepancies between situations were faced in terms of data quality and availability. Where statistical average systems could be calculated for some products, others such as fruits were mostly evaluated through expert-based scenarios (apple, peach, small-citrus) or small samples of farms (mango). If expertise can be satisfactory for estimating most inputs and agronomic data, it is insufficient to capture the actual shares of pesticides used across a population. Knowing that certain active molecules have very high toxicity potentials, not having this statistical representation constitutes an important bias in the assessment of an average system. Using a small farm sample for mango proved even weaker in its capacity to capture the diversity of pesticide treatment practices and results for toxicity impact categories for mango should be seen as very uncertain. For French fruits, an additional effect has to be reported. Due to the French ECOPHYTO program aiming at reducing drastically pesticide use in France, most toxic molecules have been banned since 2009 (last year of the period covered by the Agribalyse systems). This means that a lot of molecules of pesticides used in our systems for apple and peach are no longer certified and used. Finally, it is important to keep in mind that designing representative practices over a period of 25 years represents a contradiction in itself and a difficult challenge especially for pesticide treatments which follow constantly changing rules.

5. Recommendations and conclusions

The Agribalyse® program permitted the production of a vast and consensual LCI database for French agricultural products including 4 fruits. This was definitely an important step forward. Effort should be continued to improve the representativeness of the average systems, develop the LCA beyond the farm-gate, include water deprivation and improve the methods for estimating field emissions under perennial cropping conditions in the South.

6. Acknowledgements

This work is part of the Agribalyse® program funded by ADEME. Most authors of this paper are members of the ELSA research group (Environmental Life-cycle and Sustainability Assessment www.elsa–lca.org), and wish to thank the French Region Languedoc–Roussillon for its support to ELSA.

ABSTRACT

Climate change mitigation has recently become an important goal in our society. It is one the three objectives in the developing of last set of changes in the Common Agriculture Policy for the European Union. LCA methodology is able assess environmental impacts of food production along the food chain. Within LCA studies, carbon foot printing has becoming a popular indicator to communicate results to consumers, producers and all stakeholders involved in food sector. Sheep production is important activity in Southern Europe. Intensification of sheep farms is happening according to the global process of intensification of agriculture and livestock production in general and that involves, the decrease of people who are living in rural areas, the industrialization of the agriculture sector and this is a risk for local and small-scale producers. This paper presents results for emission intensity of two sheep milk systems in Northern Spain using different perspectives: productive (from 2.11 to 5.35 kg CO_2eq/liter of ECM), economic (from 0.84 to 13.4 kg CO_2eq/Net Margin), human resources (from 39,142.34 to 314,799.5 kg CO_2eq/Manpower Unit), and land occupation (from 964.11 to 6,882.43kg CO_2eq/ha). Lower values of emissions have been found for intensive farms per liter of FPCM and highest ones per land occupation, or manpower unit. Although improving efficiency and lowering costs are key factors reduce environmental impacts of food production, a holistic point of view is imperative to consider; and economic and social criteria need to be included in LCA assessments.

Keywords: Carbon footprint, Sheep farming, Multicriteria assessment.

1. Introduction

Climate change is one of the main issues that the livestock sector has been coping with recently (Gill et al, 2010), largely due to the importance of Greenhouse Gas Emissions (GHGs) coming from primary sector, especially from enteric fermentation of ruminants. Overall, 14.5 % of all human-induced emissions are produced by livestock sector (Gerber et al., 2013). Small ruminant's environmental impact is 10% of total methane emissions, and 18.83% of N_2O from manure management. (Gill et al, 2010).

LCA methodology has emerged as a tool useful to monitoring processes and identifies hotspots in different environmental categories, most of them focusing in food production (Flysjö et al, 2011). Global warming is one of them. Carbon footprint (CF) is becoming a popular indicator, considering its facility to understand, and communicate results from consumers and society in general.CF express intensity of kg of CO_2 per unit of product. Nevertheless, CF can generate conflict in other categories inside environmental quality indicators depending how results are reported, where high yield farms could have less emissions per unit produced. For this reason some knowledge is needed regarding the use of CF as an indicator for wider environmental impacts from food products (Röös et al, 2013).There are studies in biography which question if it's a good option increase milk yield per animal to decrease GHGs emission (Zehetmeier et al, 2012).

There is an urgent need to consider social and economic aspects in LCA studies (Flysjö et al, 2012). In addition to global warming impacts, food production also affects the environment considerably in many other ways (Röös et at, 2012) like land and resources demand (Garnett, 2014) .For the other hand, the concept of multifuncionality has become stronger (van der Ploeg & Roep, 2003; Van Huylenbroeck et al, 2007) to attribute more functions to agriculture, a part of providing food and fibres to society. The non-market functions of primary sector have been one of the midpoints of the future of the Common Agricultural Policy (European Commission, 2010) and it one of the justification with the link between the subsides with greener production systems (Matthews, 2013). Nevertheless, socio economic context which LCA results need to be situated (Edwards-Jones, et al, 2009) and different metrics to account GHGs could significantly alter the results and ranking (Reisinger & Ledgard,2013)

The overall aim of this study is to describe GHGs emissions with different functional units in order to extend the system boundary including social and economic factors to the classic environmental assessment. Carbon footprint is a useful conduct for analyzing the potential contribution of a product to climate change, but only efficiency approach (milk production) is taken into account.

This work has the following start point questions,
- How does the functional unit influence in the result of CF?
- Can we use metrics to influence in the interpretation of the results?

2. Methods

2.1. Case study

Sheep production has relevant importance in South Europe (de Rancourt et al, 2006) and in the Basque Country becomes a key sector in production of cheese (Ruíz et al, 2011) in semiextensive systems traditionally with an importance of pasture uplands during summer season. To tackle with the objective of this study, 12 sheep milk farms in the Province of Álava (Basque Country, Northern Spain) have been analyzed. All data was primary taken for SERGAL (advisory farmers association) for year 2011.The study involves this work required, more deeply data than other classical LCA studies, involving environmental, economic and social information of each farm through personal surveys and several visits every month.

Table 1. Main technical characteristics of farms analyzed in this study.

	Minimum value	**Maximum value**
Land occupation (ha)	29.1	229.1
Average annual temperature (ºC)	10.2	12.1
Workers (number)	1	5
Milk ewes (average population)	108	835.1
Annual production (liters of milk)	20,946	233,267
Liters/ewe year	109.1	399.4
Lambs (annual sales)	134	424
Lamb sold/ewe	0.4	1.16
% time grazing	0%	52.7%
Concentrate (kg/year)	29,185	388,495
Fodder (kg/year)	5,880	237,560
Oil(liters/year)	1,269.2	18,478
Electricity (kwH/year)	2,350	37,431.1
Mineral fertilizer (kg/year)	0	61,712.4
Prize milk (euros/liters milked milk)	0.77	2.4
Prize lambs (euros/kg lamb)	3.06	5.08

The main differences visible in farms are the high production of intensive farms (average yield per sheep 325 liters/year) with more traditional farms (average yield per sheep 110 liters/year); housing of intensive management flock (0% grazing per year) comparing with traditional flocks (approx. 48% grazing in natural grasslands); and price of sale of milk from 0.77 euros/liter at farm gate to those farmers who sell milk to industry to 2.4 euros/liter of milk to those who make cheese in their own farms and sell directly to consumers in local markers.

CF is been calculated following guidelines of PAS2050 (BSI, 2008) and IPCC criteria for livestock and soil emissions (IPCC, 2006).

2.2. System boundary

In order to integrate social and economic dimensions into LCA studies, environmental boundary has been integrated with social and economic boundaries. The system used in this study (Figure 1) coverts from cradle to farm gate. It includes emissions arising from manufacture and distribution of farm inputs ,the use of energy on the farm (fuels and electricity), the GHG emissions from livestock and their excreta, and emissions from soils related to fertilizer use and manure management. Nevertheless, environmental boundary does not take into account economic and social aspects as prices of inputs and sale prices, land occupation of the flock, as well as manpower units and relation of the farms with the environment. Thereby not only environmental resources are included in the assessment.

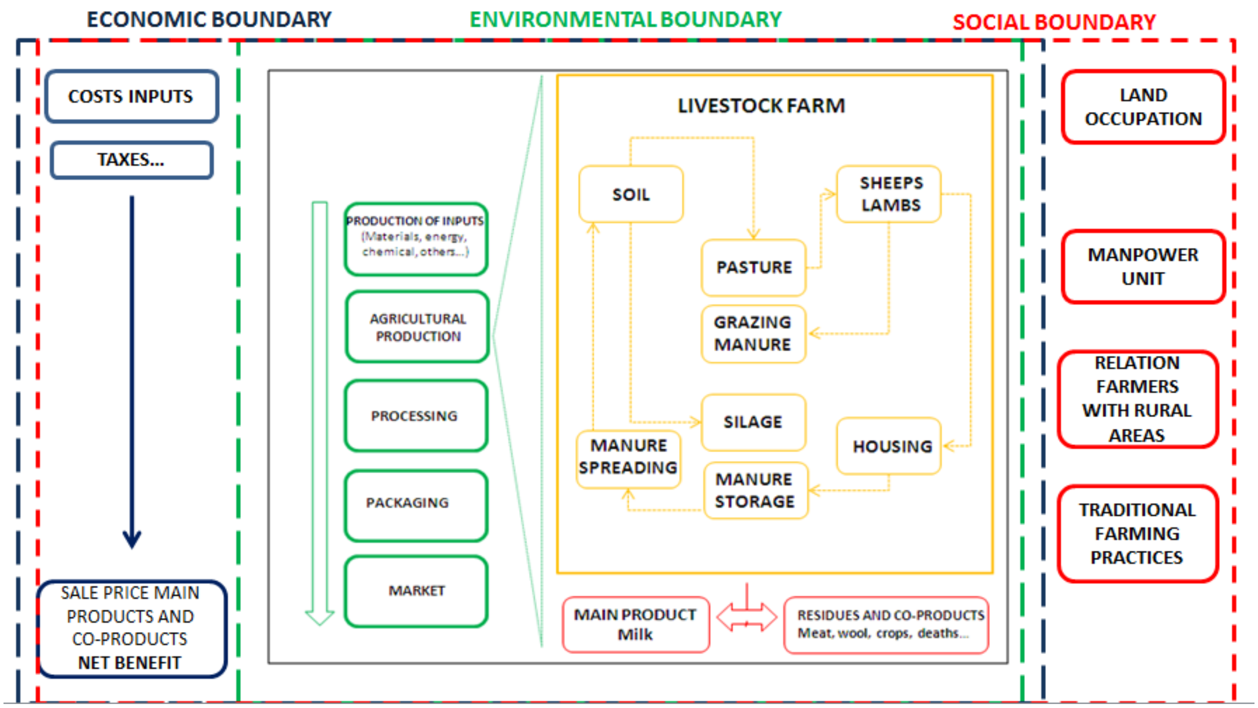

Figure 1. System boundary.

Emissions on farms and off farms (from production and manufactured of inputs) have been included in the breakdown GHG fluxes considered. According with system boundary, Table 2 shows these sources of emissions as well as the gases involved in each study and the source of the emission factor used. All the emissions are given in kg CO_2 equivalent, in accordance to the global warming potentials (GWP100) available from IPCC (2007).

Table 2. Source of emissions and models used in the study.

Sources of emissions	Gas	Source	OFF FARM/ON FARM Emissions
Enteric fermentation	CH_4	Torres et al (2004)	ON FARM
Manure management	CH_4	(IPCC, 2006)/MAGRAMA (2011)	ON FARM
Manure management	N_2O	IPCC 2006	ON FARM
- **Direct N_2O emissions**		Equation 10.25	
- **Indirect N_2O emissions**			
- **Volatilization**		Equation 10.26, 10.27	
- **Leaching**		Equation 10.28, 10.29	
Emissions from managed soils	N_2O	IPCC 2006	ON FARM
- **Direct N_2O emissions**		IPCC 2006, Equation 11.1, 11.2, 11.3, 11.4, 11.5, 11.6, 11.7, 11.8	
		IPCC 2006, Equation 11.9, 11.10, 11.11	
- **Indirect N_2O emissions**			
Emissions from liming	CO_2	IPCC 2006 Equation 11.11	ON FARM
Emissions from urea fertilization	CO_2	IPCC 2006 Equation 11.12	ON FARM
Energy use of farm (fuel and electricity)	CO_2	GES´TIM & IBERDROLA	OFF FARM/ON FARM (combustion)
INPUTS (feed, fertilizers, pesticides...)	CO_2	GES´TIM	OFF FARM

2.3. Functional unit and allocation

The functional unit (FU) is the unit which all GHGs emissions are reported relative to it. The FU is a measure of the function of the studied system and it provides a reference to which the inputs and outputs can be related, for that reason is a key element in the later work of reading the results. Traditionally, LCA studies on milk production use "1 kg of milk at farm gate" as functional unit. Table 3 shows the four functional units proposed in this study to cover economic, social and environmental boundary for the global warming potential of sheep milk production.

Table 3. Functional units proposed in the study.

Functional unit	Unit	Aspect to study
Energy Correct Milk	Kg ECM	Productive. Efficiency
Hectares	ha	Land Occupation
Manpower Unit	Number worker	Human resources
Net Margin	Euros	Economic/profitably

- Energy Corrected Milk (ECM). Milk yield from dairy sheep was corrected according to Bocquier et al, (1993) at 1200 kcal/liter of sheep milk.

$$ECM = 0,071 * fat (\%) + 0,043 * protein (\%) + 0,2224 \quad \text{Eq. 1}$$

- Hectares. Number of hectares that has been used by the sheep flock for feeding purposed during a year. This functional unit is proposed to focus the importance of land occupation by grazing for livestock, especially in less favorable areas, as uplands.

- Manpower Unit. Number of employee people on the farms. This functional unit copes to human resources necessary for milk production.

- Net Margin (NM). Difference between the sold price of outputs and the cost of all the inputs necessary for production including taxes. Profit of the farmer.

As shown in Figure 1, sheep production has edible and no edible products as outputs. Economic allocation was used to allocate GHGs emissions between milk, lamb and wool production. The reason of using economic allocation in the study is that in this case study, the main purpose of these farms, it is the milk sheep production, and lambs and wool are only co-products relative to the main production.

3. Results

Total emissions per ha, per Net Margin, per kg ECM produced and per Manpower unit are presented in Table 4 in maximum, average and minimum values.

Table 4. CF according with functional units (Minimum, average and maximum values).

Carbon footprint	Minimun values	Average values	Maximun values
Kg CO2-Equivalente / ha	964.11	3,190.75	6,882.43
kg CO2-Equivalente / NM	0.84	5.13	13.40
Kg CO2-Equivalente / Manpower Unit	39,142.34	131,309.69	314,799.50
kg CO2-eq/kg ECM	2.11	3.35	5.35

Using kg ECM corrected milk as FU, farms with high production (323 liters/ sheep year), will have lower CF. Normally these farms, are farms which lower land occupations, and with higher kg CO_2 eq/ha.

Figures 1, 2, 3 and 4 presents the correlation between emissions per functional unit and that functional unit, to highlight that depends in the functional unit chosen the way of read the results can be complete different.

Correlations between CF and functional units have been studied. There are no high correlations in any of the functional unit chosen in this study. Moderate negative correlation R^2 =-0.65 per ha (surface) and R^2 = -0.62 when Net Margin is the functional unit. On the other hand, positive correlation R^2 =0.41 for manpower unit, and high-moderate positive correlation, R^2=0.89 when liter per ewe is functional unit. Bigger differences can be seen between kg CO_2 per kg ECM and kg CO_2 per ha. If results are only given per kg ECM produced intensive production have lower emissions per functional unit, but these farms have higher emissions per land occupation.

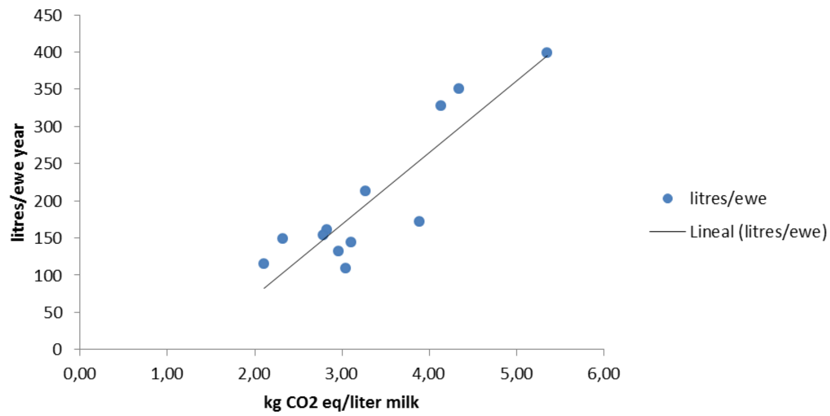

Figure 1. Relation between CF and milk annual production per sheep**.**

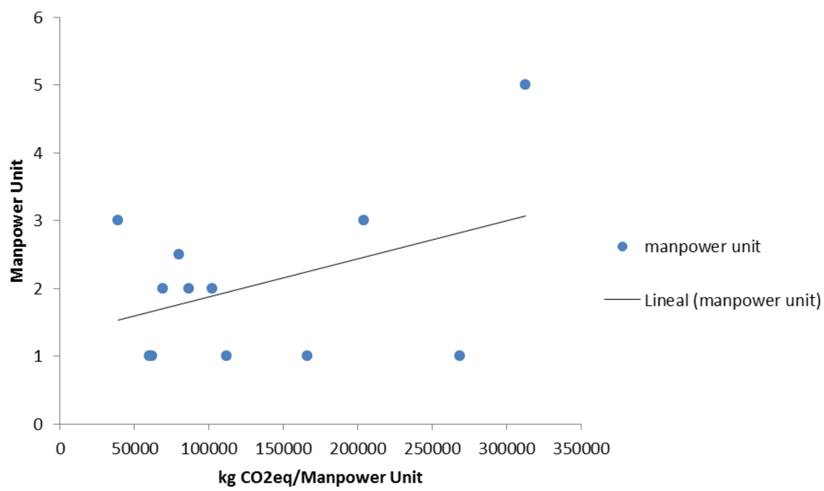

Figure 2. Relation between CF and Manpower unit.

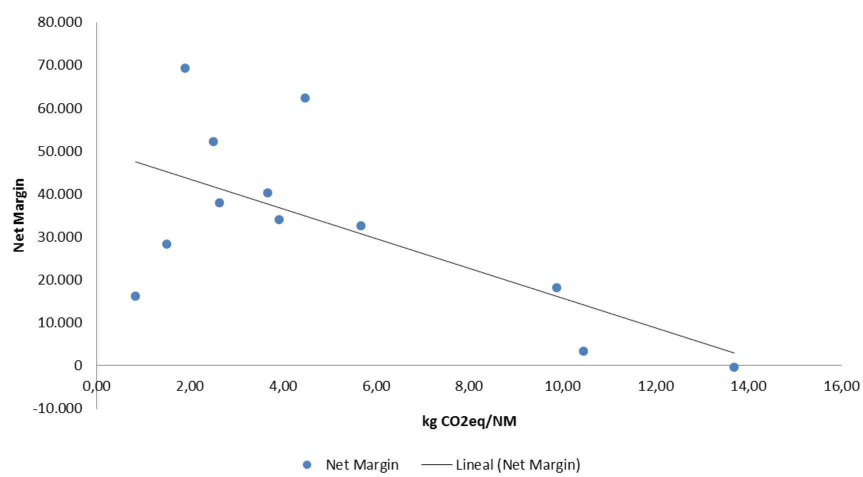

Figure 3. Relation between CF and profitability.

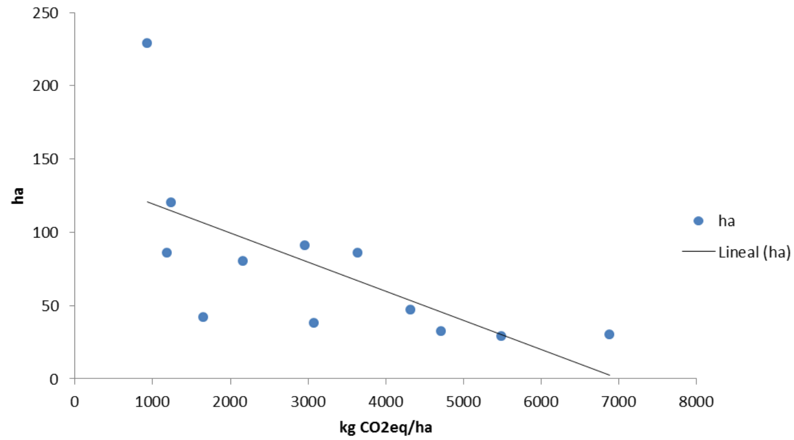

Figure 4. Relation between CF and land occupation.

4. Discussion

CF gives a number that means the contribution of one product to climate change. Table 4 shows results to the farms studied, emissions of 1 kg ECM are from 2.11 to 5.35 kg CO_2 eq/kg ECM. These results are similar to other studies, as Opio et al. (2013), Weiss and Leip (2012). If we only take into account this indicator as criteria of environmental assessment, we would choose the farm with lower CF as the most climate change friendly. In this example, the farm with lower CF corresponds to a very intensive management farm; totally different to the traditional sheep milk production in The Basque Country. Meanwhile, the one with higher CF corresponded with a traditional farm with grazing as important feed resource for the flock, typical from uplands in this territory. It is necessary not only think in productive functional unit (not only efficiency could be the criteria) and CF message could be misunderstood. Table 5 displays how farms can have the maximum and minimum value depends in which functional unit we take into account. For example, farm number 11 has one of the maximum values of CF per kilogram of ECM, but in the other hand, has one of the lowest values of emissions per hectare. This is an example of how traditional farms, less productive than the intensive could have higher intensity of emissions if we only focus in productive functional units.

Table 5. Benchmarking of the 12 farm studied depending in the different functional units.

	kg CO_2-eq/kg ECM	kg CO_2-Eq/ NM	Kg CO_2-Eq / Ha	kg CO_2-eq/Manpower Unit
Farm with maximum value	Farm 12	Farm 7	Farm 1	Farm 1
	Farm 11	Farm 9	Farm 10	Farm 9
	Farm 6	Farm 1	Farm 4	Farm 11
	Farm 7	Farm 2	Farm 12	Farm 7
	Farm 5	Farm 3	Farm 3	Farm 12
	Farm 4	Farm 6	Farm 11	Farm 8
	Farm 8	Farm 8	Farm 2	Farm 6
	Farm 10	Farm 12	Farm 6	Farm 4
	Farm 9	Farm 10	Farm 9	Farm 10
	Farm 1	Farm 4	Farm 5	Farm 3
	Farm 2	Farm 5	Farm 7	Farm 2
Farm with minimum value	Farm 3	Farm 11	Farm 8	Farm 5

Fig 5 presents kg CO_2/kg ECM and kg CO_2/ha for the farms studied. Dots represent kg CO_2/kg ECM and bars represent kg CO_2/ha. In general the one with are higher with one criteria are the lowest values for the other.

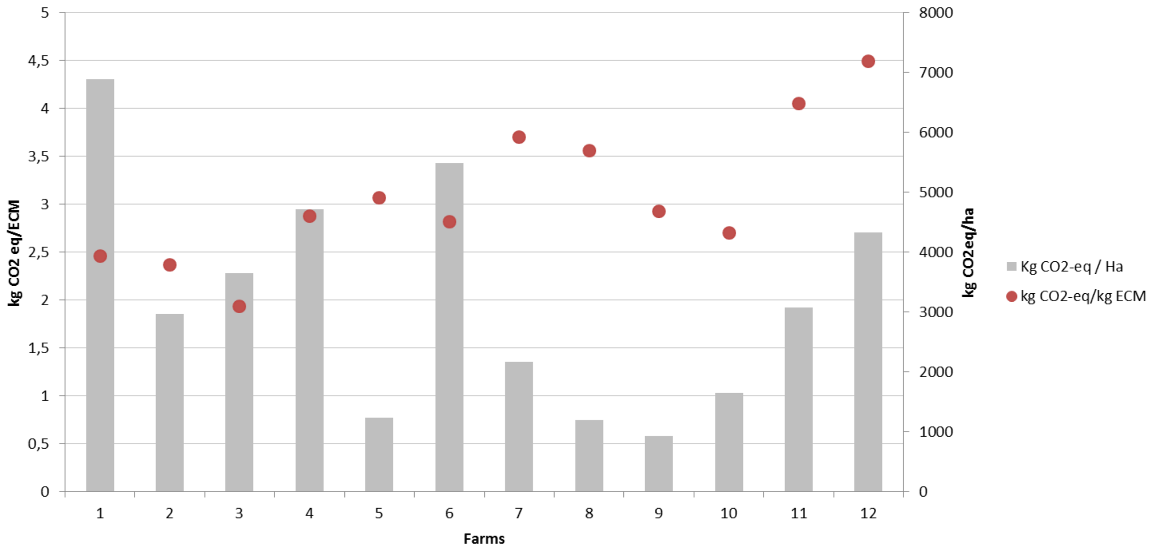

Fig 5. kg CO_2/kg ECM and kgCO_2/ha in the 12 farms studied.

5. Conclusion

Although improving efficiency, lowering cost are key factors on improve environmental impacts of food production, a holistic point of view is imperative to consider; and economic and social indicators are needed to include in LCA assessment.

CF is a useful indicator to monitor emissions by individual farms. Nevertheless, when results between farms are compared, these numbers could be misunderstood, particularly when high differences of efficiency occur within them. This work presents how using different number to express emissions, using different FU could arrive to different results, depending on the socio-economic context.

LCA studies need to take into account other aspects beyond yield to enlarge system boundary and strengthen role of alternative production systems (organic, traditional productions) and several functions given to primary sector nowadays.

ABSTRACT

In the wine sector, professionals want to reduce the environmental impact of their production but without taking the risk of reducing the quality of the grapes produced and the yield. The present study consists in combining environmental and quality assessment in order to take decisions about the vineyard management strategy. A multi-criteria assessment method will be used to combine those both aspects. But first, the LCA methodology must still be improved in viticulture, in particular for taking into account the carbon cycle (with carbon storage). As LCA results are potential impacts, the quality assessment needs to show also potential results instead of measured data as it is done today. A predictive model for quality evaluation, based on the vineyard management and the natural environment is, hence, being developed in this project.

Keywords: Life Cycle Assessment, multi-criteria analysis, quality, viticulture, practices, grape

1. Introduction

French government has developed a policy on sustainable development that includes a 50% reduction on the use of pesticides between 2008 and 2018. Viticulture sector is concerned about this policy because even if it represents only 3.7% of the French UAA (Utilized Agriculture Area) it uses 20% of pesticide (in kg) consumed in the country (Aubertot et al. 2005). The use of pesticide isn't the only concern of winegrowers. They also wish to reduce on a global way, the impact of their practices on the environment.

The vineyard technical management route (TMR)[1] implemented by the grower, soil and climate factors are the main determinants of quality and environmental impacts of the grapes. These factors have complex and sometimes opposite effects on environmental impacts and quality of grapes.

First of all, LCA methodology for viticulture (Renaud-Gentié et al. 2012) needs to be completed in particular by taking into account the carbon cycle (with carbon storage). Results of LCA that are presented through impact categories will be selected, combined or weighted for inclusion in a multi-criteria analysis to be compared with the quality assessment.

Secondly, the methodology of grape quality assessment has also to be adjusted for insuring comparison with LCA and for joining them together. As LCA permits predictive scenario analysis through potential impacts calculation, the quality assessment needs to give also potential results for predictive analysis besides the measured data that are available today. A predictive model for quality assessment, based on the vineyard management in one hand and soil and climate in the other hand is, hence, being developed in this project.

Finally, results of LCA that are composed by midpoint impact categories and results from the quality evaluation of grapes (which also gives many different variables) will be assessed jointly through the construction of a decision tree.

Methodologies are applied for a white grape variety on five vineyards plots, which represent the diversity of practices of the Middle Loire Valley (France) dry wine vineyards plots in Protected Designation of Origin (PDO) (Renaud-Gentié et al. 2014).

2. Methodological issues

The present study considers all activities at the field from the plantation to the uprooting of vines and by taking into account one year of full production. The period considered for the production year is from the end of the last harvest until the end of the harvest of the year considered. Environmental impacts of phases of planting and

---

[1] Technical Management Routes (TMRs): logical successions of technical options designed by the farmers (Renaud-Gentié et al. 2014)

uprooting of vines are amortized on the life of the vine. What happens after the harvested grapes have left the field is not considered in this study. As a consequence, winemaking process isn't considered, just as wine storage, bottle production and distribution are described in (Renaud et al. 2011).

The system boundaries include the equipment, energy, and water consumed during the viticulture period. The transportation of workers from the headquarters to the plot is considered and also the transport of all inputs.

The joint assessment method for combining Quality Assessment with LCA is being developed by Christian Bockstaller and is named CONTRA (Transparent Construction of Decision Trees) (Kaueffer 2013). It is an aggregation method based on knowledge and preferences that integrates fuzzy logic (Bockstaller et al. 2013).

LCA analysis is performed using SimaPro software (SimaPro 8). The inventories of practices come mainly from the analysis of the winemaker's practices. They are completed by data from the industry, climate data of the region studied, soils characterizations, the Ecoinvent database (version 3) and national database.

The Quality of grapes is evaluated from the incorporation of data about the practices, soil and climate of the year considered into a Quality assessment model that is being developed in this research program. This model is based on Partial Least Square (PLS) Regression 2 (Sang and Lee 2009) (Reinikainen and Höskuldsson 2007) applied on a data set of plots studied for four years in the region of the present researches. The resulting model will be validated after comparison with actual measurements of quality study plots. The approach used for developing the joint evaluation is explained through a scheme shown in Figure 1.

The experimental network concerns the Chenin Blanc grape variety, which is one of the major cultivars of the Middle Loire Valley for white wine production. Five plots representing the diversity of vineyard management strategies of the central Loire Valley PDO vineyards compose the network (Renaud-Gentié et al. 2014).

Two functional units are considered for this study; first the surface of 1 ha of a producing vineyard. This functional unit will enable us to compare the systems from the land occupation point of view. The second functional unit is the kg of grapes produced.

3. Discussion

A part of this study is to continue the adaptation of LCA on viticulture from the research lead off by Christel Renaud-Gentié (Renaud et al. 2012). Most of these adaptations consist in taking into account the carbon cycle in the assessment including carbon sequestration (Rabl et al. 2007; Helin et al. 2013).

First, the vine leaves falling on the soil each year are biodegraded by the soil fauna and provides a part of minerals and nutriments that will allow the plant to continue growing. The balance is not null but there is compensation between the material consumed by the plant for the production of leaves and the carbon released by the plant when the leaves fall.

Secondly wood is produced during one year of production by the development of the vine cane. The main part of this wood is cut every year after harvest. The wood can be mowed, left on the soil and directly biodegraded by the soil fauna, but it can also be burnt as energy source or be collected and processed by a waste treatment plant.

The quantity of wood produced yearly represents a small quantity compared to the quantity of wood available at the end of the vineyard life while the vine plants of a plot are grubbed up. At its end of life, this wood is mostly burnt through house warming or collected and processed by a waste treatment plant. In this case represents a much bigger quantity of carbon potentially released and suddenly a more significant environmental impact depending on the end of life destination of the wood. In addition, while plot are grubbed up, there is a release of carbon associated with the destruction of the cover crop, if present, at the time of pulling.

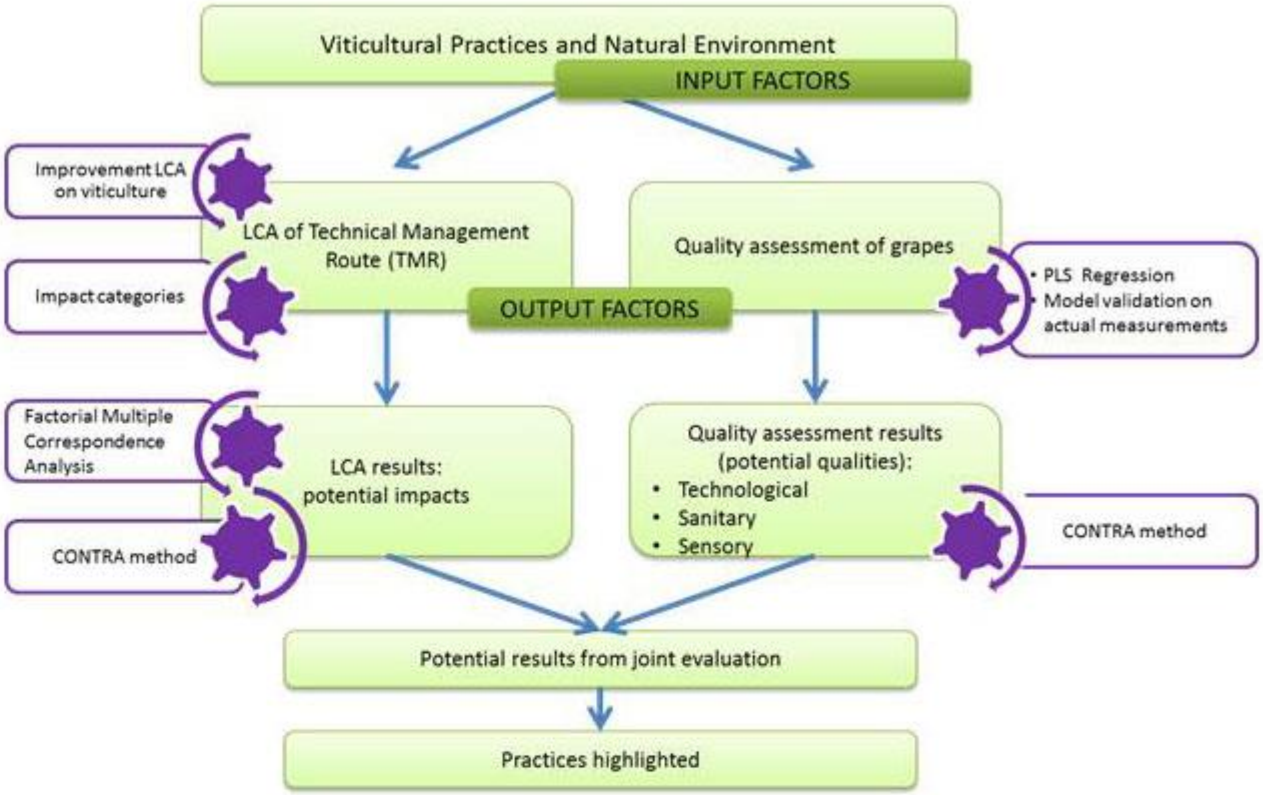

Figure 1. Overall scheme of the joint assessment process.

Concerning the environmental assessment, it should also be noted that some environmental indicators may not tie into the problems of the viticulture sector. That's why indicators used for assessment will be those, which represent an issue for the professional sector like Global Warming potential, acidification potential, toxicity indicators or even land use.

For ensuring the combination of LCA with Quality assessment a predictive model of the grape Quality based on practices and environmental factors (soil, climate…) is being developed. Most factors that influence the quality of grapes are taken into account. The notion of Quality can be defined in many different ways. In this study, the goal is to define a Quality assessment that would help the winegrower to transform its grapes into the best wine he could expect to have. To do so, Quality is assessed through the technological, sanitary and sensory evaluations of grapes. The sanitary assessment is the visual estimate of the decay rate of grapes. Technological qualities are evaluated by the sugar level, phenolic compounds by spectrophotometry (SO 280 and DO 420), pH and acidity of a representative grapes berries sample. Sensory assessment considers aromas, sugar, acidity, the grape berries texture and other properties of a representative grapes berries sample. The panel who evaluates the grapes berries is composed of industry professionals who taste the berries up to a maximum of 48 hours after collection.

For each of those components of the Quality, several parameters have been defined and are measured.

Most of those parameters have been registered in past years on different plots of Chenin Blanc in the Loire Valley, and kept in databases.

From those data previously mentioned, a mathematical relation is being built between the inputs (practices, climate and soil) and the outputs (sensory, sanitary and technological Qualities). It's important to notice that there also are interactions between input data and it's the same for output data.

Partial Least Square Regression 2 (Reinikainen and Höskuldsson 2007) is able to find relations between input and output data while there is interaction between factors. The results of the PLS Regression 2 (Reinikainen and Høskuldsson 2007) will be evaluated by a group of experts that will adjust its structure according to their expertise. They will define priorities between each input: practices, climate and soil and its degree of influence on each component of the quality (Table 1).

Table 1. Presentation of the decision tree for joint evaluation

Developing a predictive empirical model of quality may be not accurately reflecting the real phenomenon that occurs. The objective in this study isn't to reflect the exact reality but to get as close as possible from it for being able to model the consequences of a change in practice, taking into account environment factors. There are many interactions between the input factors of the model and those factors have numerous interactions that influence model outputs. Similarly, introducing the sensory evaluation of grapes quality is a challenging innovation as sensory analyzes must be adapted for each grape cultivar. Finally, there might be too many quality indicators to get the joint assessment; that's why they will have to be selected.

Thanks to the predictive method for the grape quality it should become possible to estimate the quality of grapes from the practices on the field, its soil and climate. It's important to notice that the model for evaluating the Quality of grapes from practices, climate and soil can be used only for the cultivar Chenin under the Loire Valley climate conditions. Indeed the Quality assessment is based only on this cultivar for the region considered.

At the end of the LCA and Quality assessments there are multi-results for each assessment. CONTRA can help joining both assessments but in this case there are too many results. For LCA results, a Factorial Multiple Correspondence Analysis (FMCA) will be applied on impact categories to keep only the main components of environmental impacts; avoid duplication of information and therefore reduce the number of impact categories.

The methodology CONTRA helps defining, with the user decision rules aggregation based on results from LCA and Quality assessment model.

4. Conclusion

The combination of LCA and grape quality assessments will allow understanding how to improve practices and select the ones, which prove to be the best trade-offs between quality and environmental performances.

It will be possible to analyze the input data that are responsible for the impact on the environment through one or more impact categories. And in the meantime we'll know their importance on grape quality. According to their importance on the combined assessments, advices will be given to the winegrower to point out the impact of his practices.

By working on five plots which are managed in completely different way, it will be interesting to identify practices that are able to improve both aspects of the assessment (environmental and quality) or that are able to decrease the environmental impact of the process without reducing the quality of the product. The positioning of each TMR evaluated will give a list of the vineyard management techniques responsible for results obtained. Thanks to that, advices would be given to the winegrower for adapting some of his practices for decreasing the environmental impact of his grape production without reducing or even with increasing the quality of his grapes.

The research on grapes led us to believe that those methods could also be applied on other agricultural productions; perennial products first but also annual products. It would also be interesting to even include this multi-criteria assessment in or combine it with Sustainable Life Cycle Assessment.

5. Acknowledgements

This work wouldn't be possible without the financial support of Region Pays de la Loire (France) and ADEME, SAF.

ABSTRACT

Nitrogen fertilization practices have a significant effect on the LCA results of biodiesel chains, which warrants reliable inventory data. In this study focused on the Lorraine region (eastern France), we established a typology of oilseed rape fields based on fertilization practices, and used the agro-ecosystem model CERES-EGC in lieu of generic emission factors to simulate the productivity and externalities associated with oilseed farming. The results were subsequently used to generate an LCA of biodiesel from oilseed rape. We also tested the effect of improved practices on the LCA results. In Lorraine, oilseed rape crops appeared to be frequently over fertilized compared to best management practices. Switching to improved practices with optimal fertilization has a potential to reduce the GWP of 1 megajoule of biodiesel by around 6 gr CO_2eq, against a total life-cycle of 43.9 gr CO_2eq.

Keywords: biodiesel, oilseed rape, farming practices, emissions modeling, LCA

1. Introduction

The development of the use of biofuels in the transportation sector in Europe is the consequence of policies aiming at enhancing energy security and mitigating climate change through the reduction of anthropogenic greenhouse gas (GHG) emissions. After the recognition of the unexpected effects of the development of first generation biofuels on agricultural prices and land-use, a set of sustainability criteria outlined in a directive dedicated to renewable energy must henceforth be respected (Ben Aoun et al. 2013). From 2016, the substitution of fossil fuels by biofuels should allow the saving of at least 50% of GHG emissions (European Commission 2009).

The standardized method of life cycle assessment (LCA) is currently widely recommended for evaluating the environmental balance of products. When applied to bioenergy chains, several factors may influence its outputs. Thence, LCA studies concerning the same biofuel type can lead to significantly different results (IPCC 2011). In addition to methodological choices such as system boundaries, functional unit and co-products handling, these variations are essentially due to differences in the life cycle inventory stage. Recent studies (Davis et al. 2013, Smeets et al. 2009) showed that data on the feedstock production stage account for most of this variability. According to the same studies, this arises from the fact that the larger the geographical scale of the LCA study (eg. a region or a country), the coarser the data that depend on local factors (soil type, climate conditions and farming practices). The latter include crop yields and GHG emissions, in particular nitrous oxide (N_2O). This translates into a high uncertainty band for the biofuels LCA results.

As a consequence, improving the quality of such LCAs requires a better consideration of local factors when estimating agronomic and environmental data. The use of agro-ecosystem modeling is one of the solutions proposed to avoid the use of generic, fixed emissions factors (EFs) with a worldwide scope as suggested in the Tier 1 methodology of IPCC guidelines (2006). Such an approach would make it possible to obtain site-specific and reliable values when estimating N_2O emissions from soils (Dufossé et al. 2013, Cherubini 2010).

The objective of this study was to reduce the uncertainty surrounding biofuels LCAs through the use of an agro-ecosystem model (CERES-EGC) to estimate the agricultural and environmental variables needed for establishing the life-cycle inventory. It was applied to biodiesel from oilseed rape, the main biofuel produced in Europe, in the context of the Lorraine region (eastern France). Given that organic and inorganic nitrogen fertilization is responsible for 90% of the life-cycle GHG emissions related to oilseed rape production in France (Cerrutti et al. 2013), the effect of improved fertilization practices on LCA results was explored.

2. Methods

2.1. Goal and scope

This study focused on improving the quality of the inventory phase for the LCA of biodiesel from oilseed rape, using agro-ecosystem modelling and farm surveys. Biodiesel LCA results were compared to those of LCA of fossil-based gasoline. The effects of improved fertilization practices on the initial biodiesel LCA results were also examined.

For reasons of data availability, this study only focused on biodiesel made from oilseed rape harvested during the year 2012 in the Lorraine region in France. A study on the whole France is currently in progress.

The evaluated system includes five main stages: oilseed rape production, delivery to a biorefinery, conversion to biodiesel, storage in the plant and distribution, i.e. well-to-wheel boundaries. One mega-joule of biodiesel is the functional unit retained for this study. Rape meal, acid oils and glycerin are co-produced during the biodiesel conversion stage. To share environmental burdens between biodiesel and its co-products, the energetic allocation was applied, as recommended in the renewable energy directive (European Commission 2009).

2.2. Life cycle inventories

2.2.1. Crop management and biomass conversion data

Information on farming practices were derived from survey data conducted on behalf of the French technical center of oilseeds and hemp (CETIOM). A typology of fields producing oilseed rape in Lorraine was established according to farmers' nitrogen fertilization practices. In this typology, we assumed that the amount of inorganic nitrogen fertilizers applied on oilseed rape depends on three key factors: whether organic fertilizers were regularly applied (i.e. at least once every four years) or not, whether organic fertilizers were applied before sowing, and whether a decision support tool was used or not. This allowed us to identify 10 different fertilization practices (Table 1).

Table 1. Typology of oilseed rape management in Lorraine

Fertilization practice type	Regular fertilization	Organic fertilization before sowing	Use of decision support tool	Percentage of occurrence in the region
1	No	No	No	13.4%
2	No	No	Yes, well-respected	1.1%
3	No	No	Yes, non-respected	22.9%
4	No	Yes	No	6.3%
5	No	Yes	Yes, non-respected	3.2%
6	Yes	No	No	5%
7	Yes	No	Yes, well-respected	0.6%
8	Yes	No	Yes, non-respected	13.4%
9	Yes	Yes	No	15%
10	Yes	Yes	Yes, non-respected	19.1%

The decision-support tool was developed by CETIOM and calculates the optimal amount of inorganic fertilizer N to be applied in spring, based on a balance-sheet method. Therefore its use allows to avoid situations of both under and over-fertilization, which can largely influence crop yields and emissions of reactive N (Nr).

Particular attention was given to the form of organic fertilizer applied, as it can have considerable effects on Nr emissions (Dambreville et al. 2008). Still, for the sake of simplification only the most commonly-used forms were retained. Therefore, we considered that cattle manure was the only form of organic fertilizer applied to oilseed rape in Lorraine.

Data on machinery and inputs production (i.e. fertilizers, pesticides, fuel, etc.) were taken from the French data base AGRIBALYSE, recently developed by the French Environment Agency (Koch and Salou 2013). Data on oilseed rape transport and its conversion to biodiesel were taken from the Ecoinvent data base (v2.0). Those concerning biodiesel distribution were taken from a recent study carried out by ADEME (Biois 2010). Table 2 summarizes the data sources used for the life cycle inventory of biodiesel from oilseed rape in Lorraine.

2.2.2. Crop simulations

The agro-ecosystem model CERES-EGC can simulate yields, soil carbon dynamics and reactive nitrogen emissions including N_2O, as detailed by Gabrielle et al. (2006). To make possible the use of the model on larger scales while taking into account the variability of local conditions, a GIS database containing geo-referenced informations on the administrative borders, land cover, soil properties and climatic conditions was built. The corresponding layers of spatial information were overlaid to delineate elementary spatial units. These units represent a unique combination of soil type and climatic conditions to be used in the CERES-EGC simulations (Dufossé et al. 2013, Gabrielle et al. 2014).

Table 2. Sources of data for life-cycle inventory of the pathway investigated.

Stage	**Source**
Feedstock production	
Crop management	CETIOM
Crop yield	CERES-EGC simulations
Machinery & inputs production	AGRIBALYSE
Direct N2O emissions	CERES-EGC simulations
Indirect N2O emissions	CERES-EGC & IPCC 2006 guidelines
Other Nr losses	CERES-EGC simulations
Soil c dynamics	CERES-EGC simulations
Transport	Ecoinvent database
Conversion to biodiesel	Ecoinvent database
Distribution	ADEME

For each practice, daily simulated fluxes of direct Nr emissions were accumulated from the harvest of the previous crop to the harvest of oilseed rape. Indirect emissions of N_2O due to nitrogen leaching were calculated following the 2006 IPCC guidelines as 0.75% of the nitrate losses and 1% of ammonia and nitric oxide emissions, as simulated by CERES-EGC.

To simplify the regional modeling, we assumed an uniform distribution of management practices (as detailed in the above typology) over the whole region, i.e. assuming the occurrence of fertilization practices in each CERES-EGC simulation unit was the same as that on a regional scale. Therefore yields and externalities related to each fertilization practice have been simulated for each simulation unit. Then, results obtained from these simulations make it possible to estimate a representative regional yield and nitrogen emissions by weighting the simulations results of each practice by its percentage in the region (via Equations 1 & 2).

$$\sum_{i=1}^{10} y_i * perc_i = Y_{Lorraine} \qquad \text{Eq.1}$$

$$\sum_{i=1}^{10} e_i * perc_i = E_{Lorraine} \qquad \text{Eq.2}$$

With :
i : fertilization practice n° i
y_i : yield of the fertilization practice n° i
e_i : emissions related to oilseed rape production via the fertilization practice n° i
$perc_i$: percentage of the fertilization practice n° i in the region
$Y_{Lorraine}$: regional oilseed rape yield
$E_{Lorraine}$: regional emissions due to oilseed rape farming

2.2.3. Impact characterization and interpretation

LCA was conducted for each fertilization practice using Sima-Pro software package (v7.2). The environmental impacts were characterized with the CML 2000 method at mid-point level. The following impacts categories were analyzed: global warming, eutrophication, acidification, depletion of abiotic resources, photochemical ozone formation. Results were subsequently aggregated on the regional scale

3. Results

3.1. Current fertilization practices may still be improved

We used the CETIOM survey data to determine the quantities of inorganic nitrogen currently applied on oilseed rape for each fertilization practice described above. We found that oilseed rape producers apply about 158 kg of inorganic nitrogen per hectare in Lorraine on average.

We also calculated the recommended amount of inorganic nitrogen to be applied for each fertilization practice using the nitrogen balance method. Results show that inorganic nitrogen rates currently applied exceed the recommended ones (Table 3). Indeed Lorraine farmers tend to over fertilize oilseed rape: only less than 2% of oilseed rape fields receive the recommended dose of inorganic nitrogen.

3.2. Field emissions of reactive N

Table 4 lists the regional yields and emissions of reactive nitrogen for the various oilseed rape fertilization practices obtained with the ecosystem model CERES-EGC.

Table 3. Differences between current and recommended fertilization practices (in kg N/ha)

Fertilization practice type	**Percentage in the region**	**Current inorganic Nr fertilization**(1)	**Recommended inorganic Nr fertilization**(2)	**Fertilization gap** (1-2)
1	13.40%	160.35	117.03	43.32
2	1.10%	170.00	166.05	3.95
3	22.90%	156.15	122.75	33.40
4	6.30%	158.88	100.30	58.58
5	3.20%	176.75	96.29	80.46
6	5.00%	175.89	94.37	81.52
7	0.60%	165.00	159.50	5.50
8	13.40%	148.83	86.43	62.40
9	15.00%	156.18	82.89	73.29
10	19.10%	158.14	91.11	67.03
Average	100.00%	158.17	102.12	56.05

Compared to yields reported in the CETIOM survey, predicted oilseed rape yields in 2012 for the various fertilization practices were over-estimated by around 15%. As the model does not take accidents such us crop diseases or weeds into account, and since the year 2012 was marked by a significant occurrence of this type of accident in Lorraine region, these simulated yields can be accepted and the risk of a systematic modeling bias may be considered low. Also, harvest losses are not included in the modelled yields and may amount to the 15% discrepancy observed.

According to CERES-EGC, the highest direct emissions of N_2O occurred with fertilization practices in which organic nitrogen is applied before sowing of oilseed rape in the fall (i.e. fertilization practices no 4,5,9 and 10). For the practices involving only inorganic fertilization, direct N_2O emissions were much lower. Here, one should mention that for the various fertilization practices, direct N_2O emissions simulated by CERES-EGC are 2 to 3 fold lower than would be estimated when using the Tier 1 IPCC guidelines. In contrast, calculated indirect N_2O emissions were higher than what could be found using the IPCC methodology. This is due to the high nitrate losses simulated by the model.

Regarding optimal fertilization practices, results show that both direct and indirect N_2O emissions and nitrate decreased by 10 to 15% when recommended practices were simulated in lieu of current ones, whereas crop yields were less sensitive to these changes (Table 5)

3.3. Life-cycle impacts of biodiesel from oilseed rape chain

Table 6 reports the environmental performance of biodiesel from oilseed rape for the various fertilization practices adopted by farmers during the feedstock production phase in Lorraine.

Our results show that all impact categories selected in this study are sensitive to nitrogen fertilization practices, except for the ozone formation and abiotic depletion categories which remained unchanged regardless of the fertilization practice. Thus, Nr emissions, in relation to N fertilization have a significant effect on biofuels LCA results, whether from direct field emissions or upstream inputs manufacturing. This is in line with findings by Gabrielle et al. (2014).

Table 4. Nitrogen losses and oilseed rape yields predicted by CERES-EGC with current practices

Fertilization practice type	**Yield (Kg ha^{-1})**	**Direct N_2O (Kg N-N_2O ha^{-1}**	**Nitrate (Kg N-NO_3 ha^{-1})**	**NH_3 (Kg N-NH_3 ha^{-1})**	**NO (Kg N-NO ha^{-1})**	**Indirect N_2O (Kg N-N_2O ha^{-1})**
1	3077	0.59	26.03	22.14	1.31	0.88
2	3037	0.66	26.44	20.57	1.30	0.88
3	3074	0.58	26.04	22.16	1.31	0.87

Average	3229	1.09	54.95	50.04	2.01	1.90

Concerning the global warming potential (GWP), all fertilization practices currently adopted by Lorraine farmers allow the whole biodiesel chain to emit less GHG than fossil diesel if land use change effects are not considered. On a regional scale, the GHG intensity of 1 mega joule of biodiesel from oilseed rape in Lorraine is about 43.9 gr CO_2 eq. The European sustainability criteria are thus not met because the 50% abatement threshold for GHG emissions is not reached.

Table 5. Nitrogen losses and oilseed rape yields predicted by CERES-EGC with optimal practices

Fertilization practice type	**Yield (Kg ha^{-1})**	**Direct N_2O (Kg N-N_2O ha^{-1}**	**Nitrate (Kg N-NO_3 ha^{-1})**	**NH_3 (Kg N-NH_3 ha^{-1})**	**NO (Kg N-NO ha^{-1})**	**Indirect N_2O (Kg N-N2O ha^{-1})**

Adopting best fertilization practices for oilseed rape production may significantly improve the environmental balance of biodiesel in Lorraine. Overall, the life-cycle GHG emissions of biodiesel may decrease from 43.9 to 37.6 g CO_2 eq per MJ of biofuel (Table 7). This translates as an abatement of 56% when substituting gasoline with oilseed rape biodiesel, and thus ensures compliance with European sustainability criteria.

Figure 1 compares the environmental performance of biodiesel from oilseed rape produced with current fertilization practices to biodiesel processed by rape produced with optimal fertilization practices. It shows that balancing the inorganic nitrogen fertilization to crop nitrogen needs could allow reducing GWP and eutrophication by 15%, while mitigating acidification by 35%.

Table 6. Environmental performances of 1 MJ of biodiesel from oilseed rape with current practices in Lorraine

Fertilization practice type	GWP (100 years) (g CO_2 eq)	Acidification (kg SO_2 eq)	Eutrophication (kg PO_4 eq)	Ozone formation (kg CFC-11 eq)	Abiotic depletion (kg Sb eq)

4. Discussion

4.1. Reliability of simulated yields and nitrogen emissions

The modeling approach used here with CERES-EGC to estimate oilseed rape yields and Nr emissions related to its production takes into account the variability of local conditions and nitrogen fertilization practices adopted by farmers in the Lorraine region. However, since the model was run only for the year 2012 because of data availability, the effect of interannual climate variability was not tackled in this study. Thus, it would be desirable to run simulations for a longer duration and thus make it possible to place oilseed rape in a representative crop rotation of the region. This would probably significantly affect the modeled outputs.

In this study, we chose to accumulate simulated fluxes from the harvest of the previous crop to the harvest of oilseed rape because of lack of meteorological data availability. We thus attributed the emissions associated to the residue management of the previous crop. However some studies (eg, Gabrielle et al. 2014) opted for simulations from the sowing of the considered crop to the sowing of the following crop.

Direct N_2O emissions simulated by CERES-EGC were consistently lower than the estimates based on the Tier 1 IPCC guidelines. Regarding indirect N_2O emissions, the opposite trend was found. Thus, the total N_2O emissions simulated by CERES-EGC are quite similar to those obtainable with the IPCC methodology. By contrast, when comparing regional emissions related to current fertilization practices to those related to optimal practices, the difference between the two methodologies becomes significant. The decline in direct N_2O emissions after the adoption of optimal practices simulated with CERES-EGC is 5 fold lower than the decline calculated by using IPCC methodology. Thus, using IPCC guidelines would result a greater benefit of best management practices on the environmental balance of biodiesel from oilseed rape.

This study shows that practices based on organic fertilizers are causing significant emissions of N_2O compared to practices with only inorganic fertilizers. Because organic nitrogen remains available in the soil for the following crops and contribute to their yields, allocating part of the emissions occurring in the year following application to these following crops could be considered.

The simulated oilseed rape yields during the year 2012 were slightly overestimated. This could impact the environmental balance of biodiesel since using the observed yields instead would result in higher emissions per ton of grains harvested. However, the simulated yields were overall very similar to the oilseed rape yield recorded during the past five years, on average. They may thus be considered more representatives of yields for the area.

4.2. LCA outputs

With the current fertilization practices, the GWP intensity of biodiesel from oilseed rape obtained in this study is quite similar to that estimated by the European Commission for the whole Europe (i.e. 44 g CO_2 eq per MJ) , which used the same method of co-product handling. However, our estimated environmental performance of biodiesel from oilseed rape in Lorraine is most likely not representative of the whole France or Europe because of the specific characteristics of this region, in which yields are also usually below the national average.

In addition to the effect of yields and nitrogen emissions on the outputs of the LCA, the chosen allocation method has a key role in the environmental performance of biodiesel from oilseed rape. For example, the use of a mass-based allocation could reduce life-cycle GHG emissions of the biodiesel chain. The opposite could be observed if co-products were handled by system expansion. However when using this method, it should be borne in mind that some unrealistic assumptions which simplify market mechanisms are inevitable.

The modifications occurred in the inventory data related to feedstock production when we tested the effects of optimal fertilization practices are the source of the environmental balance of biodiesel improvement. Improving the environmental performance of the biorefinery would further reduce the LCA indicators of biodiesel.

5. Conclusion

The environmental impacts of biodiesel from oilseed rape were assessed in the French Lorraine region. The use of an agro-ecosystem model allowed considering local conditions and fertilization practices heterogeneity when estimating oilseed rape productivity and related reactive nitrogen emissions. LCA results showed that the GHG saving currently permitted by the substitution of fossil diesel is not consistent with the sustainability criteria to be respected at the European scale. Famers must opt for optimal nitrogen fertilization practices in order to mitigate the environmental impacts of the whole biodiesel chain. Such improvement in the crop management can lead to produce a more environmental friendly biodiesel, at least when land use change effects are neglected (both direct and indirect). However, these effects may be large and are currently coming in sharp focus from a policy and sustainability perspective.

ABSTRACT

The Global Reporting Initiative's (GRI) recently launched fourth generation guidelines (G4) strongly emphasising the concept of materiality as a key concept for choosing where an organization should put its focus within its sustainability-related activities. What *are* those issue areas in which an organization has its most significant economic, environmental and social impacts? How can they be identified and prioritized? Environmental life cycle assessment (E-LCA) and Social life cycle assessment (S-LCA) are timely and useful solutions to operationalize the Materiality principle in the agri-food industry. Conducted together, E and S-LCA allow for identifying significant social and environmental impacts of an organisation's activities throughout its products' life cycles, pinpointing the Social and Environmental Material Aspects. These tools can complement other methods used to assess materiality, such as stakeholder surveys, by adding additional objective and scientific verification.

Keywords: Global Reporting Initiative (GRI), Materiality principle, Material Aspects, Aspects Boundary, Reporting, Social and Environmental LCA

1. Introduction: The new GRI G4

The Global Reporting Initiative (GRI) is an organisation promoting "sustainability reporting as a way for organizations to become more sustainable and contribute to sustainable development" (globalreporting.org). GRI is mostly known for the reporting framework it developed: a holistic set of economic, social and environmental indicators. Reporting organisations are invited to present data covering GRI indicators and also information about business partners within reach of their sphere of influence, which can extend more or less within the value chain.

Until the recent release of the fourth version of the Global Reporting Initiative (GRI) guidelines (G4), the concept of the sphere of influence was leading sustainability report's boundary setting. Therefore, if the reporting organisation had the known ability to influence the practices of some of its business partners, on its own, these were reported on.

With G4 the focus has shifted from the concept of sphere of influence to materiality. In an effort to help companies assess and report on "what really matters", GRI is encouraging organisations to think beyond their fenceline and analyse the perceived and assessed significant economic, social and environmental impacts that their activities have on the planet, society and individuals.

Materiality is a concept stemming from accounting and being defined differently by standards such as SASB, IIRC and GRI. In this article, we will stick to the definition offered by GRI. G4 defines Material Aspects as issues "that reflect the organization's significant economic, environmental and social impacts" and incentivizes reporting organisations to only provide information on those aspects. Therefore GRI simultaneously try to limit the Aspects reported on and enlarge the scope of the value chain for which reporting is desirable. Organisations are encouraged to conduct a "materiality assessment" to identify the significant sustainability impact and the value chain links they should be focussing on.

Conducting a value-chain materiality assessment to understand where the biggest impacts occur, regardless of whether those impacts are within direct control, may be one of the greatest benefits and potential challenge for companies. Whether companies have a good grasp on their value chain sustainability impacts or need to build this exercise into their strategy, the new requirement will undoubtedly be a step forward helping companies to understand the bigger picture of sustainability performance across all their activities.

2. The importance of materiality for agri-food sector organization's sustainability strategy

Used in financial circles for decades, materiality assessment identifies issues that are critical to an organization's success, typically because of their implications to the company's financial situation or due to a high level of interest from their stakeholders. Outcomes can be used to direct business strategy, including fiscal investment, toward the most strategic areas.

The GRI's understanding of material aspects similarly narrows the universe of issues that a company reports on to those most critical to both the company and its stakeholders. The most significant change in materiality is the new consideration of the boundary attributes when determining material issues. This means that companies must not only consider what, but where an issue is relevant across the organization and its value chain (which sites, subsidiaries, countries, suppliers, products, etc.). It also means that a company may report a different boundary for different issues. For example, child labor could only be reported on from the perspective of the supply chain or specific buying categories or geographies in the supply chain, while greenhouse gas emissions could be reported on from the perspective of the company-owned fleet or the downstream impacts associated with product use.

A big potential gain with the increased importance and new approach to determining materiality is a more targeted and meaningful identification of relevant issues. One potential concern around materiality is that companies become too selective, screening out issues that they should be reporting. Deciding on a realistic list of material issues will be a critical element of the G4 reporting process.

This is especially relevant for agri-food sector companies characterised by complex and often overlapping supply chains with low transparency and numerous interacting environmental and social issue areas. While many agri-food companies have a good grip on Life Cycle Assessment, CERES and Sustainanalytics (2014) evaluation of the 24 companies of the CERES Gaining Ground report shows that while food and beverage companies have improved their sustainability performance overall, a more focused look at how they are addressing agricultural sourcing highlights the need for more action by the sector. In particular, it appears clearly that companies are just getting started. For example, almost half of the companies (11 of 24) do not disclose any evidence of conducting risk assessments of their agricultural suppliers.

Among CERES and Sustainanalytics key findings, current goals and commitments are often narrowly focused and targeted primarily on agricultural inputs, such as coffee, soy, and palm oil, which are subject to third-party verification schemes. Managerial oversight is weak with the vast majority of companies not adequately disclosing how these issues are managed internally. According to CERES, this raises concerns about the priority placed on addressing agricultural risks to the business.

In addition and across the board, companies are failing to effectively measure and disclose how their efforts are addressing sustainability risks, such as increased exposure to the adverse effects of climate change, and ultimately changing farmer practices. In contrast to the lack of risk assessment practices, 75 percent (18 of 24 companies) outline at least a basic strategy to mitigate one or more supply chain risks. In other words, rather than developing a corporate-wide approach that is based on a broad assessment of supply chain risk, most companies appear to addressing these issues on an ad hoc or project-specific basis.

CERES concludes that risk assessments are a critical component of prioritization, and companies should look to increase disclosure of these efforts to give stakeholders a better understanding of how the company plans to have impact. Tellus and Sustainanalytics (2012) also highlighted the lack of sustainability and especially social sustainability disclosure of agri-food companies. In the same line, OXFAM (2013) recently urged agri-food companies to foster more transparency, implement sustainability policies and codes of conduct effectively, and report more thoroughly on their sustainability impacts.

GRI G4 offers the right incentive for agri-food sector's companies to integrate more effectively their sustainability efforts.

3. The role of LCA in assessing materiality

What does a materiality assessment for the sustainability space look like? It's flexible, and there's not yet a clear precedent or procedure. Many companies are therefore struggling with questions of how to conduct such an assessment and how to know that a given approach has been thorough enough. To best characterize the set of issues that are material to a company, it makes sense to combine a science-based, objective approach offered through tools like life cycle assessment (LCA) with a more qualitative and subjective approach that can better account for stakeholder perceptions.

For the assessment of stakeholder perceptions, input from internal and external stakeholders is required. This might come in the form of interviews, surveys or both. A frequent option is to ask a set of stakeholders to rank issues in order of their importance to the company and in terms of the importance to the stakeholders and then to see where the issues fall in these rankings.

Crosswalk the importance of issues to internal stakeholders with their importance to external stakeholders to identify sustainability topics that rise to the top in every conversation. Combining stakeholder dialogue with quantitative tools can provide a robust approach for identifying material sustainability issues.

Although qualitative assessment of stakeholder input is useful, used alone it suffers from a potential for "group think", where all stakeholders rank highly the things that they hear and talk about frequently without objective checks of whether these are really the key issues. A more quantitative, science-based approach can be used to validate and/or provide some corrections to the list of issues identified by stakeholders. Many companies—through their work on product LCA and corporate footprinting—already have available some tools to do this.

Environmental LCA, social LCA and life cycle costing (LCC) enable us to compare the materiality of issues on an objective and quantitative basis. While stakeholder outreach identifies importance based on stakeholders' perspectives, LCA quantifies importance from the vantage points of the environment and society. Coupling these tools provides an organization with a robust approach to identifying its material issues.

How can we answer these questions with LCA tools? An LCA of a company's key products or a multi-indicator corporate footprint can identify the relative importance of issues. In fact, answering such questions is exactly the purpose of the endpoint metrics available in the most commonly used LCA impact assessment tools. An environmental LCA might indicate, for example, that the largest impact a given company has on the environment is in the areas of climate change, water use and toxic substance emissions, while issues such as ozone depleting substances, acidifying emissions, land use and smog-forming emissions are of much lesser importance. Regardless of whether these outcomes reinforce or contradict the input from stakeholders, they provide a valuable additional source of input to the materiality assessment process.

A multi-criteria footprint can tell us about the relative importance of various issues of concern. We can compare the categories at the "endpoint" to identify which are most impacting. This example justifies a heavy focus on a few issues.

The same now holds true for social issues. A report underscoring the importance of a life cycle-based approach to understanding and managing social risk in support of policies and decision-making was recently published by the European Union Joint Recent Center. The report, conducted a macro-scale analysis of the social risk profile of EU-27 imports by combining trade statistics regarding imports from intra- and extra-territorial trading partners in 2010 with country and sector-specific social risk indicator data in five thematic areas: Labour Rights and Decent Work; Health and Safety; Human Rights; Governance; and Community Infrastructure. It compared the apparent social risk profiles of EU-27 imports based on consideration of country/sector-of-origin social risk data only, compared to a life cycle-based social risk assessment which took into account the distribution of social risk along product supply chains.

The report shows that (1) the majority of social risks associated with imports to EU-27 countries are attributable to extra-territorial rather than intra-territorial imports, and (2) the risks of Injuries and Fatalities make the largest proportionate contribution to an overall, single-score measure of risk. However, these two approaches provide otherwise dissimilar "signals" as to the magnitude and distribution of social risk. The former approach would invariably prioritize interventions targeting only those direct trading partners known to have high levels of social risk in the sectors providing exports to EU-27 Member States. In contrast, the latter approach provides insight as to the distribution of risk along supply chains, which may be low in the sector of a given country exporting products to Europe, but high overall for those products due to the social risks associated with the activities that support production in that sector. Such supporting activities include physical flows of inputs such as raw materials and energy, and also the activities of service sectors. The life cycle approach hence affords a much more nuanced consideration as to for whom, where, and to what extent social risk may be of particular concern.

The study was conducted using the Social Hotspots Database (www.socialhotspot.org), a repository of social indicator data covering 225 countries and 57 economic sectors and relevant to five overarching thematic areas:

Labour Rights and Decent Work; Health and Safety; Human Rights; Governance; and Community Infrastructure. These indicators were developed based on the recommendations of the UNEP/SETAC Guidelines for Social Life Cycle Assessment (UNEP/SETAC, 2009), the ISO 26000 Guidelines for Social Responsibility (ISO, 2010), the Global Reporting Initiative (GRI) G3 Guidelines, (GRI, 2006) and the Global Social Compliance Programme (GSCP) Reference tools (GSCP, 2012) and are making use of over 200 sources of data. The Social Hotspots database also include a Global Input-Output model based on the Global Trade Analysis Project general economic equilibrium model.

The report demonstrates that it is now feasible for organizations to implement a life cycle approach to assess not only environmental impacts, but also social footprints, and that doing so will provides crucial insights regarding the materiality sustainability issues and this especially in economic sectors such as agri-food.

This example from the EU also helps to demonstrate that life cycle-based materiality assessment can quantitatively assist in identifying material impacts, issues, and risks which are themselves best measured in qualitative or judgemental ways. And this is both true and relevant for environmental as well as social issues of concern. While traditional LCA works with data reflecting units of "elementary flow" per unit of process output (e.g., kg of CO2 released to air or liters of water consumed, per unit of process output), this approach can be complimented by Life Cycle Attribute Assessment (Norris 2006).

Some issues of concern are better characterized through a qualitative or a summary expert judgment assessment about the overall attributes of processes. For example, forestry operations may be certified as sustainable or unsustainable, based on extensive, expert-based, site-specific assessments which take all sorts of context-relevant nuances into account in a systematic and pre-determined way. These assessments can provide *more* information than a purely quantitative characterization of the same forestry operation. Thus, a company or its stakeholders may want to assess to what degree the company's supply chain is sourcing sustainably-sourced forest product output, and to push for and document continuous expansion of such sourcing. Conversely, the company or stakeholders may identify as material any major instances of non-certified forest sector output in the supply chain.

Life Cycle Attribute Assessment (LCAA) enables users to harness quantitative models of product supply chains together with a mix of quantitative and qualitative information about the processes in those supply chains in order to identify material risks and opportunities for sustainability improvement. LCAA provides information about the *share of relevant activity* within supply chains that has any attributes of interest or concern to the company and its stakeholders.

In the case of the EU social supply chain assessment, the results highlighted the share of worker-hours which were at elevated risk relative to a comprehensive set of social indicators. And in the case of sustainable forestry assessment, LCAA can identify the share of forest acreage at elevated risk of unsustainable management – pinpointing where such management is occur geographically, where within the supply chain, and at what quantitative level of participation across the supply chain. Specific to the Agri-food sector, an LCAA could identify the share and major instances of land use which occur in high-risk zones for biodiversity, or the share and instances of crop cultivation which is certified organic, as two examples. Materiality can also arise via the interaction of two or more attributes, such as being located in region with endangered species and lacking certification of management practices which respect or enhance survivability of the relevant species.

This however shows that contrarily to financial materiality assessment where standardised revenue-related quantitative cut-off criteria exist to determine whether an item is material or not (a 10% threshold is suggested by many audit manuals), LCA-based materiality assessment for CSR reporting also needs to take into account subjectivity and judgment in the process. Stakeholders' perception, business strategy, geopolitical context, etc. all provide relevant yet qualitative information which must be addressed in the analysis.

4. Applying LCA-based materiality assessment in the Agri-food sector

As we stated in the introduction many agri-food companies and associations are already experienced applying LCA based tools. However, as we highlighted, frequently LCAs are conducted on a project basis and not as part of a corporate-wide approach. We selected three case studies to demonstrate how LCA can be mobilized in a wider strategic context.

4.1. The case of a leading coffee roaster

A coffee roasting company has an interest to understand the materiality of various social and environmental issues to support its strategy for measuring and disclosing its performance in the sustainability area to its business customers, investors and others. In addition to a questionnaire and set of interviews conducted with stakeholders, a review has also been done of several existing environmental LCAs of coffee systems to understand: a) among which environmental impact categories do the most important environmental impacts occur; and b) within which stages of the coffee life cycle are these impacts occurring.

Applying an endpoint impact assessment methodology allows the results to speak directly to the first of these two issues, providing a science-based weighting of more than a dozen mid-point impact categories based on the extent to which they cause impairments on ecosystem quality, human health and resource availability. In this case, it is found that carbon footprint is a highly important issue for both human health and ecosystems, land use is an additional important issues for ecosystems, and fossil fuel consumption is most important for resource availability. Many other environmental issues, such as ozone depletion, acidification and others are shown to be of much lesser importance. It is further acknowledged that because none of the references reviewed allowed for the inclusion of water quantity issues in the endpoint analysis, the review does not adequately address this issue (although this could be done with an LCA that does address this issue at the endpoint).

Regarding stages of the coffee life cycle, the work shows that for each of the key impact categories identified, the growing of coffee beans is a highly important stage. This stage is where the great majority of the land use impact occurs. It also corresponds to a significant area of focus for climate change. The brewing of coffee is a significant area of impact of fossil fuel consumption and for climate change. In addition, the cleaning of coffee brewing equipment and/or cups is identified as a potentially important area of focus, although this will vary widely depending on consumption and washing habits.

The value of this work is that it provides a science-based confirmation of several issues that have been identified by the company and its stakeholders as important, as well as providing additional justification for avoiding spending time on several of the issues that are shown to be of lesser importance.

4.2. The case of Pet Food

Several Pet food companies were interested to jointly identify their most significant social hotspots as a key input to the development of key performance indicators. The social hotspots database was used to provide a scoping assessment completed by a literature review and a stakeholder survey.

The study aimed at providing an overarching perspective on pet food social impacts. It was first necessary to identify the relevant sector, food products nec, from a specified list of 57 sectors used in the SHDB. This sector list corresponds to the sectors defined by the Global Trade Analysis Project's (GTAP) economic equilibrium model, which is used to develop the SHDB Worker Hours Model.

Next data on the location of the last manufacturing activities for pet food products sold in the US had to be found. The United States International Trade Commission's Interactive Tariff and Trade DataWeb indicated China, Canada, Thailand and the US to be pet food products sources for the US market. These countries, food products nec sector were tested using the SHDB to assess their supply chain impacts. The results were prioritized based on labour intensity, risk level and overlap.

The results showed that respectively, China, India, Thailand, Cambodia, Vietnam, Mexico and the US were countries responsible for a significant share of the total social impacts. The economic sectors of fisheries, food products nec, vegetables, fruits and nuts, were identified most often as being at high risk overall.

Labor rights and decent work, health and safety and to a lesser extent human rights were the most prominent types of impact identified. Low wages, migrant labour risks and fatal and non-fatal injuries were the most prominent contributing issues.

The results of the scoping assessment provided a necessary overview of some of the most salient social risks attributed to the pet food sector for products sold in the US. In particular the results served as a starting point to literature review and were a key consideration in the development of key performance indicators along with the stakeholder survey results.

5. Using LCA results in reporting – GRI and SAFA

Several Canadian Agri-food companies associations (for instance Canadian Sphagnum Peatmoss Association and the Fédération des producteurs de porcs du Québec) were interested to gain a better understanding of their environmental and socioeconomic performance. In these cases, the LCAs culminated years of efforts to document each association's sustainability profile by building on previous initiatives. In order to structure and organize in a coherent and synthetic way the results of these efforts but also to enhance and ease the communication of the work done so far, these two organisations commissioned CSR reports based on the FAO's SAFA framework (to be published in Spring 2014).

The SAFA Guidelines have been developed to "provide an international reference tool for assessing the sustainability performance of food and agriculture enterprises" [1] all across a product' supply chain, from production to retailing. To do so, SAFA draws upon several internationally recognised reference tools, including the ISO norms for Life Cycle Assessment and the GRI Sustainability Reporting Guidelines.

Integrating LCA results to the SAFA reporting framework was an opportunity for these organisations to focus on those issues that were identified as social and environmental "hotspots" and to define and communicate objectives directly related to them. For instance, the Quebec Pork Producers Federation decided to adapt the reporting framework – originally built on 4 dimensions (Governance; Economic resilience; Environmental integrity; Social well-being) – to add "Animal welfare" as a core aspect of social responsibility within the industry as the S-LCA demonstrated. On the environmental side, the Canadian Sphagnum Peatmoss Association has reported in more details and has adopted more ambitious commitments related to the sector's water and carbon footprints since these issues were identified as important "hotspots" within the sphere of influence of the companies, i.e. on which the sector could directly act. In these two cases, the LCA result provided sound and credible data that have legitimated the organizations, both internally and externally, in the choice of information to report and in the nature of the engagements to adopt.

6. Conclusion

GRI G4 positions materiality assessment as a crucial component of sustainability reporting. Since G4 also expands the scope of reporting to supply chains issues, it makes materiality assessment even more relevant. G4 is not the only Social Responsibility instrument to invite companies to conduct supply chains risk assessments. The UN Business and Human Rights framework also encourages companies to conduct comprehensive supply chain due diligence.

Life Cycle Assessment is a technique which provides science-based information related to the potential sustainability impacts of companies, products and services. It can be used on a project basis but it can also be used to develop or support a comprehensive sustainability strategy. It supports materiality assessment by providing an objective overview of supply chains impacts, their relative contributions to the overall risk, and which phases and locations appear to be most significant.

LCAs supplement stakeholder surveys by providing comprehensive risk information that can include issues or phases of the supply chain which may otherwise be overlooked; at the same time, it may illuminate the small relative impact of issues or activities which were perceived as being more critical in the absence of a holistic and systemic assessment. It provides companies additional support in prioritizing the key activities and issues that truly drive their sustainability impacts and performance..

Two of our examples demonstrated how Agri-food sector companies are using LCAs to identify and prioritize impacts as part of reporting and KPI development processes. Our third example presented how this information helps companies to then report using sector specific reporting guidelines such as SAFA.

ABSTRACT

Many environmental impacts can be attributed to fish farming and there is a need to explore new ways of reducing environmental impacts, such as fish genetic improvement. The environmental consequences of genetic improvement in thermal growth coefficient (TGC) and in feed conversion ratio (FCR) were investigated, therefore, in an African catfish farm in Recirculating Aquaculture System. A Life Cycle Assessment study was conducted and combined with a bioeconomic model of genetic response. Results show that environmental consequences of genetic improvement in TGC and FCR are different among impact categories, depending on their main contributors and on the factor limiting production at farm level. Genetic improvement of FCR always leads to lower environmental impacts while improving TGC decreases environmental impacts only when density was the limiting factor. Those results are important for the future development of selective breeding programs in fish farming taking into account environmental impacts.

Keywords: genetic improvement, life cycle assessment, fish farming, feed conversion ratio, thermal growth coefficient

1. Introduction

Fish farming can have many environmental impacts, such as emission of pollutants (Read and Fernandes, 2003), use of natural resources (Naylor et al., 2000) and eutrophication (Folke et al., 1994). Using life cycle assessment (LCA), feed production and farm operations were shown to be the main stages contributing to environmental impacts of fish farming (Aubin et al., 2006; Pelletier et al., 2009). The environmental impacts of alternative feed compositions or alternative rearing systems were, therefore, investigated. Some studies explored the potential of plant-based diets or organic feed to reduce impacts (Boissy et al., 2011; Papatryphon et al., 2004; Pelletier and Tyedmers, 2007), whereas other studies explored the potential of a recirculating aquaculture system to reduce impacts (Aubin et al., 2009; d'Orbcastel et al., 2009). These studies, however, clarified existing trade-offs between different environmental impacts when changing feed composition or rearing conditions. It appeared difficult, therefore, to decrease all environmental impacts of fish farming. Consequently, there is a need to explore new ways of reducing environmental impacts of fish farming systems.

Genetic improvement, realised through selective breeding programs, is expected to change environmental impacts of livestock production by increasing productivity or improving production efficiency (Wall et al., 2010). The magnitude and the direction of this change in fish farming is, however, not known. Wall et al. (2010) suggested to model emissions at farm level in order to determine the environmental consequences (or environmental values) of a change in traits in order to evaluate the capacity of each trait to decrease environmental impacts. This approach is similar to the framework used to calculate the economic value of economic important traits (Groen, 1988).

We explored, therefore, the capacity of a genetic improvement in thermal growth coefficient (TGC) and in feed conversion ratio (FCR) to decrease environmental impacts of 1 t of African catfish produced in a recirculating aquaculture system (RAS). We chose to investigate TGC and FCR for two reasons. First, fish breeders consider TGC as the main trait to improve in order to increase farm profitability. FCR is also an important trait because the majority of fish reared in intensive systems are carnivorous species, which require high amounts of protein and lipid in their diet, making fish diets expensive. Second, we investigated TGC and FCR because genetic improvement of these two traits is susceptible to affect environmental impacts through higher productivity and better production efficiency. A RAS was studied for three reasons: (1) it is a highly controlled system, which is easy to model, (2) it has a potential as a development model for fish farming because of better waste and water management and (3) the existence of technical limiting factors for production level is well known. In practice, limiting factor can influenced farm management and breeding goals have to be adapted for such limiting factor (Gibson, 1989; Groen, 1989). The factors limiting production are the maximum nitrogen treatment capacity of the bio-filter and the maximum fish density in rearing tanks. Changing TGC and FCR is expected to change the limiting factor and the limiting factor might influence environmental values of both traits.

The capacity of a genetic improvement in TGC and in FCR to decrease environmental impacts was investigated through environmental values calculated using a bioeconomic model combined with a LCA.

2. Methods

2.1. System boundaries

A cradle-to-farm-gate analysis was applied including three stages: feed production, farm operation and waste water treatment (figure 1). The farm studied was a typical commercial Dutch farm producing 500t of African catfish per year in an indoor RAS. Fish processing, hatchery operations as well as sludge agricultural utilization were not taking into account.

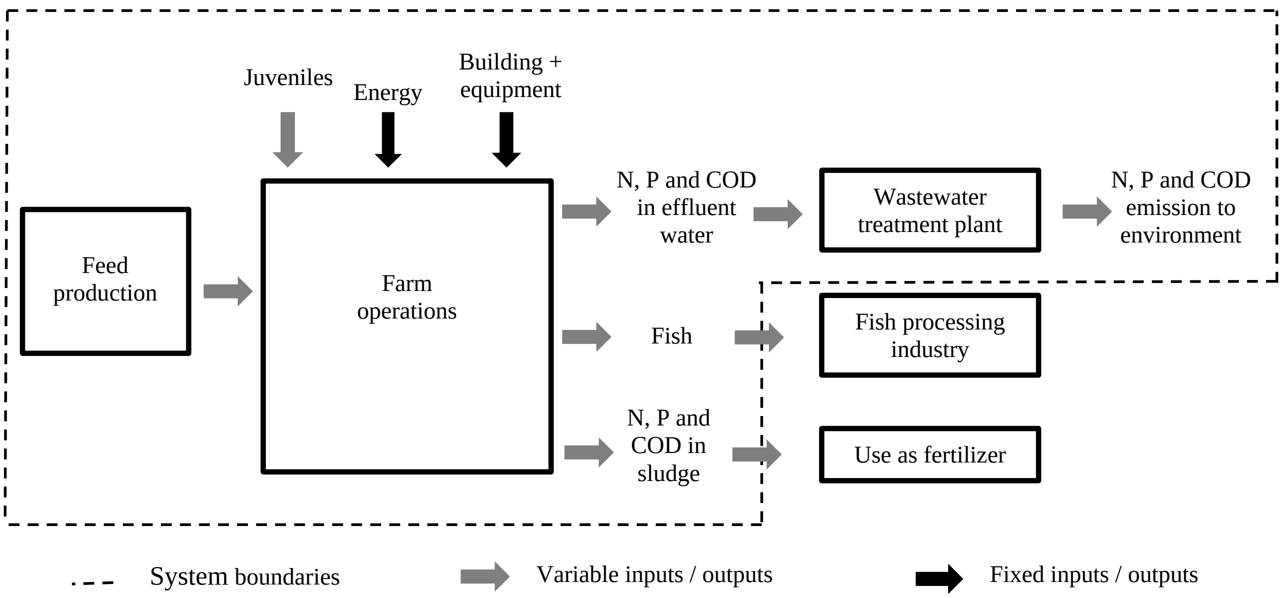

Figure 1. Diagram of the system studied.

2.2. Life Cycle Inventory

Feed production. Crops-derived ingredients were coming from Brazil and France. Fish-derived ingredients were coming from Peruvian fish milling industry and from by-products of Norwegian fish milling industry. In case of a process yielding multiple products, such as soy bean oil and meal, the environmental impact of the process was allocated to the multiple outputs based on their relative economic value (i.e. economic allocation). The transport of feed ingredients to feed manufacture in France was assumed to be by transoceanic ship and by lorry (>32t). The resources required to produce the feed were found in the literature (Pelletier et al., 2009). The transport of pellets from France to the fish farm in Eindhoven were assumed to be by lorry (>32t).

Farm operations. We investigated a farm producing 500t of African catfish per year in an indoor RAS. In this indoor system, water was thermo-regulated around 27 °C through regulating the ambient air. The RAS was composed of four main parts. (1) Rearing tanks growing fish from 13g to 1300g. The maximum density in the tank was 230 kg/m^3, which was one of the limiting factors. (2) A mechanical filter which removed solid waste.

(3) A bio-filter processing nitrification with a nitrification rate of 100%. The nitrification capacity of the bio-filter was limited to 40 kg of dissolved NH_3-N per day, which was the second limiting factor. (4) A denitrification reactor using manure of the fish as C-source with a denitrification rate of 80%.

The amount of equipment used (i.e. pump, tanks), the surface of building needed and the consumption of energy at farm level were considered fixed. The emission of nutrients, the consumption of feed and the production of fish were, however, dependent on growth rate and feed efficiency, which could affect the level of production. In this study, growth rate was expressed through Thermal Growth Coefficient (TGC) (Dumas et al., 2007) and feed conversion was expressed through Feed Conversion Ratio (FCR). A bioeconomic model was developed to calculate annual fish production, annual feed consumption at farm level and annual emissions of nutrients after waste water treatment according to TGC and FCR values. The individual emission of nitrogen (N), phosphorus (P) and chemical oxygen demand (COD) were calculated using a mass-balance approach (Cho and Kaushik, 1990). The proportion of dissolved and solid fractions emitted by the fish was estimated from the digestibility of feed components. Retention capacity of the drum filter, nitrification capacity of the bio-filter and denitrification capacity of the denitrification reactor were used to calculate emission of nutrients in effluent water and in sludge.

Waste water treatment. Effluent water, highly concentrated in nutrients, coming from the fish farm was disposed in a waste water treatment plant. We considered a typical waste water treatment plant running in Europe, including three treatment stages: mechanical treatment, biological treatment, chemical treatment. It also included sludge digestion via fermentation. The treatment capacity of the waste water treatment was used in order to evaluate the amount of nitrogen, COD and phosphorus released into water. 28% of the COD, 75% of the nitrogen and 52% of the phosphorus coming from the farm were, therefore, released into water. Life cycle inventory of water treatment as well as the secondary data were extracted from ecoinvent v2.2 database (Swiss Centre for Life Cycle Inventories, 2010).

2.3. Life cycle impact assessment

The environmental impact of the analysed system was related to a functional unit of 1 t of fish. Four environmental categories were investigated: eutrophication, acidification, climate change and cumulative energy demand (CML2 method and Simapro software) and expressed per t of fish. Land use change, however, was not taking into account. The analysed system was divided in the following sub-systems: (1) feeds consumption, including processing, production of feed ingredients and transportation; (2) N, P and COD emission from biological transformation of the feed at farm level and after waste water treatment; (3) effluent water treatment at wastewater treatment plant; (4) equipment use, including its manufacturing, transport and use; (5) buildings use, including material production and transportation, construction and use; (6) energy consumption (electricity, gasoline, heat gas), including production, transportation and use. Environmental impacts of each of these sub-systems were calculated separately.

Then, the results of these environmental impacts were multiplied by the quantity required at farm level calculated from the bioeconomic model. Feed consumption and nutrients emission are variable at farm level depending on TGC and FCR values. Environmental impacts at farm level of the two sub-systems feed production and nutrients emission are, therefore, variable. In contrary, use of building, use of materials and energy consumption at farm level are considered fixed. Environmental impacts at farm level of those three sub-systems are, therefore, fixed.

Environmental impacts at farm level were divided by annual fish production to expressed environmental impacts per ton of fish. Environmental impacts were calculated for four TGC values corresponding to three generation of selection from the current population mean with a percentage of genetic improvement of 6.8 as calculated by (Sae-Lim et al., 2012). TGC values tested were: 8.33, 8.93, 9.53 and 10.11. For FCR, a wide range of values was tested from current population mean FCR = 0.81, which is a value commonly observed in African catfish farms, to FCR = 0.64.

2.4. Environmental values

The environmental values (ENV) of the four impact categories (eutrophication = E_V, acidification = A_V, climate change = CC_V and cumulative energy demand = CED_V) of a trait t {FCR,TGC} express the environmental impact, in percentage, of a unit change in one trait while keeping the other trait constant. ENV of both traits were calculated in three steps:

1) Calculate environmental impact per ton of fish (i.e. $A_{\mu t}$) using current generation means for trait t (μ_t). The current generation mean (or reference scenario) is 8.33 for TGC and 0.81 for FCR. The TGC of the current population is the result of 119 days required for the fish to grow from 13 to 1300 g with a daily average temperature of 27°C. FCR was set at 0.81 in order to balance cost with revenue when TGC = 8.33.

2) The mean of trait t is increased by Δ_t while keeping the mean of the other traits constant. $\Delta_{TGC} = \mu_{TGC} \times 6.8\%$ and $\Delta_{FCR} = \mu_{FCR} \times -7.6\%$ as calculated by (Sae-Lim et al., 2012). The next generation means are, for instance, TGC = 8.93; FCR = 0.81 and TGC = 8.33; FCR = 0.75. The model was run a second time to calculate environmental impacts.

3) ENV were calculated for trait t as:

$$A\_V_t = \frac{(\mathbf{A}_{\mu t+\Delta t} - \mathbf{A}_{\mu t})}{\mathbf{A}_{\mu t}} \quad \text{Eq. 1}$$

Environmental values were calculated for 2 situations where the combination of TGC and FCR was: TGC = 8.93; FCR = 0.81 and TGC = 8.93; FCR = 0.69. These two situations were chosen because the limiting factor was different and also because one generation of selection in both trait did not change the limiting factor.

3. Results

Table 1. Percentage of contribution of the different sub-systems to the four impact categories in the reference scenario where TGC = 8.33 and FCR = 0.81.

	Feed production	Nutrients emission	Effluent water treatment	Building use	Material use	Energy use
Acidification	57.5%	0%	0.3%	10.2%	27.3%	4.7%
Eutrophication	33.6%	62.2%	0.2%	0.1%	0.3%	3.1%
Climate change	72.3%	0%	0.8%	1.5%	3.9%	21.4%
Cumulative energy demand	68.7%	0%	0.68%	2%	4.9%	23.6%

Table 1 shows the contribution of each different sub-system to the four impact categories in the reference scenario where TGC = 8.33 and FCR = 0.81. The impact of nutrient emission on acidification is 0% because effluent water are directly directed to effluent water treatment plant, which is responsible of 0.3% of the total acidification. In table 1, we can see that the main contributors to the four impact categories are different. For acidification, climate change and cumulative energy demand the main contributor is feed production (respectively 57.5%, 72.3%, 68.7%). The second contributor to those three impact categories are fixed sub-systems at farm level, building use for acidification (27.3%) and energy use for climate change (21.4%) and for cumulative energy demand (23.6%). In opposite, the two main contributors of eutrophication are nutrients emission (62.2%) and feed production (33.6%).

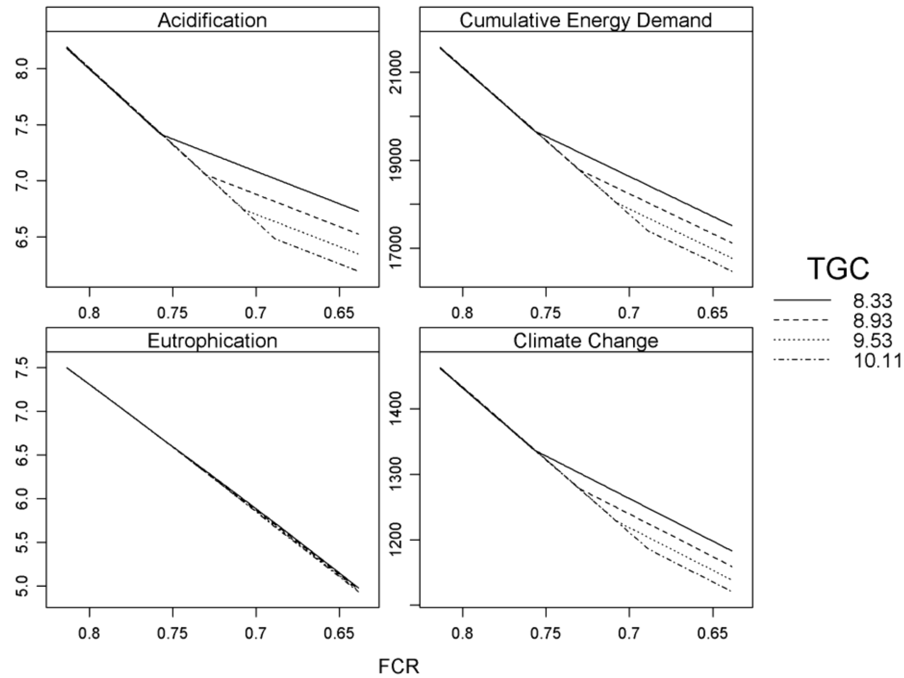

Figure 1. Environmental impacts calculated per t of fish for four impact categories as a function of FCR for four values of TGC.

Figure 1 shows the results of environmental impacts for the four impact categories investigated. First of all, the combination of TGC and FCR defines whether dissolved NH_3-N or density is the limiting factor. Environmental response to genetic improvement in TGC and FCR are different among impact categories according to the factor limiting production. These differences are because TGC and FCR have different effects on production. Two effects are capable of decreasing environmental impacts per unit of fish produced: increasing productivity (annual fish production) and increasing production efficiency (feed consumed per ton of fish). Increasing productivity, while keeping the same production efficiency, dilutes fixed environmental impacts at farm level, such as building use, over more fish produced. Increasing production efficiency, while keeping the same productivity, decreases the amount of feed required to produce one ton of fish and decreases the amount of nutrients emitted per ton of fish which decreases environmental impacts. Depending on the limiting factor, improving TGC or FCR changes either productivity, production efficiency or both.

Dissolved NH_3-N as limiting factor. For instance, when TGC is 8.33 and when FCR decreases from 0.81 to 0.75, the factor limiting production is dissolved NH_3-N. In this situation, improving FCR decreases environmental impacts of the four impact categories while improving TGC does not influence it.

Improving FCR decreases environmental impacts because individual daily excretion of nutrients decreases, which allows to stock more fish per batch to reach dissolved NH_3-N limitation. Consequently, when FCR is improved, both productivity and production efficiency increases, which decreases environmental impacts per ton of fish produced (figure 1).

Additionally, improving TGC does not influence environmental impacts because individual daily excretion of nutrients increases, which constrains to stock fewer fish per batch. This lower number of fish per batch is offset by rearing more batches per year. Consequently, when TGC is improved, productivity and production efficiency remain constant, which keep the environmental impacts at the same level (figure 1).

Density as limiting factor. For instance, when TGC is 8.33 and FCR is lower than 0.75, the factor limiting production is the density of fish in rearing tank. In this situation, the number of fish harvested per batch if fixed.

Improving FCR, therefore, decreases feed consumption per ton of fish and decreases nutrients emission per ton of fish. Consequently, when FCR is improved, only production efficiency increases, which decreases environmental impacts per ton of fish produced but with a lower rate than in dissolved NH_3-N limitation situation (figure 1).

Additionally, improving TGC increases the number of batch harvested per year, which increases annual production of fish. Consequently, when TGC is improved, only productivity increases, which decreases environmental impacts (figure 1).

Different environmental responses to genetic improvement in TGC can, however, be observed when density is the limiting factor. Improving TGC decreases acidification, climate change and cumulative energy demand while the response in eutrophication is smaller. The response to genetic improvement in TGC for eutrophication is smaller because improving TGC increases productivity only, which dilute fixed environmental impacts at farm level, such as use of material, over more fish produced. The contribution of fixed environmental impacts to eutrophication is, however, smaller than the contribution of fixed environmental impacts to acidification, climate change and cumulative energy demand (table 1).

Table 2 gives ENV_{TGC} and ENV_{FCR} of the four impacts categories investigated in both situations, when dissolved NH_3-N is the limiting factor and when density is the limiting factor.

When dissolved NH_3-N is the limiting factor, all ENV_{TGC} are null as TGC do not alter environmental impacts. These results can be explained by the fact that increasing TGC does not influence productivity nor production efficiency. The ENV_{FCR} are, however, negative because when dissolved NH_3-N is the limiting factor, increasing FCR increasing productivity and production efficiency, which decreases environmental impacts.

When density is the limiting factor, ENV_{TGC} have a negative value because increasing TGC increases productivity which dilutes fixed environmental impacts at farm level over more fish produced. E_V_{TGC} is, however, very close to zero because eutrophication is relatively insensitive to fixed environmental impacts at farm level compare to other impacts categories (table 1). The ENV_{FCR} are also negative but CED_V_{FCR}, E_V_{FCR} and A_V_{FCR} are lower when density is the limiting factor than when dissolved NH_3-N is the limiting factor because increasing FCR when density is the limiting factor increases production efficiency only. Moreover, E_V_{FCR} is higher than CED_V_{FCR}, E_V_{FCR} and A_V_{FCR} because the two main contributors of eutrophication are nutrients emission and feed production, which are sensitive to production efficiency.

Table 2. Environmental values of TGC (ENV_{TGC}) and FCR (ENV_{FCR}) of four impacts categories (eutrophication = E_V, acidification = A_V, climate change = CC_V and cumulative energy demand = CED_V) calculated when dissolved NH_3-N is the limiting factor (TGC = 8.93, FCR = 0.81) and when density is the limiting factor (TGC = 8.93, FCR = 0.64).

ENV	Trait	TGC = 8.93 FCR = 0.81 Limiting factor = dissolved NH_3-N	TGC = 8.93 FCR = 0.69 Limiting factor = density
A_V	FCR	-10.3%	-4.3%
	TGC	0%	-2.7%
E_V	FCR	-11.8%	-13.4%
	TGC	0%	-0.3%

	TGC	0%	-2.0%

4. Discussion

The results of our simulations show that environmental response to genetic improvement in TGC and FCR is different when density and when NH_3-N are the limiting factors. When NH_3-N is the limiting factor, only genetic improvement in FCR decreases environmental impacts because it increases productivity and production efficiency. On the contrary, when density is the limiting factor both genetic improvement in TGC and FCR decreases environmental impacts because improvement in FCR increases production efficiency and improvement in TGC increases productivity. When density is the limiting factor, however, environmental response to genetic improvement in TGC and FCR are different across impact categories depending on their main contributors. Eutrophication is mainly driven by feed production and nutrients emission, which are influenced by production efficiency. Conversely, other impact categories are mainly driven by feed production and building use or energy use, which are influenced by productivity.

d'Orbcastel et al. (2009) investigated the impact of a RAS producing rainbow trout using two different values of FCR, 1.1 and 0.8. This range corresponds to 27.3% of improvement, or to 3.6 generations of selection when percentage of improvement in FCR is 7.6%. They found, therefore, that decreasing FCR by 7.6% decreased acidification by 5.8%, eutrophication by 4.3%, climate change by 6% and cumulative energy demand by 2.4%. It is, however, difficult to use the results from d'Orbcastel et al. (2009) as a comparison basis for our results because they didn't take into account changes that could occur in farm management when FCR changes. d'Orbcastel et al. (2009) considered that improvement in FCR increased production efficiency but, using dynamic modelling of the relationship between genetic improvement and farm management, our results show that improving FCR can also increase productivity when NH_3-N is the limiting factor. Changes in FCR can also lead to changes in limiting factor.

The results presented here confirm that FCR would be the major trait to include in the breeding goals for decreasing environmental impacts. In fish breeding, however, FCR is a difficult trait to improve as it is difficult to measure individual feed intake. FCR is expected to be correlated to TGC, however, studies diverge on this subject. In rainbow trout, Kause et al. (2006) predicted that selection only for daily gain increases daily gain by 17.6% per generation and simultaneously increases feed efficiency (1/FCR) by 8.4%. In parallel, some other studies in salmonids did not observe any correlation between growth rate and feed efficiency and showed that genetic gain in growth is due to higher feed intake, while feed efficiency remain unchanged (Mambrini et al., 2004; Sanchez et al., 2001).

5. Conclusion

Environmental values could be included in breeding programs in a similar way as economic values and could help fish breeders to design effective breeding programs in terms of environmental consideration by putting more emphasis on the relevant traits, in a specific limiting factor situation. Our results have, therefore, important implications for fish breeders who may need to alter their breeding objectives depending on what is limiting production on the farms of their customers. We show that environmental values of FCR and TGC are dependent on the factor limiting production. Improvement of feed efficiency always improves environmental impacts in any situation. However, selecting for increased growth rate is only relevant in situations where nitrogen emissions are not limiting production. Those results are important for the future development of selective breeding programs in fish farming taking into account environmental objectives.

ABSTRACT

As highlighted in several recent reviews, there is a need to harmonize the way LCA of perennial crops is conducted (Bessou et al. 2013; Cerutti et al. 2013). In most published LCA on perennial crops, the agricultural production is based on data sets for just one productive year. This may be misleading since performances and impacts of the system may greatly vary year by year and the evolution of the stand over the cycle induces specific mechanisms (nutrient re-mobilization, yield alternating, resistance etc.) that must be included. Without a proper mechanistic model, the only way to account for such phenomena is to wider the data sets to at least account for each stage of the stand development and, if possible, all years of the crop cycle. Three modeling choices for the perennial crop cycle were tested in parallel in two contrasted LCA case studies: oil palm fruits from Indonesia, and small citrus from Morocco. Modeling choices tested were: i) a chronological modeling over the complete crop cycle of orchards (Bessou et al. 2013), ii) a three years average from the productive phase and iii) a selection of different single years from the productive phase. In both case studies, the system boundary included all processes from the seed production until the harvested fruits at farm-gate. The functional unit was 1 kg of fresh fruits. The chosen approach to model the perennial cycle influences the final results and deserves specific attention.

Keywords: perennial crop, LCA, chronological modeling,

1. Introduction

First LCAs including perennial crops were mostly cradle-to-grave assessments of renewable products or services based on agricultural feedstock, e.g. biofuel, heat and power, biomaterial. Despite the importance of the cropping system in terms of impact contribution over the whole process chain (e.g. 10%-80% of the total primary energy input and more than 25% of the GHG balance in most bioenergy chain *In* JEC, 2008), cultivation remained secondarily addressed (Fazio and Barbanti 2014; Monti et al. 2009). Hence, in most published LCAs on perennial crops, data on the cropping system is scarce and is often based on one productive year without accounting for the whole perennial production cycle (Bessou et al. 2013). However, assessing perennial crops in the same way as annual ones may induce bias notably due to the variability in practices and yields over the plantation lifespan or the potential importance of changes in carbon stocks (Mithraratne et al. 2008). Recent reviews highlighted the need to better account for the specificities of perennial cropping systems within LCA and to harmonize the way LCA of perennial crops is conducted (Bessou et al. 2013; Cerutti et al. 2013; Cerutti et al. 2011).

The aim of this study is to illustrate the potential bias due to varying choices in modeling the perennial crop cycle within cradle-to-gate LCAs. The baseline assumption is that a chronological assessment is the closest way to model the real perennial crop cycle, since it uses a continuous data set for a single plantation plot followed over its whole lifespan (Bessou et al. 2013). We hence compared this chronological assessment with two other ways to model the cycle: 1) a three-year average of three consecutive productive years; and 2) various single years taken randomly within the productive phase, which may be seen as approximating perennial to annual crop. We selected two contrasted case studies in different pedoclimatic conditions and with different crop managements in order to test the sensitivity of the modeling choices to contrasted perennial cropping systems. The first case study concerns oil palm fruit production in Indonesia; the second one implies small citrus produced in Morocco. We first present the data sets used for the LCI and the LCIA results, then we discuss the effect of modeling choices and further needed improvements to increase the accuracy of perennial crop LCAs.

2. Methods

2.1. LCA goal and scope

The LCA goal is to assess the environmental impacts of the production of 1 kg fresh fruit from continued agricultural land use. The approach is an attributional LCA without any assessment of rebound effect. There is hence no consideration of any direct or indirect land use change. The system boundary is a cradle-to-farm gate one (Figure 1), including land preparation and all upstream processes to produce, transport and apply inputs to the field, plus field operations and field emissions up to fruit collection at the edge of the orchard or plantation. Downstream processes to conserve or transport the fruits to storehouses are excluded. The land preparation consists of the destruction of the previous crop (as for a re-planting procedure), hole digging, and seedling planting. Seed and seedling productions are accounted for as field inputs. Seed and seedling productions, as well as land preparation, are amortized over the whole crop cycle. At the field gate, there is no co-product production; crop residues are recycled internally in the field. Allocations or system expansion were not needed in these case studies.

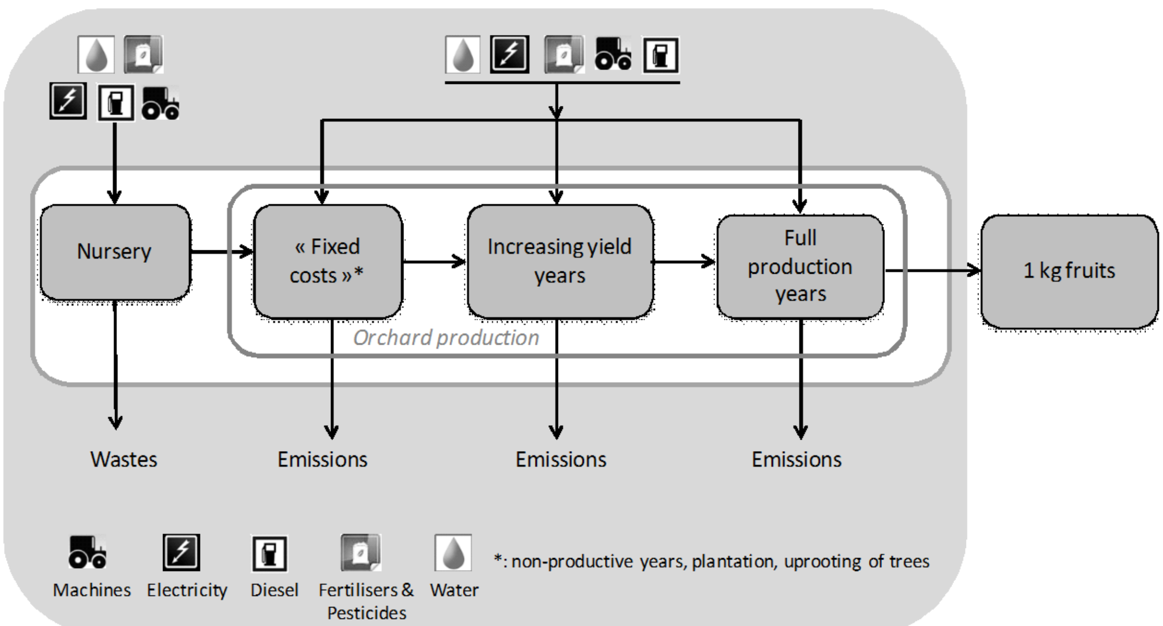

Figure 1. Simplified flow diagram for studied systems for oil palm from Indonesia and small citrus from Morocco

2.2. Data source and LCI

Primary data were collected through field surveys (2010-2013) and are recorded within the CIRAD LCA DATABASE ©-2014. These encompass the following parameters characterizing the cropping systems: input origins, types, doses, and transport distances; fuel consumption for all field operations; planting density and yield outputs. Details are given for each case study in sections 2.2.1.-2.2.2. Secondary data were taken from Ecoinvent v.2.2 database and encompass: production of synthetic inputs (fertilizers, pesticides, material to the nursery) and energy vectors (fuels, electricity); machines and fuel consumptions for input transportation (oversea and road transports); machines for field operations.

2.2.1. Oil palm fruit system

The studied oil palm production system consisted of an industrial plantation block on mineral soil (Typic Dystropept, Acrisol) in Riau Province, Sumatra, Indonesia. Data on seed and seedling productions were based on both company standards and field interviews. Data on land preparation were also based on company standard. The palms were planted in 1992 with a density of 136 trees/ha. The plantation was not irrigated, and water use only took place at seed and seedling production stages as well as for pesticide dilution. Primary data on fertilizer inputs were collected over the period 1992-2012. Yield records started after the immature phase and covered the period 1995-2012. Finally, pesticides and field operations were recorded over the period 2008-2012 (Table 1). Fertilizers were applied mechanically twice a year, whereas pesticide application and harvest were done manually.

* Minimum and maximum values encountered in specific years over the time period of the productive years. Treatments during the non-productive years do not vary annually. Pesticides are herbicides used on a routine basis to clean circles and harvest pathways.

2.2.2. Small citrus system

In agreement with our Moroccan partner: a big producer of agricultural products, a 9-years old small citrus orchard was selected from the region of Beni Mellal in Morocco. This orchard showed recent technologies of production and had already reached its full production phase. The variety of small citrus was “Sidi Aïssa” grafted on “Citrange Troyer”. Over the first 9 years, detailed accounting data were collected to describe all agricultural operations. Large variations of input rates and yield were observed across the first nine years. The orchard was assumed to last 25 years. From the 10th to the 25th years an annual agronomical scenario was designed with the partner based on average data for all inputs and yield for the years 7, 8 and 9. The average yield of 42 t/ha corresponded to the expected yield by the farmer. Key agronomic data for the different phases of the small citrus orchard are presented in Table 2. The orchard, planted at a density of 5 x 4 m was fertigated. Several pumps were used to pump water in the groundwater and lagoons allowed 10 days of autonomy in water during the dryer season in case of pumps’ failure.

Table 2. Key agronomic data for the three phases of a nine years old small citrus orchard in Morocco. Data for the full production phase are extrapolated from the average data for the 3 previous years (7-9). [min and max values]

	Units	Non-productive years (0 - 3 years)	Increasing yield years (3 - 9 years)	Full production years (9 - 25 years)
Fertilizers				
N	kg/ha/yr	55 [46 ; 69]	155 [66 ; 224.5]	214
P_2O_5	kg/ha/yr	24 [8.5 ; 43]	48 [24 ; 67]	65
K_2O	kg/ha/yr	1.6 [0 ; 4.6]	140 [57 ; 221]	186
Fe	kg/ha/yr	0.45 [0.44 ; 0.46]	0.4 [0.04 ; 1.5]	0.8 [0.17 ; 1.48]
Zn	kg/ha/yr	0	0.39 [0.12 ; 0.9]	0.43 [0.20 ; 0.64]
Mn	kg/ha/yr	0	0.51 [0.03 ; 1.31]	0.57 [0.21 ; 0.91]
Irrigation				
Water (groundwater)	m3/ha/yr	6112 [5835 ; 6496]	7982 [6633 ; 11054]	8906

Total pesticides	kg/ha/yr	3.10	5.27	7.04
Yield	t/ha/yr	0	29 [5.5 ; 66]	42

2.2.3. Field emissions

For oil palm system, field emissions were calculated as following. Emissions due to fertilizer field application were estimated according to IPCC 2006 Tier 1 guidelines for both N- and C-compounds. P-compounds emissions were estimated based on SALCA-P model (Prasuhn, 2006) considering only run-off and leaching risks, in our case studies of perennial plantation with permanent soil cover on zero-slope land area (0-3%). Finally, heavy metals and active substances from applied pesticides were assumed to all end up completely in the soil. Heavy metals contents were recorded for synthetic fertilizers (Freiermuth, 2006) and organic fertilizers (primary data from measured recycled crop residues).

For small citrus: Ammonia, NO_2, phosphate and pesticides emissions were estimated following recommendations from Nemecek and Kägi (2007). Nitrous oxide emissions were based on IPCC emission factors but following Brentrup et al. (2000) approach. Following Brentrup et al. (2000) again, the nitrate leached was evaluated by calculating the leachable nitrogen from a nitrogen budget and by applying a drainage factor based on a water budget and the field capacity of the soil. As part of the N budget, N export in fruits was based on Vannière (1992) and N sequestered in trees (roots, stand, branches) was modeled using expertise from H. Vannière.

2.3. Modeling of the perennial crop cycle

Three modeling choices for the perennial crop cycle were tested in parallel in the two contrasted LCA case studies. Modeling choices tested were: 1) a chronological modeling over the complete crop cycle of orchards, 2) a three years average from the full production phase and 3) a selection of different single years from the full production phase. The chronological assessment consists in describing the whole cycle following the historical course of the crop development (Bessou et al., 2013). This approach is the closest way to the reality of a perennial crop development, since delayed effects from agricultural practices or intrinsic crop physiology features can be accounted for. However, the data set on the whole cycle of a perennial crop is hardly available in most of the cases. Therefore, it is important to try to quantify the bias due to truncated perennial crop modeling.

When individual years or the 3-year average were considered in this study, inputs upstream the investigated years were not accounted for, *i.e.* land preparation and planting, seeds and seedling production and all other years, including the costs of the non-productive years. The comparison between individual years and the 3-year average aimed at assessing how much of the inter-annual variability could be captured and how far it might then a better proxy to model the whole cycle compared to individual years.

2.4. Impact characterization method

The impact assessment was performed using the ReCiPe Midpoint life cycle impact assessment method (Goedkoop et al., 2009), adopting the Hierarchist perspective. The following environmental impact categories were considered: climate change (100 years IPCC 2007; kg CO_2eq), terrestrial acidification (g SO_2eq), freshwater and marine eutrophication (g P-eq and g N-eq respectively, based on the nutrient-limiting factor of the aquatic environment), terrestrial and freshwater ecotoxicity (g 1,4-DB-eq: 1,4-dichlorobenzene), agricultural land occupation (m^2.year), water depletion (m^3-eq) and fossil depletion (kg oil-eq). The non-renewable energy consumption (fossil and nuclear; MJ-eq) was assessed using the Cumulative Energy Demand method (Hischier et al. 2009).

3. Results

Across the cradle-to-farm-gate life cycle of oil palm fruit (Figure 2a), the productive years that account for 18/21 of the whole cycle contributed to the larger share of most impact categories (75-95%) except for freshwater eutrophication and water depletion. Since the palm plantations were not irrigated, the water depletion category, which only considers used tap water, was half related to used water to produce seeds (germination cycles) and irrigate the seedlings in the nursery, and half due to pesticides dilution during both non-productive and productive years. Across the other impact categories, fertilizers (production, transport and field emissions) during productive years contributed greatly to climate change, terrestrial acidification, marine eutrophication, and fossil depletion (70-90%); whereas other interventions (including mostly pesticides application) contributed more to the toxicity impact categories (~75%) but also to freshwater eutrophication (25%), water depletion (28%), and fossil depletion including fuel use (22%). Fossil depletion is notably related to fossil fuel used for field operations such as annual plantation maintenance or fertilizer broadcasting.

Across the cradle-to-farm-gate life cycle of small citrus, the tree planting and non-productive years (non-productive stage) contributed between 6.5% for terrestrial acidification and 29% for terrestrial ecotoxicity (Figure 2b). For categories other than toxicity impacts and land occupation, fertilization and irrigation represented the two main contributors. This was due to the production of fertilizers and fossil fuel (for irrigation) and their emissions after use at field level. For terrestrial ecotoxicity, the on-field emission of pesticides was the almost exclusive contributor shared between the non-productive stage (29%) and the productive years (70%). The share of non-productive stage was large for terrestrial ecotoxicity due to the application of toxic insecticides at the nursery stage (abamectin) and during the three first years of trees (methomyl). The freshwater ecotoxicity was due primarily to irrigation (production and combustion of fossil fuel) and secondarily to field pesticide emissions for productive years (27.6%) and for non-productive years (18.8%). Water depletion was due almost exclusively to water use for irrigation shared between non-productive years (8.8%) and the rest of the orchard's life (91%). Finally, agricultural land occupation was mostly due to the productive years (87.4%) and secondarily to non-productive years (12%).

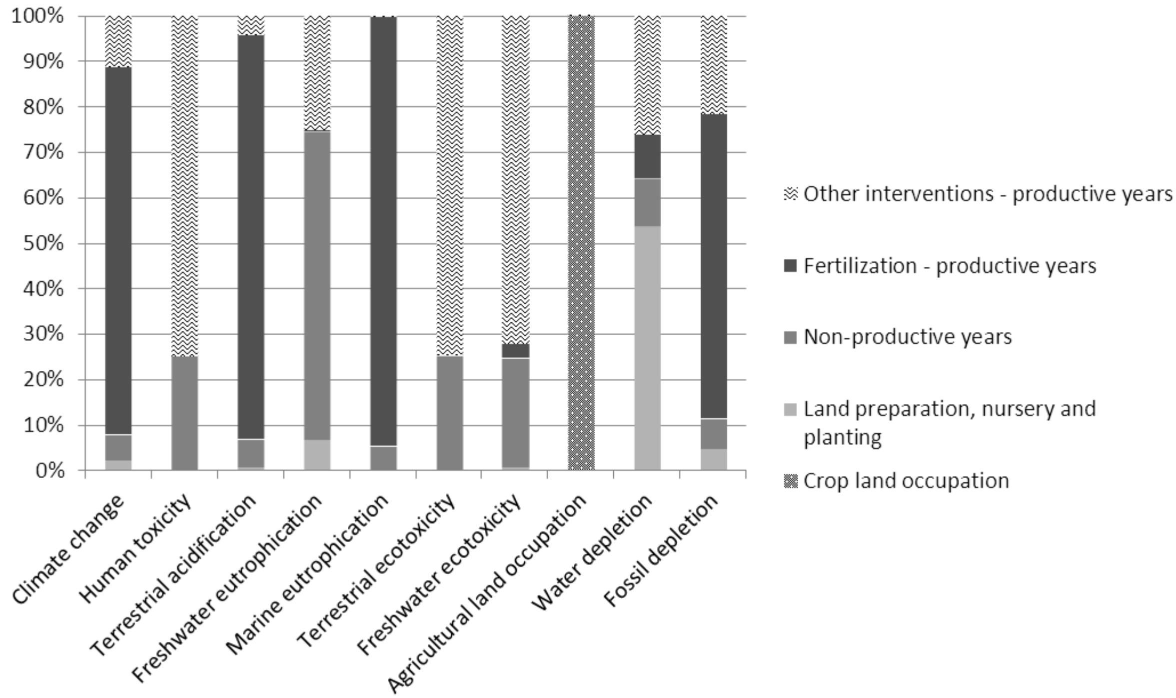

Figure 2a. Contribution analysis from cradle-to-farm-gate for environmental impacts (ReCiPe-Midpoint (H)) of palm oil fruit from Indonesia. Results are expressed per kg of fresh fruit bunches

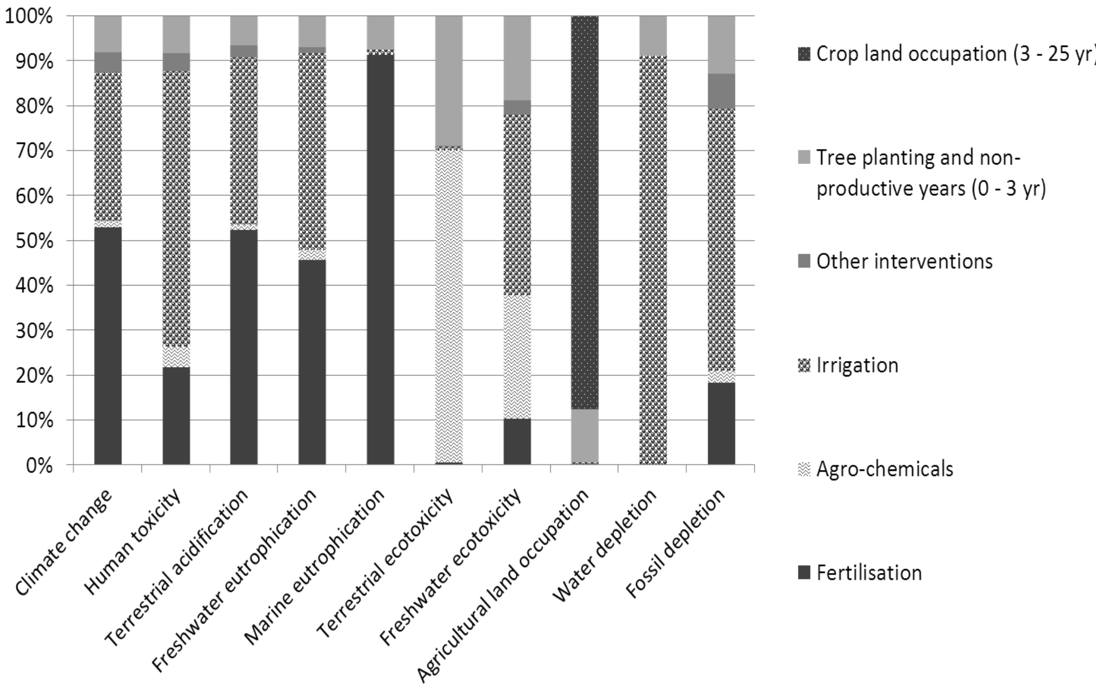

Figure 2b. Contribution analysis from cradle-to-farm-gate for environmental impacts (ReCiPe-Midpoint (H)) of small citrus from Morocco. Results are expressed per kg of raw fruit.

3.1. Sensitivity analysis to modeling approach for perennial crop cycle

In Figures 3a and 3b, modeling approaches are compared to the baseline scenario modelling the whole cycles. In both cases, the results were highly sensitive to the modeling approach used for the perennial crop cycle. Relative variations in results among the approaches are not homogeneous across impact categories.

In the case of oil palm fruit, the year 1995 showed a very specific pattern with lower yields and more inputs that the average productive years.

In the case of small citrus, compared to the full cycle scenario, the 3-years average scenario showed results between 47% for freshwater ecotoxicty and human toxicity up to 138% for marine eutrophication. As such, it did not appear as a good proxy for the full crop cycle because it excluded the non-productive years but also because it relied only on three years over 25 and did not reflect the whole orchard cycle properly. The single year scenarios showed extreme variations due to the yield variations, ranging from 20 t/ha for year 9 to 66 t/ha for year 8, but also to annual variations of rainfall, water use for irrigation and input rates. For instance, the year 9 scenario showed a very high marine eutrophication due to both a low yield and a high nitrate leaching due to a humid weather while year 7 and year 8 were very dry and associated to a nil nitrate leaching.

By selecting randomly one single year from the full production phase to evaluate a full crop cycle, the results could either be dramatically overestimated or underestimated. The most variable results were observed for the most climate-dependent impacts such as marine eutrophication and toxicity impacts due to variations in rainfall and pest pressure but also for toxicity impacts, to the use of different active molecules from one year to the other.

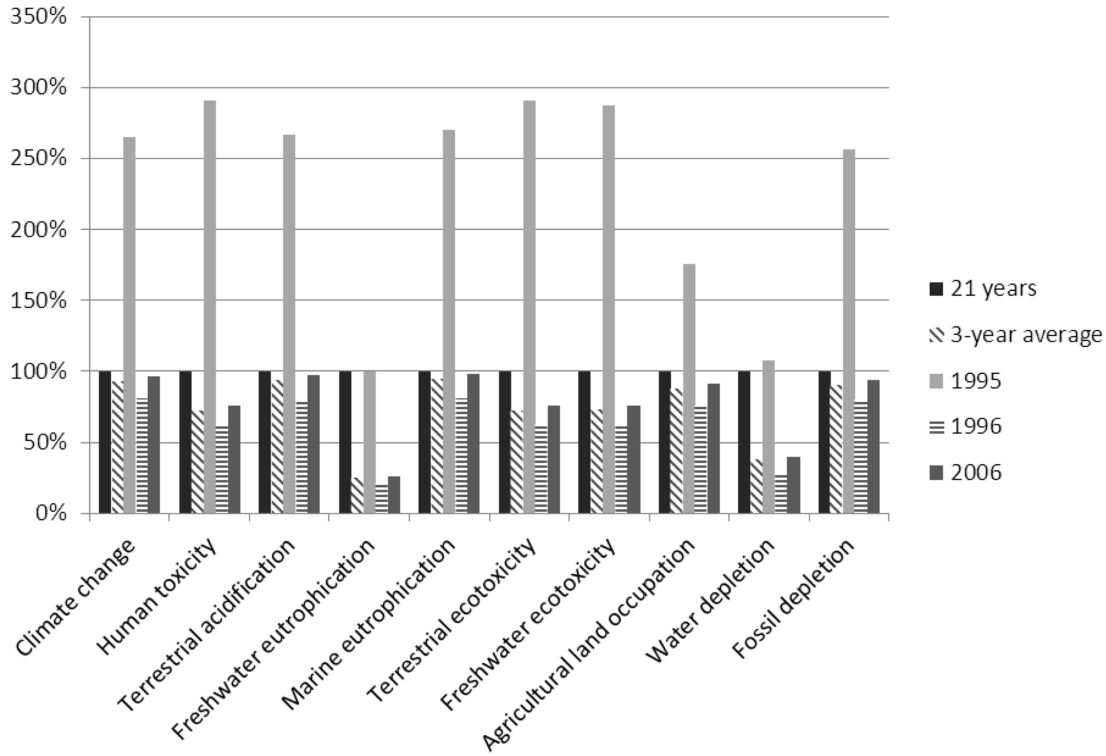

Figure 3a. Environmental impacts (ReCiPe-Midpoint (H)) for different modeling approaches of the perennial crop cycle for oil palm fruits from Indonesia: full cycle modeling (21 years, reference baseline 100%), 3-years average, years 7, 8 and 9. Results are compared per kg of fresh fruit bunches.

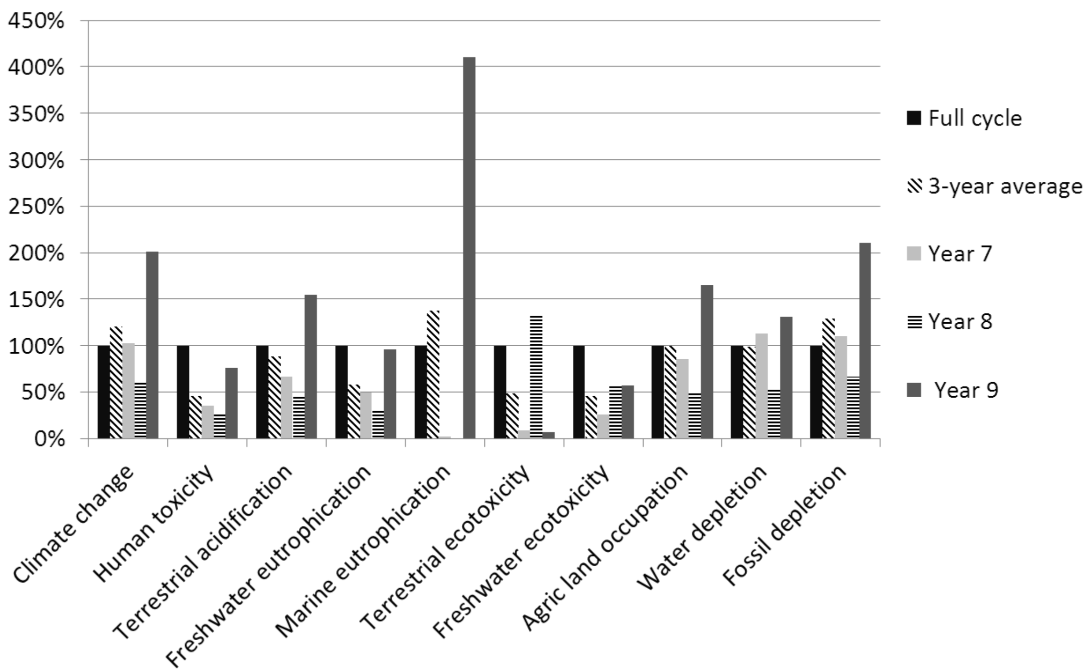

Figure 3b. Environmental impacts (ReCiPe-Midpoint (H)) for different modeling approaches of the perennial crop cycle for small citrus from Morocco: full cycle modeling, 3-years average, years 7, 8 and 9. Results are expressed per kg of raw fruit.

4. Discussion and conclusion

In two contrasted perennial case studies, one on palm oil from Indonesia, the other on small citrus from Morocco, different modeling approaches were developed to account for the perennial crop cycle. The baseline scenario included a complete modeling of the crop cycle while a 3-year average scenario and 3 single year scenarios were also tested. Key insights from these two analyses were consistent:

1. non-productive years have a large share in the environmental impacts of orchards and should be included;
2. choosing one single year from the full production phase leads to highly uncertain results and should be avoided especially for strongly alternating yield crops;
3. even a 3-year average scenario is not sufficient to capture properly the full perennial crop cycle and can be misleading
4. an effort should therefore be made to include the whole crop cycle ideally based on real data when available or at least on expert knowledge.

Although showing very different features, the two case studies contributed to draw consistent conclusions on the modeling of perennial crops in LCA. Analysing two contrasted LCA case studies, we highlighted the specific character of perennial crops in LCA and how important is the inclusion of all their phases in the assessment to account for their highly variable inputs and outputs over years. Other crucial and specific aspects of perennial crops especially in the Southern countries, which are under-represented in current statistical models to estimate field emissions (Bouwman et al. 2002; Stehfest and Bouwman 2006), still warrant further research and better modelling notably regarding:

(i) the inclusion of land use change (if any);
(ii) the modeling of field emissions of nutrients and pesticides combining parameters of soil, climate and practices and long-term recycling and re-mobilising mechanisms;
(iii) the inclusion of impacts due to water use.

5. Acknowledgement

The authors would like to thank the French National Research Agency (ANR) for its support to field work in Indonesia, within the frame of the SPOP project (http://spop.cirad.fr/) Agrobiosphere program. They are also very grateful to their local partners in Morocco and Indonesia who provided all the data used in these studies. Most authors of this paper are members of the ELSA research group (Environmental Life-cycle and Sustainability Assessment www.elsa–lca.org), and wish to thank the French Region Languedoc–Roussillon for its support to ELSA.

ABSTRACT
In an analysis of climate effects, increased soil organic carbon will have a dual effect due to both increased soil fertility and carbon sequestration. Even so, soil carbon changes are neglected in many crop production LCAs. In the present study, the introduction of grass-clover crops in cereal-dominated crop production was evaluated. The grass-clover crops were used for biogas production, and the digested residue was recycled to the farm as biofertilizer. A shift from the cereal-dominated crop rotation to integrated production of food crops and one or two years of grass-clover crops used as biogas feedstock would result in avoided emissions of 2-3 t CO_2-eq. ha^{-1} a^{-1}. Integrated food and energy crop production would in this case improve soil organic carbon content at the same time as resulting in considerably decreased greenhouse gas emissions from the cultivation system.

Keywords: soil organic carbon, energy crop, biogas, integrated production

1. Introduction

The use of crops or the removal of crop residues from farm land for biofuel production is often controversial, and has been identified as having negative impact on soil quality and food crop productivity (Lal 2010). The range of crops that can be used for biofuel production is, however, large, and it can be contra productive to generalize since the impact of crop choice on the cultivation system is complex and variable. An important aspect in the evaluation of changed land use is the impact on soil organic carbon (SOC) content. In an analysis of climate effects, increased SOC will have a dual effect due to increased soil fertility and crop yields and due to the carbon sequestration (Lal 2004). Even so, changes in SOC are neglected in many crop production life cycle assessments (LCAs) (Brandao et al. 2011). Loss of SOC, erosion and compaction are some of the degradation processes that are threatening soil fertility throughout the EU (EEA 2002; Soilservice 2012). Restoration of SOC content can be achieved by e.g. application of biofertilizers containing organic matter and by including green manuring, catch and cover crops in the crop rotation (FAO 2002). However, intensive agriculture is often niched to either crop production or animal husbandry. In Sweden, farms with animal husbandry cultivate grass-clover crops for forage, and have access to animal manure as biofertilizer, both which positively impacts soil SOC content (Jordbruksverket 2014). In regions with intensive food crop production on the other hand, there is no market for forage crops and the biofertilizer availability is low.

In the present study, which is presented in two parts, the purpose was to evaluate the introduction of grass-clover crops in a cereal-dominated crop rotation in a region with stockless farming and intensively cultivated clay rich soils. The calculations were performed as a farm based case study. At the case farm, the low input of carbon in the intensive food crop production the last decades has been identified as problematic with regards to the high clay content in the soils. Problems with soil compaction and crop losses due to standing water are common, and the grain yield is lower on the farm than in the region in general due to soil compaction in combination with low soil carbon content. Thus, the conventional food crop production maintained for decades was no longer seen as sustainable. The approach investigated in the present study was to integrate 1-2 years of grass-clover crops in the food crop rotation and use this as feedstock for biogas production. The purpose was to evaluate a scenario where a biogas plant has been integrated in an agricultural region with mainly stockless farming, where the biogas plant takes on the role of the absent ruminants. The presence of the biogas plant could create a market for the grass-clover forage as energy crop, and the biogas process also produces a digestate (the liquid residue after the biogas production), which can be used as biofertilizer. The overall objective of the project was to analyse how an integrated production of food crops and energy crops for biogas production impacts SOC and food crop production, which is presented in Part I of the study (Prade et al. 2014), and greenhouse gas emissions per land area, which is presented in the present paper, compared to the presently used food crop rotation.

2. Scenarios for crop production

The case farm (56°N, 12°E) includes 650 hectare (ha, 10 000 m^2) of medium to very heavy clay soils with soil clay content up to 65%, with a 4-year cereal based crop rotation typical for the region, including winter oil seed rape, winter wheat, winter wheat and oats. The reference scenario in the present study is based on data on yields measured at the farm for this crop rotation. In two scenarios, the crop rotation is extended to also include one year of grass-clover crops following oats (Scenario GC1), or two consecutive years of grass-clover crops following oats (Scenario GC2). This reduces the land used for production of food crops within the farm by 20% (GC1) and 33% (GC2).

The information on cultivation inputs for each investigated crop rotation is given as average per ha and year (a, annum) in Table 1. Operations include crop cultivation, fertilization with mineral fertilizer or biofertilizer, harvest, and for the biogas feedstock grass-clover also ensiling, transport to biogas plant and feed-in at biogas plant. Use of machinery and materials in different production operations was analyzed in order to calculate direct and indirect greenhouse gas (GHG) emissions, and include emissions from a large range of inputs as seeds, pesticides, concrete and plastics for ensiling etc and are summarized as corresponding GHG emissions as carbon dioxide equivalents (CO_2-eq) (Table 1). For details on these inputs, please refer to Björnsson et al. (2013). The main contributors to GHG emissions in cultivation (fertilizer production and diesel consumption) are given separately as amounts (kg fertilizer or liter of diesel) (Table 1). The fertilizer demand is the average demand of nitrogen (N), phosphorous (P) and potassium (K) in the crop rotations.

Table 1. Crop cultivation inputs

Scenario			Reference	GC1	GC2
		N	196	183	179
Crop fertilizer demand	[kg ha^{-1} a^{-1}]	P	28	27	28
		K	42	76	103
Diesel	[l ha^{-1} a^{-1}]		69	84	87
Materials	[kg ha^{-1} a^{-1}]	CO_2-eq	192	197	176
Machinery	[kg ha^{-1} a^{-1}]	CO_2-eq	92	107	94

Crop yield data and coefficients used for calculation of crop residues and SOC are presented in Part I of this study (Prade et al. 2014). Amounts of crop residues are calculated based on Nordic data in the base case, and in the sensitivity analysis the methodology presented by IPCC is applied (IPCC 2006). The amounts of crop residues are important for calculations of SOC, and in addition give rise to biogenic nitrous oxide (N_2O) emissions. The N content of the crop residues as presented by IPCC are used (IPCC 2006) for these calculations.

3. Biogas production

The problems with soil compaction and the declining grain yields at the case farm were the main reasons for constructing a biogas plant within the farm boundaries in 2006. Biogas is there produced from mainly food industrial waste. The digestate is used as biofertilizer on all land within the farm since 2007. Life cycle inventory data from a LCA performed for the biogas plant within the boundaries of the investigated case farm was used as input for the biogas part of the present study (Lantz and Börjesson 2014).

For the grass-clover as biogas feedstock, the emissions from cultivation inputs given in Table 1 include cultivation and harvest, field drying (to 35% dry matter, DM), transport to biogas plant, ensiling in bunker silos (assuming a DM loss of 5%) and feed-in at the biogas plant. The amounts of grass-clover silage available as biogas feedstock after losses are shown as average per ha of the crop rotation in Table 2. After feed-in, the grass-clover silage is assumed to be pretreated by extrusion to improve the properties as biogas feedstock, where after it is kept at 37°C under oxygen free conditions in the stirred tank biogas digester. The digestate is stored in a covered digestate storage tank and subsequently recycled to the farm as biofertilizer. Loading, transport to field and spreading of the digestate as biofertilizer is included in the cultivation inputs shown for GC1 and GC2 in Table 1. The biogas produced is upgraded, compressed, spiked with propane (a requirement to compensate for the lower energy value of the upgraded biogas compared to the gas in the Swedish natural gas grid) and delivered to the natural gas grid. The compression to 200 bar required at the vehicle filling station is also included.

GHG emissions were calculated based on mass of biogas feedstock, mass of digestate or the biogas produced for each scenario as presented in Table 2. Background information on emissions or primary energy demands are given as footnotes below the table. Emissions in biogas production are calculated to represent only the emissions related to the grass-clover, even if in practice this feedstock will be co-digested with other biogas feedstock. Similarly, the amount of biofertilizer in the form of digestate is calculated to correspond only to the product from grass-clover digestion. Thus, the emissions or benefits from digestate originating from other organic feedstock (food industrial waste etc.) are excluded.

Table 2 shows the amount of digestate and the content of N as total nitrogen (N-tot) and ammonium nitrogen (NH_4-N), P and K. These calculated concentrations are based on measured content in the grass-clover feedstock (Björnsson et al. 2013) and a calculation model for nitrogen mineralization during biogas production based on methane yields as presented by Lantz et al. (Lantz et al. submitted). This digestate is used as biofertilizer in the GC1 and GC2 scenarios, and then partly replaces the mineral fertilizers needed to fulfil the crop fertilizer demand (Table 1), while in the reference scenario, mineral fertilizers only are used.

Table 2. Input and outputs from biogas production in the grass-clover scenarios

Scenario			**GC1**	**GC2**
Amount biogas feedstock [a]	[t ha^{-1} a^{-1}]		5.9	10.5
Biogas production [b]	[GJ ha^{-1} a^{-1}]		17.3	30.9
Amount of digestate [c, d]	[t ha^{-1} a^{-1}]		4.8	8.5
Applied to field as digestate [e]	[kg ha^{-1} a^{-1}]	N-tot	54	87
		NH_4-N	28	42
		P	6	10
		K	32	52

[a] Primary energy input per t feedstock: electricity for extrusion 50 MJ t^{-1}, electricity for pumping and stirring 54 MJ t^{-1}, natural gas for process heat 121 MJ t^{-1} (Lantz and Börjesson 2014).

[b] Based on methane yields of 261 m^3 t^{-1} DM and 221 m^3 t^{-1} DM for 1st and 2nd cut grass-clover (Björnsson et al. 2013) and after methane losses in production (0.29%) and upgrading (1%) (Lantz and Börjesson 2014). Primary energy input in gas handling: upgrading 3.0% of energy in upgraded gas, compression 2.6% of energy in upgraded gas. Propane addition; energy corresponding to 25% of the energy in the upgraded biogas.

[c] Calculated as average for the crop rotation (as if the amount is distributed evenly spread evenly on the farm).

[d] Losses of nitrogen and organic material during digestate storage under roof cover are subtracted: 1% of total nitrogen (N-tot) is lost as ammonia nitrogen (NH_3-N). Methane emissions are calculated based on the IPCC model for manure (IPCC 2006) with a scenario specific calculated maximum methane potential (B_0) and a methane conversion factor of 3.5% (Naturvårdsverket 2013), resulting in methane emissions during digestate storage of 0.4% (GC1) and 0.5% (GC2) of the produced methane (Björnsson et al. 2013).

[e] Only the N present as NH_4-N is assumed to replace mineral N. P and K are assumed to replace mineral fertilizer without losses.

4. Method

The LCA was performed according to the ISO standard (ISO 2006), with focus on quantifying emissions of greenhouse gasses (GHG). The functional unit was set to 1 ha of arable land. The assessment included cultivation, harvest and storage of crops, biogas production, upgrading and compressing, digestate storage and application and soil carbon changes. The majority of the LCI data are summarized in Tables 1 and 2. Additional emission and characterization factors are summarized in Table 3. Data on harvest yields, SOC modelling and SOC changes are presented in Part I of the study (Prade et al. 2014). A systems expansion approach, in accordance with the recommendation in the ISO standard, was applied. In the systems expansion, the total output of grains (wheat and oats) and oil seed (rape seed) was equivalent in the different scenarios. Thus, a reduced output of grains and oil seeds per ha in the crop rotation as a whole, due to the introduction of grass-clover crop cultivation, was compensated for by additional grain and oil seed production outside the farm. The potential benefit of improved food crop yields due to SOC increases as outlined in Part I of this study was thus not taken into account here (Prade et al. 2014). The required additional cultivation was assumed to take place within the region on excess farmland, not leading to any indirect land use changes due to displacement effects. Regional data for GHG emissions in cultivation (Börjesson et al. 2010) were used, and recalculated per kg DM of crop grain or seed (Table 4). The output of upgraded biogas delivered to vehicle filling stations via the natural gas grid was assumed to replace fossil vehicle fuels (EU 2009) (Table 4).

Table 3. GHG emission and characterization factors

Characterisation factors in aggregation of emissions		Reference
CH_4	23 g CO_2-eq (g CH_4)$^{-1}$	(IPCC 2006)
N_2O	296 g CO_2-eq (g N_2O)$^{-1}$	(IPCC 2006)
Life cycle emissions from input energy or materials		
Diesel	84 g CO_2-eq MJ^{-1}	(EU 2009)
Swedish electricity mix [a]	10 g CO_2-eq MJ^{-1}	(Gode et al. 2011)
Nordic electricity mix [b]	69 g CO_2-eq MJ^{-1}	(Gode et al. 2011)
Wood chips [b]	2 g CO_2-eq MJ^{-1}	(Gode et al. 2011)
Propane [c]	74 g CO_2-eq MJ^{-1}	(JRC 2011)
Natural gas [a]	69 g CO_2-eq MJ^{-1}	(JRC 2011)
Fertilizer production – N	6.6 g CO_2-eq g^{-1}	(Börjesson et al. 2010)
Fertilizer production – P	2.9 g CO_2-eq g^{-1}	(Börjesson et al. 2010)
Fertilizer production – K	0.4 g CO_2-eq g^{-1}	(Börjesson et al. 2010)

[a] Used in base case calculations.
[b] Used in sensitivity analysis for electricity or heat demand in biogas production.
[c] Propane required for spiking the biogas replaces natural gas in the grid.

Table 4. Product GHG emissions used in systems expansion

Emissions from replacing crops or fossil fuels	
Oats grain	407 kg CO_2-eq (t DM)$^{-1}$
Rape seed	829 kg CO_2-eq (t DM)$^{-1}$
Wheat grain	407 kg CO_2-eq (t DM)$^{-1}$
Fossil fuels	84 kg CO_2-eq MJ^{-1}

Direct biogenic emissions of N_2O were calculated based on the IPCC model, where 1% of the N contained in crop residues is assumed to be converted to N_2O-N (IPCC 2006). This IPCC N_2O emission factor (EF) of 1% was also applied for the N added through biofertilizer, while a national EF of 0.8% (Naturvårdsverket 2013) was used for mineral fertilizer in the base case, and the IPCC EF in the sensitivity analysis.

Nitrogen losses to air after field application were calculated as corresponding to 15% of digestate content of NH_4-N when applied in cereals/rape and 30% when applied in grass-clover (Naturvårdsverket 2013). The corresponding loss at mineral fertilizer application was 0.9% (Naturvårdsverket 2013). Nitrogen leakage to water was calculated based on regional data to 42, 43 and 35 kg N ha^{-1} a^{-1} for the crop rotations in the reference, GC1 and GC2 scenarios respectively (Johnsson et al. 2008). For indirect N_2O emissions, 1% of nitrogen emitted to air or water was assumed to be converted to N_2O-N (IPCC 2006).

The increases in SOC for all scenarios as presented in Part I (Prade et al. 2014) are in the present study given as average annual CO_2-uptake. In addition, N in a mass ratio of 1:10 to accumulated SOC is assumed to be made unavailable for biogenic N_2O formation in the soil due to the integration in soil organic matter.

Sensitivity analyses were performed for a range of the input assumptions as summarized in Table 5. For details on these assessments and the selection of data, please refer to Björnsson et al. (2013).

Table 5. Background data and assumptions in base case and sensitivity analyses

Variable	Base case	Sensitivity analysis
Time span	40 years [a]	20 years [b]

Soil organic matter	-98	-271	-307
BIOGAS PRODUCTION			
Process and pre-treatment energy	-	55	99
Upgrading energy and propane	-	30	54
Process methane leakage	-	25	45
Upgrading methane leakage	-	87	155
Digestate storage	-	34	79
SOIL ORGANIC CARBON (SOC)	-769	-2 124	-2 401
NET EMISSION	**2 081**	**801**	**643**
PRODUCT OUTPUTS			
Oats [t DM ha^{-1} a^{-1}]	1.00	0.80	0.67
Winter oil seed rape [t DM ha^{-1} a^{-1}]	0.63	0.50	0.42
Winter wheat [t DM ha^{-1} a^{-1}]	3.25	2.60	2.17
Biogas [GJ ha^{-1} a^{-1}]	-	17.3	30.9

The avoided GHG emission due to carbon sequestration by SOC incorporation has a strong impact on total GHG emissions in all scenarios, but especially in the GC scenarios, where grass-clover root biomass and biofertilizer give additional SOC contributions. In the reference scenario, the crop residues left in the field give a low and slow build-up of SOC content to 2.9% after 145 years, while in the GC scenarios, 3% SOC is reached already after 30 years, with a steady state level after 125 years of 4.1-4.4% (Prade et al. 2014). Emissions related to inputs in cultivation (diesel, fertilizers, materials, machinery) decrease in the GC scenarios due to the decreased fertilizer demand when biofertilizer is used. Biogenic N_2O emissions, however, increase due to larger emissions from biofertilizer and from the nitrogen in crop residues from grass-clover. At the same time, the SOC build-up in the GC scenarios also gives a large incorporation of N into soil organic matter, which decreases the N_2O emissions, giving a similar net emission of biogenic N_2O in all scenarios. Emissions related to the production of biogas in the GC scenarios give a relatively small contribution. All in all, the conventional food crop rotation gives an average GHG emission of 2.1 t CO_2-eq ha^{-1} a^{-1}. The emissions from the GC scenarios with integrated food crop and grass-clover production are much lower, 0.6 to 0.8 t CO_2-eq ha^{-1} a^{-1}.

In the systems expansion, the 20-33% lower production of food crops in the GC scenarios (Table 6) is included as an added climate impact from cultivation of these crops elsewhere in the region, while the avoided GHG emission when the upgraded biogas (Table 6) replaces fossil vehicle fuels is subtracted. The resulting total GHG emissions after systems expansion are shown in Figure 1, where the striped bars show the emissions summarized per category from Table 6, and the dotted bars show the impact of systems expansion. The resulting net GHG emission is negative for both GC scenarios; -0.2 t CO_2-eq ha^{-1} a^{-1} when one year (GC1), and -1.2 t CO_2-eq ha^{-1} a^{-1} when two years of grass-clover crops is integrated in the food crop rotation (GC2).

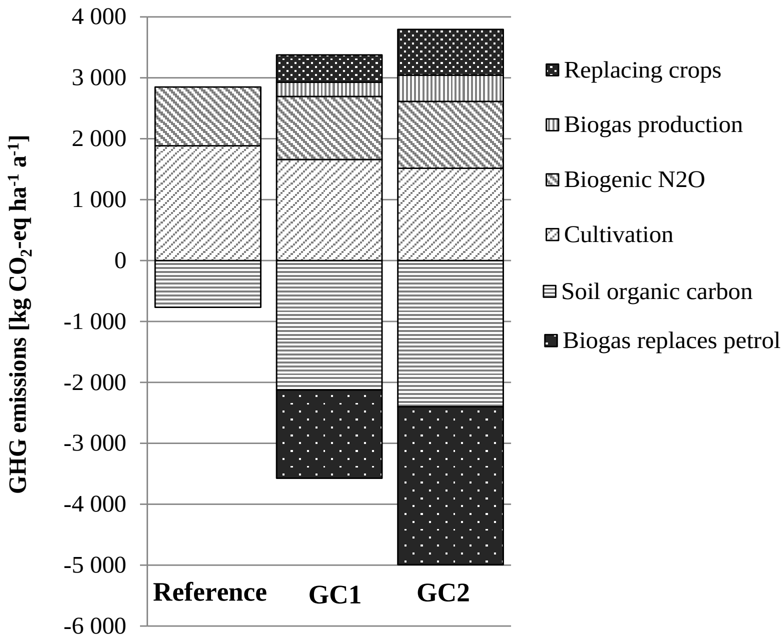

Figure 1. GHG emissions summarized per category in Table 6 (striped bars), and after systems expansion (dotted bars).

The net GHG emissions per scenario from Figure 1 are shown as the base case in Figure 2, together with the impact of changing input parameters in SOC modelling, cultivation and biogas production in the sensitivity analysis. In the base case, the annual SOC change was calculated over a time span of 40 years, to reflect the slow process (125-145 years) of achieving steady state SOC levels. IPCC suggest a 20 year timespan, which is applied in the sensitivity analysis and give lower annual GHG emissions for all scenarios. In the base case calculations, amounts of crop residues are calculated based on Nordic data on ratios between harvested crop and crop residues (Björnsson et al. 2013; Prade et al. 2014). The IPCC methodology evaluated in the sensitivity analysis differs mainly in suggesting much higher cereal straw yields (IPCC 2006). IPCC data thus give higher SOC accumulation and lower GHG emissions for all the investigated scenarios, but with larger impact on the reference scenario with 75% cereals in the crop rotation. The straw yields suggested in the IPCC calculation model are, however, unrealistically high compared to actual straw yields in cereal cultivation in Sweden (Nilsson and Bernesson 2009). The only other aspect in the sensitivity analysis with a noticeable impact on the net result is the assumption about increased methane emissions from digestate storage, which is based on an experimental study on digested cattle manure (Digestate storage CH_4, Figure 2). The risk of methane leakage is an important aspect to consider, since digestate from grass-clover digestion will contain quite a high residual amount of undigested organic material. This makes the digestate interesting as biofertilizer, but also increases the risk of methane leakage during storage. Since 99% of the digestate methane leakage has been shown to occur during the warmer months of the year, (Rodhe et al. 2013), a way of minimizing leakage is to make sure the storage is emptied in spring, which is what is assumed in the base case in the present study.

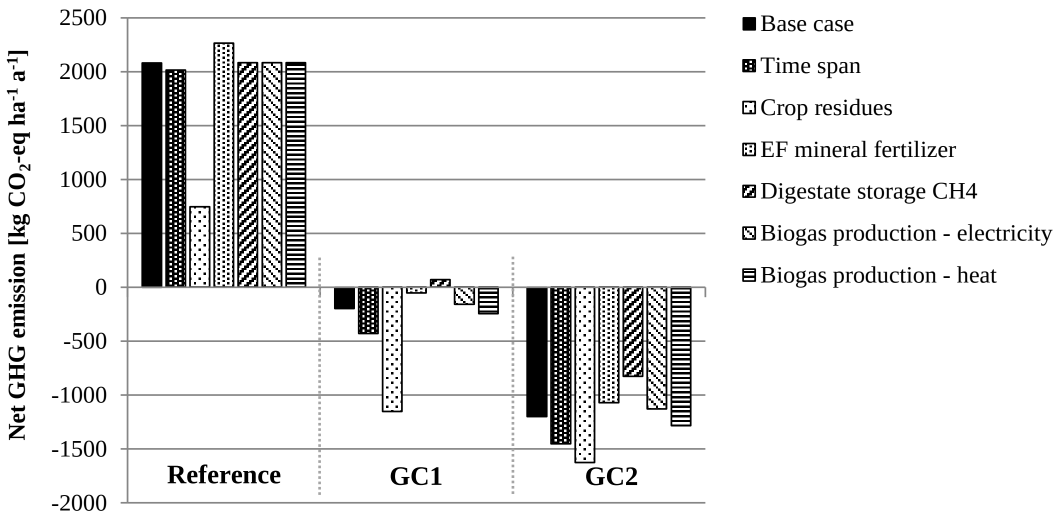

Figure 2. Net GHG emissions for the three analysed scenarios in the base case (black bars) and after varying a range of input parameters in the sensitivity analysis.

Looking at the difference between emissions in the reference scenario and the investigated GC scenarios, the shift from the 4-year cereal dominated food crop rotation to a 5-year crop rotation that includes one year of grass-clover as an energy crop for biogas production would result in avoided emissions of 2.3 t CO_2-eq ha^{-1} a^{-1} (ranging from 1.9 to 2.4 t CO_2-eq ha^{-1} a^{-1} based on the variation shown in the sensitivity analysis, Figure 2). Shifting to a 6-year crop-rotation with two years of grass-clover would give avoided emissions of 3.3 t CO_2-eq ha^{-1} a^{-1} (ranging from 2.4 to 3.5 t CO_2-eq ha^{-1} a^{-1}, Figure 2).

6. Conclusions

Combining food production with renewable energy production has been suggested as one possible approach to achieve food systems with lower GHG emissions and to combine food security with energy security (FAO, 2011). The studied change from a cereal dominated food crop rotation to a system with integrated production of food and energy crops was shown to strongly reduce GHG emissions from the cultivation system. Since production of energy crops on farm land is sometimes seen as conflicting with sustainable food crop production, it is important to also highlight cases where an integrated approach can have multiple benefits. The possibility of using grass-clover crops for biogas production opens up for a possibility of integrating grass-clover in the crop rotation in regions with no demand for cattle feed. Grass-clover crops will diversify the crop rotation and have a strong impact on the build-up of SOC. Such a change in cultivation practice could in turn improve long term soil fertility at the same time as giving significantly decreased GHG emissions, in the range of 2-3 t CO_2-eq ha^{-1} a^{-1}, for the investigated cultivation system.

ABSTRACT

Consuming water can affect human health (e.g. by reducing availability of irrigation water and hence food availability), ecosystems (by decreasing water availability for terrestrial/aquatic species) and future generations (by depleting non-renewable resources). However, no standard method exists to quantify the stress on water without favoring any of these areas of protection. Stress/scarcity indexes have focused on an anthropocentric perspective, and a few on an ecocentric perspective. We explore the possibility of developing an indicator considering the water resource as a whole and propose a method which is not centered on an area of protection but rather assesses the extent to which all water demand and availability differ within a watershed (i.e. hydrocentric). This concept can eventually serve as a single metric to assess potential impacts from water use and be used consistently in the application of the upcoming ISO standard and for eco-labelling of food and energy products.

Keywords: water use impact assessment, Water Footprint, environmental impacts, water stress, water scarcity

1. Introduction

Life Cycle Assessment (LCA) has served as a decision-making tool to help reduce environmental impacts for several decades. Recently, the methodology was used to assess water-specific impacts and group them in a new water footprint concept, currently being framed in an upcoming ISO standard (ISO/FDIS 14046, 2014). While this document provides principles, requirements and guidelines, no specific characterization method is recommended even though several have emerged in the last five years to assess impacts from water use (Kounina et al. 2013). The need for a consensus-based method is clear and particularly relevant for food production systems where product-level environmental labels and declarations are already emerging. In 2013, the UNEP-SETAC Life Cycle Initiative recognized the need for a consensual method following the many existing water use impact assessment methods described by Kounina et al. (2013), and solicited the Water Use in LCA Working Group (WULCA), fostering method development and applications since 2007, to undertake this task.

By bringing together method developers and experts from the fields of LCA, hydrology, ecology, etc., WULCA will propose by the end of 2015, consensus-based indicators to assess impacts from water use, which can be used to comply with the requirements of the ISO document. This paper presents the water footprint concept as defined in the upcoming ISO 14046 standard, and WULCA's progress towards a consensus-based method. As agriculture accounts for over 70% of water withdrawal and its water consumption is estimated to increase by a 20% by 2050 (WWAP, 2014), combined with the fact that agri-food global businesses are expanding and hence putting new stress on local aquifers (WBCSD, 2012), the food sector is benefitting most from such methodological developments.

1.1. LCA and water footprinting

In contrast with an LCA, an LCA-based water footprint is the fraction of LCIA results which are related to water resource. These LCIA results include impacts associated with water use, and the subsequent effect on water availability for humans and ecosystems, as well as direct impacts on the water resource and its users from relevant emissions to air, soil and water (see Fig.1). These latter impacts are quantified using traditional LCA impact categories (e.g. freshwater eutrophication, freshwater acidification, human toxicity and eco-toxicity).

A water footprint may be presented as the result of a stand-alone assessment or as a sub-set of results of a larger environmental assessment, such as an LCA. As per the ISO standard, a qualifier is used when a water footprint study is limited to certain aspects only. A “water scarcity footprint” and a “water availability footprint” assess impacts associated with water use only, whereas a water footprint (no “qualifier”) assesses all relevant impacts related to water, hence including relevant emissions that occur without any water use and yet still impact water (e.g. SO_x emissions to air causing freshwater acidification).

In the recent years, businesses have started to include scarcity indicators (sometimes also called stress indicators) to assess potential impacts of water use. In the context of the standard, this is the equivalent of a “water scarcity footprint”, or a “water availability footprint” (if the change in water availability caused by water degradation is also included). However, at this point no consensus-based approach exists for doing so and results are not always comparable when different scarcity/stress indicators are used for characterization.

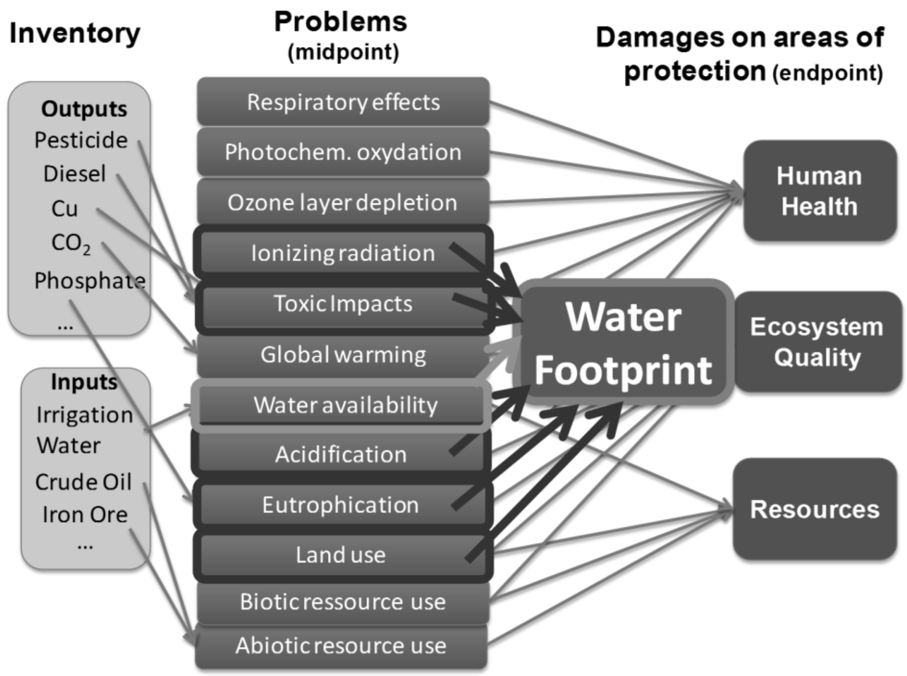

Figure 1: Representation of a water footprint with respects to LCA impact categories (figure from Impact World + (Bulle et al. 2014)).

1.2. Scarcity

From the ISO definition, scarcity is the “extent to which demand for water compares to the replenishment of water in an area, such as a drainage basin” (ISO 14046 2014). Up until now, water scarcity indexes have been built to reflect the problem as one for either humans or ecosystems. Most indexes (Pfister et al. 2009; Boulay et al. 2011; Frischknecht et al. 2009; Gassert et al. 2013) considered only human water use divided by water availability (see Eq.1). A few others (Smakhtin et al. 2004; Hoekstra et al. 2012) have considered that water scarcity should exclude water requirement for ecosystems to be maintained in “fair” condition, resulting in an index that shows whether the human’ water use impairs ecosystems (>1) or not (<1) (see Eq.2). Hence, none of these indicators represents a neutral assessment of the relationship between all water demand and availability.

The main gap is that no indicator exists where demand for water in an area is compared with availability in such a way that modeling choices and interpretation of the physical meaning are explicit and transparent.

$$Scarcity_{Anthropocentric} = Fn\left(\frac{human\ water\ use}{water\ availability}\right) \quad \text{Eq. 1}$$

$$Scarcity_{Ecocentric} = Fn\left(\frac{human\ water\ use}{water\ availability - ecosystem\ water\ requirement}\right) \quad \text{Eq. 2}$$

1.3. Consensus-based indicator project from WULCA

WULCA commenced a new two-year activity in January 2014 aiming at developing consensus-based indicator(s) for water use impact assessment. The first steps defined a framework (based on previous WULCA deliverable (Bayart et al. 2010; Kounina et al. 2013)) and led to the identification of the three sets of indicators on which to focus (see Fig.2): 1) The impact pathway leading to damages on human health is already modeled by different methods and ready for harmonization (Boulay et al. 2014). Hence it was included in the work and a consensus-based methodology defining this impact pathway is under development. 2) The ecosystem impact pathway includes several methodologies with possible complementary assessments (Kounina et al. 2013). A sub-group was formed to harmonize the different impact pathways in this category, by defining a consistent framework and possibly identify a midpoint indicator early in the impact pathway. 3) Answering the demand from industry for a generic (not human- or ecosystem-oriented) and recommended stress/scarcity indicator, a specific sub-group focused its efforts on the development of such a metric. It was set out as an indicator independent of other impact pathways and not leading directly to any endpoint damages. Further harmonization with the conventional midpoint-endpoint framework may come later as the indicators further develop. This paper is presented by the sub-working group focusing on this last stress-based midpoint indicator and presents results of the findings to date. The impact pathways leading to impacts on resources or compensation processes were considered not sufficiently mature to be included in this consensus building phase.

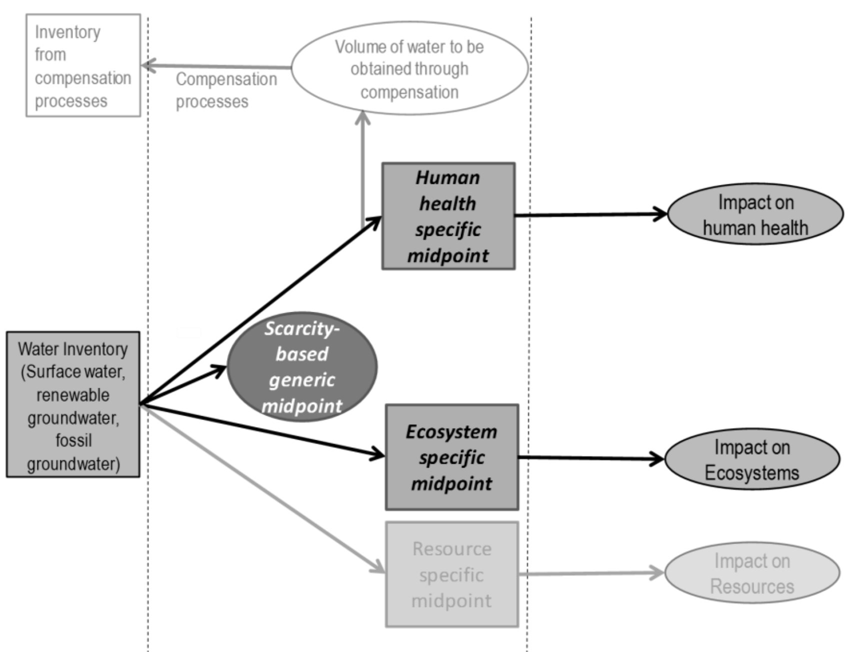

Figure 2. Chosen impact pathways for WULCA's consensus building work.

2. Methods

In order to provide a scarcity indicator which represents a generic assessment of the demand and availability of water in a region, we define scarcity following ISO/FDIS 14046 definition, as shown in Eq.3, where the total water demand includes all users, human and non-human, and water availability includes the available renewable resource. This indicator is therefore not anthropocentric or ecocentric, but simply based on the water resource, i.e. hydrocentric.

$$Scarcity_{hydrocentric} = Fn\left(\frac{Total\ water\ demand}{Renewable\ water\ availability}\right) \quad \text{Eq.3}$$

To illustrate the difference in scarcity definitions, we compare the three approaches using eq. 1-3 without a scaling function (just the ratios) in a simple preliminary assessment. Not all necessary high quality data was available at this early stage of the project and proxy data was used to illustrate the concepts. Human water consumption (HWC) from WaterGap (Alcamo et al. 2003) was used to represent water demand from humans. Environmental water requirements (EWR) assessment from Smakthin et al. (2004) were used to represent ecosystem water demand. These values represent the portion of the available flow required to maintain ecosystems in a "fair" condition, defined by the authors as "moderate or considerable modification from the natural state where the sensitive biota is reduced in numbers and extent". This state represents a modeling choice which should be agreed on and assessed with corresponding data. This data is regionalized and readily available for the entire globe, and was used as a first assessment to illustrate the concepts; it does not yet include terrestrial ecosystems water requirements and may not represent the best data available. Water availability (WA) data from WaterGap (Alcamo et al. 2003) was used for this first assessment.

3. Results

Figures 3, 4, and 5 illustrate the different scarcity ratios: anthropocentric, ecocentric and hydrocentric, respectively. They are calculated using the ratios presented in Eq. 1, 2 and 3 respectively. The difference between anthropocentric and ecocentric scarcity is negligible for most of the world, with few watersheds showing visibly higher scarcity in the ecocentric case (hardly visible on a black and white scale). This makes sense, since the scarcity level is increased by environmental flow requirements but the pattern is not changed.

Not surprisingly, results on Fig.5 show higher scarcity in most regions of the world for the hydrocentric indicator since this includes ecosystem water demand within the numerator of the equation and therefore also regions with no human water consumption show some scarcity. Figure 6 shows the difference in results between the anthropocentric indicator and hydrocentric indicator. At a minimum, scarcity increases in comparison to the anthropocentric approach between 0.2-0.3 around the world. Most of North and South America, Europe and Central Asia increases between 0.3-0.4, and some watersheds in the USA and Eastern Europe increase by up to 0.47. This difference represents exactly the EWR percent of available water assessed by Smakhtin et al. (2004), which varies from 0-47%. By integrating ecosystem's water requirement, this approach therefore gets rid of the artifact that water scarcity in desert areas is 0 if no human is using water, as discussed in Berger et al (2014).

Figure 7 shows the difference in results between the hydrocentric approach and the ecocentric indicator. In this case, some highly scarce regions show a higher indicator with the ecocentric indicator than with the hydrocentric approach, but these regions are still consistently at the top of the scarcity scale. As a mathematical demonstration, if one hypothetical region shows a water availability of 100 m^3, with 90% of this amount being consumed by humans (90 m^3), yet having a EWR value of 40% (40 m^3), the ecocentric indicator would result in 90/(100-40) = 1.5, indicating that the water use is tapping into the ecosystem's requirements. A hydrocentric approach results in (0.9+0.4)/100 = 1.3, indicating the shared pressure on both human and ecosystem needs for water.

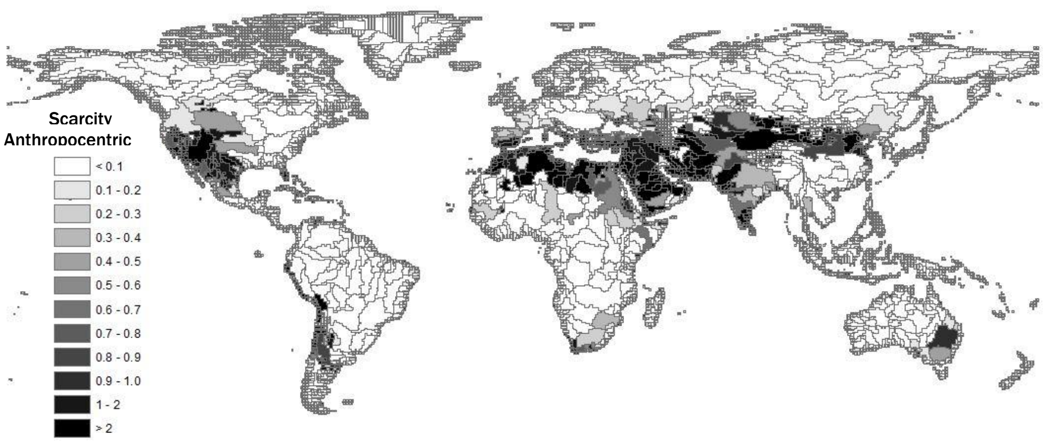

Figure 3. Anthropocentric scarcity assessment showing the ratio of consumed water by humans to available water (HWC/WA).

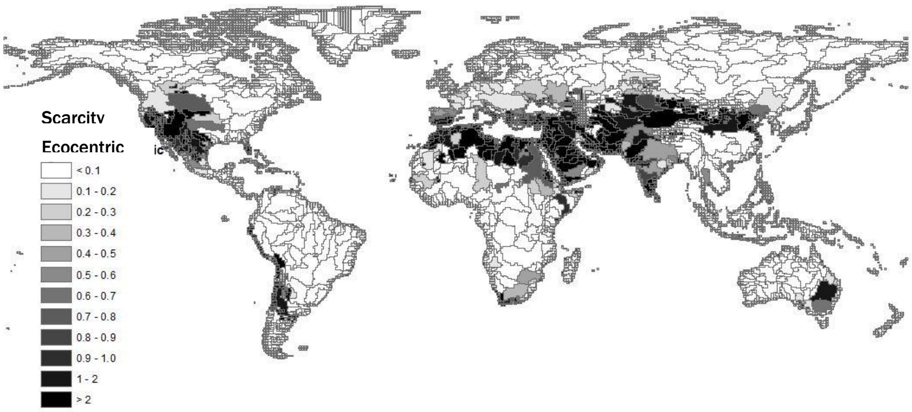

Figure 4. Ecocentric scarcity assessment showing the ratio of consumed water by humans to available water, to which water for ecosystem has been subtracted (HWC/(WA-EWR)).

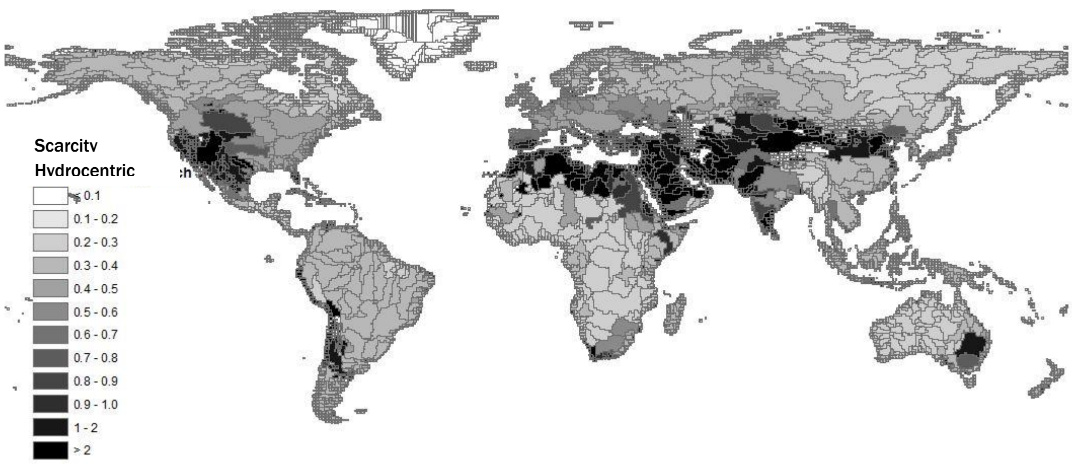

Figure 5. Hydrocentric scarcity assessment based on the ratio of all water demand to all water available, showing the pressure on the water resource ((HWC+EWR)/WA).

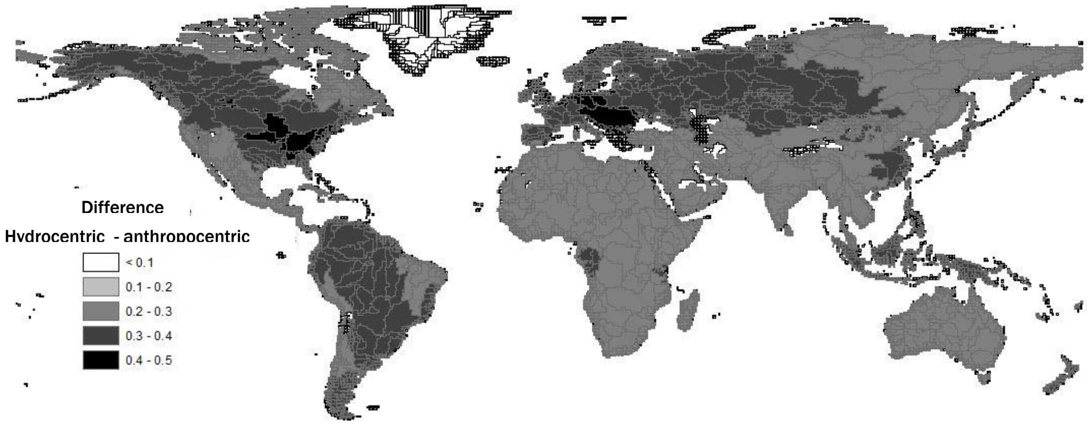

Figure 6. Difference (decimal percentage) between the hydrocentric approach as shown in Fig.5 and the anthropocentric scarcity shown in Fig.3.

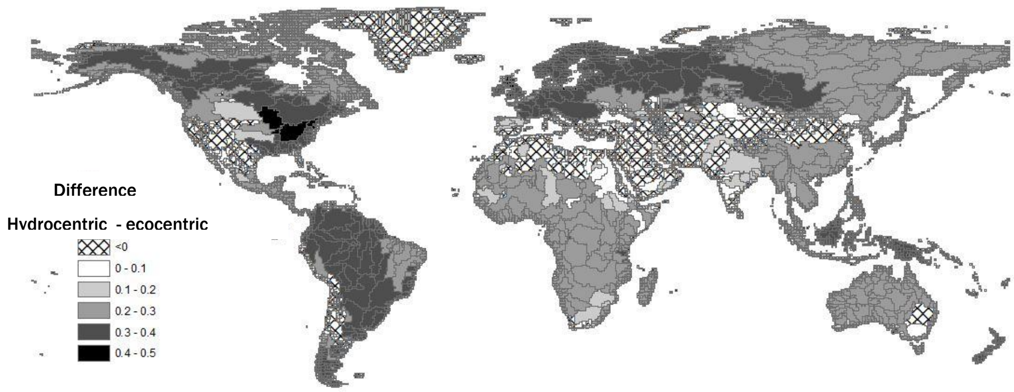

Figure 7. Difference (decimal percentage) between the hydrocentric approach as shown in Fig.5 and the ecocentric scarcity shown in Fig.4.

4. Discussion

Results presented in this paper show intermediate work as the working group progresses towards a consensual indicator. At this point, we have identified that scarcity indicators used until now have been focused mainly on potential impacts on humans, and some towards ecosystems, but none reflected simply the pressure on the resource coming from the demand of all local water users in comparison with the availability. At this point, potential impacts on ecosystems from water use have only been accounted for at the endpoint level (e.g. Pfister et al. 2009, Hanafiah et al. 2011). A combination of human and ecosystem impacts based on endpoint methods and subsequent weighting of these indicators have been suggested by Ridoutt and Pfister (2013). However, such aggregated endpoint-based CF integrate a weighting scheme, which is only allowed by ISO as an additional and subsequent step following impact characterization, after first obtaining separated impact category indicator results. This ensures that value choices are transparently provided and eventually can be adapted to the values of the decision maker. While such weighted methods are still being investigated (Ridoutt and Pfister, 2014), the objective of the approach presented in this paper is rather to provide a generic indicator representing potential problems associated with water use in relation with the local scarcity, without focusing on one area of protection.

Findings of this paper indicate that an indicator that assesses scarcity following the ISO definition and considering all water demand can provide an alternative perspective and better reflect the potential consequences of using water in different areas around the world. Hydrocentric scarcity values are higher than anthropocentric scarcity values and generally higher than ecocentric scarcity values (except in highly (eco)scarce regions), and hence may allow the quantification of potential problems in such regions that have been excluded so far on the scarcity level.

However, the main challenges lie in the proper attribution of ecosystem water needs compared to human water consumption and the data availability to develop a global indicator of reasonable quality for robust assessments. In this paper, human water consumption was used, along environmental water requirements for ecosystems based on “fair conditions”, which is not based on the same reference and hence still introduces some bias. Results would likely differ and scarcity values increase if the same perspective on “demand” is taken. However, this was performed as a preliminary assessment with readily available data, and defining and assessing the water demand from humans and ecosystems with the same underlying basis (e.g. actual water demand, ideal/pristine water demand, etc.) is necessary to reduce bias and remain transparent. Best available data should be used to represent the water demand both from a human and an ecosystem perspective, including aquatic and terrestrial ecosystems, with special attention to wetlands (Verones, Pfister, et al. 2013; Verones, Saner, et al. 2013). Different definitions and sources of data exist to quantify water availability, whether current or pristine for example, and this aspect should be investigated and the most relevant source for this indicator chosen. Also, while this work has shown only blue water-related data, interactions with green water and the change in blue water associated with land use change should be investigated. Coherence among the sources of data, the geographic and temporal resolution, and close analysis to prevent double counting are important aspects that should be analyzed.

5. Conclusion

This work provided an overview of the relationship between LCA, water scarcity, water availability and water footprinting, in light of the upcoming ISO standard 14046. It quantifies the characterization factors for different interpretations of the scarcity concept and applied directly the ISO definition to provide a first glance at a generic hydrocentric indicator of water scarcity quantifying the pressure on the water resource in a region by relating the water demand and availability. Results show higher scarcity in comparison with the currently used anthropocentric methods as it encompasses a larger problematic. The WULCA working group is further developing this indicator through ongoing investigating of data sources, hypothesis, data resolutions and choices associated with this novel approach.

From wheat to beet – challenges and potential solutions of modeling crop rotation systems in LCA

ABSTRACT

One of the remaining methodological challenges of agricultural LCAs is the inclusion of crop rotation effects. They are caused by changes in physical, chemical and biological properties of the agricultural land over time (e.g. soil structure, presence and availability of nutrients, phytosanitary conditions) and cannot be easily measured. LCA studies, focusing on only one vegetation period, have a limited ability to include those crop rotation effects, unless explicit modeling measures have been taken to include them. A summary on existing approaches is given and remaining gaps are identified. A new approach for the modeling of crop rotation effects is suggested. It includes the alignment of system boundaries with the whole crop rotation system, a systematic description of crop rotations, the inclusion of all inputs and all outputs and as a last step, allocation to the crop specific burdens using the agriculture-specific Cereal Unit.

Keywords: Agriculture, LCA, Crop rotation, System boundary, Cereal Unit allocation

1. Introduction

One particular challenge for proper description of agricultural reality is the consideration of crop rotations in LCA. Crop rotation describes the sequence of different agricultural crops, grown on the same field. “If an LCA study focuses on just one crop (such as wheat) it fails to account for the interactions between this crop and preceding and subsequent crops.” (Cowell et al., 1995)

Features of crop rotations are explained, several examples for positive crop rotation effects are mentioned and the need for including crop rotation effects in LCA is derived from this. Different approaches for including those effects are described, but none of them is completely satisfactory. A consensus on a uniform approach has not been achieved yet – even though crop rotation effects are physical reality, are described in agricultural publications and do have strong influence to the agricultural practice, e.g. cultivation planning, plant protection and plant nutrition.

1.1. Features and the need for inclusion of crop rotations in LCA

By means of growing different crops in chronological sequence, positive effects from the current to the succeeding crop can be achieved, e.g. improvement of phytosanitary conditions (hereby avoiding diseases) or the improvement of nutrient availability of succeeding crop (by using different nutrients or leaving different nutrients in residues or sourcing the nutrients from different soil horizons). These crop rotation effects can be physically measured by long term field experiments, are well described in agricultural publications and are very important for the agricultural practice, e.g. in terms of crop planning and supply of nutrients to plants (Blanco-Canqui and Lal, 2009; Forsyth, 1804; Russell and Russell, 1973; Wirghtson, 1921). “Use of crop rotations can help maximise productivity because different crops and farming practices have varying impacts on the soil, affecting properties such as fertility, texture, structure, population of microorganisms, number of weed seeds and so on.” (Cowell et al., 1995) Zegada-Lizarazu and Monti summarized several advantages of crop rotations:

- “Enhanced soil fertility and higher yields
- Improved soil structure and maintenance of long-term productivity and organic matter.
- Longer period of land cover with subsequent lower erosion.
- Reduced use of agricultural inputs such as agrochemicals and synthetic fertilizers [lower disease pressure due to changing crops].
- Diversified production with greater marked opportunities and lower economic and climatic risks.
- Increased biodiversity and less monotony of the landscape.
- Time-diluted farming activities [seedbed preparation, sowing process, plant protection, harvesting].” (2011)

1.2. Existing approaches to include crop rotation effects in LCA and their limitations

There are several approaches to consider the shift of nutrients from a current crop to the subsequent crop in agricultural LCAs. But in detail, the existing approaches differ. For the nutrients phosphorous (P) and potassium (K), corrections are made for residues that either remain on the field – by deducting the environmental impacts from the total impacts and allocating it to the subsequent crop (Nemecek et al., 2011; Nemecek and Schnetzer, 2011) – or removed from the field – by allocating the burden to those harvested co-products (Nemecek and Kägi, 2007; Nemecek et al., 2008). For the nutrient nitrogen (N), remaining in crop residues on the field, a credit can be given if reduced a fertilizer dose is recommended for the subsequent crop (Nemecek et al., 2011). Van Zeijts et al. suggest to allocate N completely to one crop; to allocate P and K according to the uptake and uptake efficiencies of the various crops; to allocate the application of organic matter according to their land use share in the cropping plan. Furthermore, they recommend to intensively study each agricultural activity in the cropping plan and to decide whether done for individual crops or more than one crop (1999). Van Zeijts et al. underline, that agricultural activities, e.g. fertilization or crop protection, are typically "meant to benefit more than one crop" (1999).

"If an LCA focuses on just one crop (such as wheat) it fails to account for the interactions between this crop and preceding and subsequent crops." (Cowell et al., 1995) If agricultural fertilization is studied using a limited observation period – e.g. one single vegetation period – there is a certain probability for overlooking several aspects of the overall fertilization strategy for the studied agricultural farm (Flisch et al., 2009). "This raises the question of whether it would be more appropriate to draw a system boundary around a crop rotation rather than a particular crop." (Cowell et al., 1995) Cowell et al. argue, the farmed soil should be within the system boundary, "because it is an integral part of the production system" and even the soil does not cross the spatial system boundary, the soil quality must be taken into account (Cowell et al., 1995). Audsley et al. add, that the soil crosses the temporal system boundaries, and thus needs to be considered in LCA (Audsley et al., 1997).

The complexity of effects between elements in a crop rotation can be understood by studying GRUDAF (Grundlagen für die Düngung im Acker und Futterbau; Principles for fertilization in arable and fodder production). GRUDAF has been developed and released by the Swiss agricultural research institutes Agroscope Changins-Wädenswil ACW and Agroscope Reckenholz-Tänikon ART (Flisch et al., 2009). GRUDAF contains natural science based recommendations for the fertilization of arable crops and fodder. The document is oriented towards agricultural advisory service and farmers in order to assist the development of economically and ecologically sound fertilization strategies. In order to be in line with latest scientific knowledge and most recent production technologies, it is updated regularly (Flisch et al., 2009). The document reveals the complexity of fertilization and offers an excellent view into the vast number of dependencies of fertilization planning and concrete fertilizer amounts. Based on natural science based long-term experiments, Flisch et al. describe the following agricultural management aspects and soil properties that shall be considered for determining the fertilizer amount:

- Management aspects: Crop rotation design, Types previous crops, Usage of intermediate crop, Crop residue management, Number of grassland cuts or gazing of pasture, Long-term effects of organic fertilization (correction factors for second year after application), Animal-type specific nutrient composition of organic fertilizer, Consideration of organic farming practices, Amount of precipitation during several time periods (e.g. outside vegetation period).
- Soil properties: Mineralized nitrogen content, Soil organic matter, Humus content, Clay content, Soil skeleton, Nutrient content (nutrient supply categories A – E), pH value, Soil depth (shallow to deep), etc. (2009).

For each of those aspects, numerical correction factors are provided for adapting the actual fertilization practice (Flisch et al., 2009). Many of these aspects need to be considered on a broader time horizon, than just one vegetation period. This reveals that the nutrient availability and the uptake of individual crops are not only determined by fertilization activities, taking place after seedbed preparation. Instead, activities taking place months and even years before growing the considered crop, significantly affect the quantity and quality of the respective crop (Flisch et al., 2009). Because this situation applies for all different agricultural crops, one could state, the same error is acceptable for all agricultural crops – but one must acknowledge, each agricultural crop has individually different nutrition requirement profiles.

Besides the removal of crop residues from the field and hereby affected presence of nutrients, many further aspects contribute to crop rotation effects. For example the change of crops help to reduce phytosanitary stress. The use of nutrients from different soil horizons and the improvements in soil structure lead to improved soil fertility and higher yields. These positive effects are plant-specific and have been proven by long-term field experiments.

Even though previously described approaches are suitable for integrating the nutrient shift from one to the succeeding crop into LCA, they fail to integrate the whole range of positive crop rotation effects. Improved phytosanitary conditions, reduced need for agrochemicals and increased yields are not covered at all. Because of their relevance to agricultural practice, we suggest including these effects in the LCA-methodology and propose a respective approach in the next sections.

2. Material and methods

This section contains descriptions of helpful methods for the application of the new approach for including crop rotation effects in agricultural LCAs.

2.1. Systematic description of crop rotations

In order to assess agricultural production systems, containing crop rotations or to carry out calculations with crop rotation elements, a systematic description of the crop rotation might be helpful. Such systematic mathematical representation and classification of crop rotations was carried out by (Castellazzi et al., 2008). General types of crop rotations are fixed rotation, flexible cyclical rotation with fixed rotation length, flexible cyclical rotation with variable rotation length and flexible non-cyclical rotation with variable rotation length; shown in Figure 1.

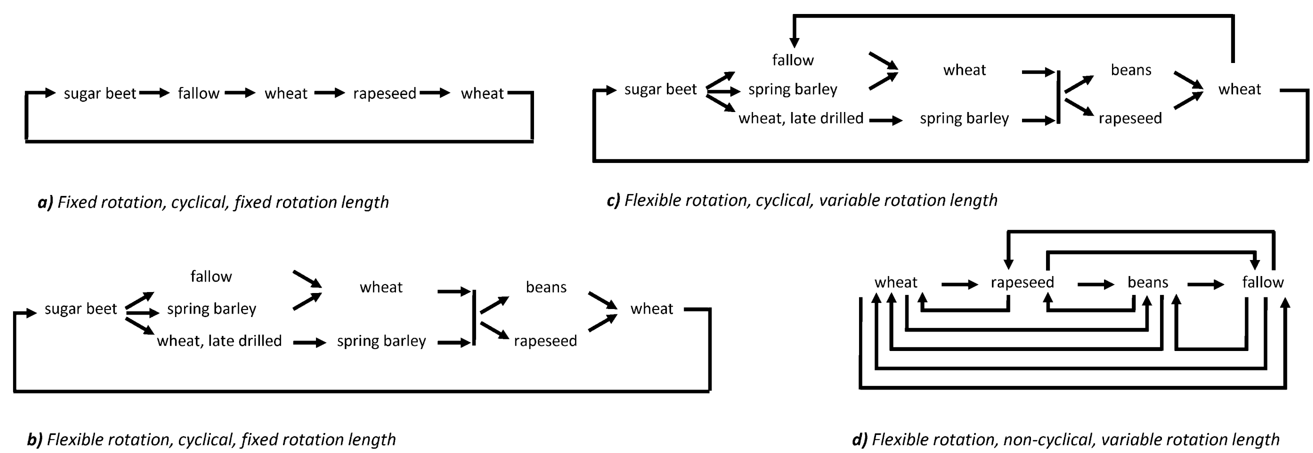

Figure 1. Examples of classified crop rotations; obtained from (Castellazzi et al., 2008)

2.2. By-product allocation approaches and system expansion

Besides a proper systematic description of crop rotations, an appropriate way of allocating environmental burden between various agricultural products and by-products is helpful. Additionally to existing allocation approaches, such as mass allocation (based on mass), energy allocation (based on lower heating value) and economic allocation (based on market prices), a biophysical allocation approach based on the Cereal Unit was proposed by Brankatschk and Finkbeiner (2014). The Cereal Unit allocation is based on the Cereal Unit; it "has been used as common denominator in agricultural statistics for decades ... [and] is valid for vegetable and animal products" (Brankatschk and Finkbeiner, 2014). Cereal Unit conversion factors are used to make all agricultural products and co-products comparable. These factors are calculated mainly based on the nutritional value for animals, because 80% of the agricultural area in the world is used to feed animals (Brankatschk and Finkbeiner, 2014; FAO, 2009).

Well known in the LCA community and recommended by ISO to avoid potential allocation steps, is the product system expansion approach. When applying system expansion, the product system is expanded "to include the additional functions related to the co-products" (ISO 14044, 2006).

In the next section it is described, how the advantages of changing system boundaries, the use of the Cereal Unit allocation and systematic representations of crop rotations can be combined in order to include whole crop rotations into one LCA and hereby automatically consider crop rotation effects.

3. Proposal for a new approach to include crop rotation effects in LCA

Within this section we propose an approach for the inclusion of the previously described crop rotation effects into the inventory analysis of environmental life cycle assessments (according to ISO 14040 and ISO 14044). The presented steps are not meant to be an exhaustive description for performing an LCA. Rather, they shall be understood as supplement to the existing steps in the inventory analysis of an LCA. We would like to emphasize that the below proposed modification of the system boundary is only relevant during the collection of data for the Life Cycle Inventory and not the LCA as such. The overall scope of the LCA, the functional unit and the reference flow of the LCA do not need to be changed.

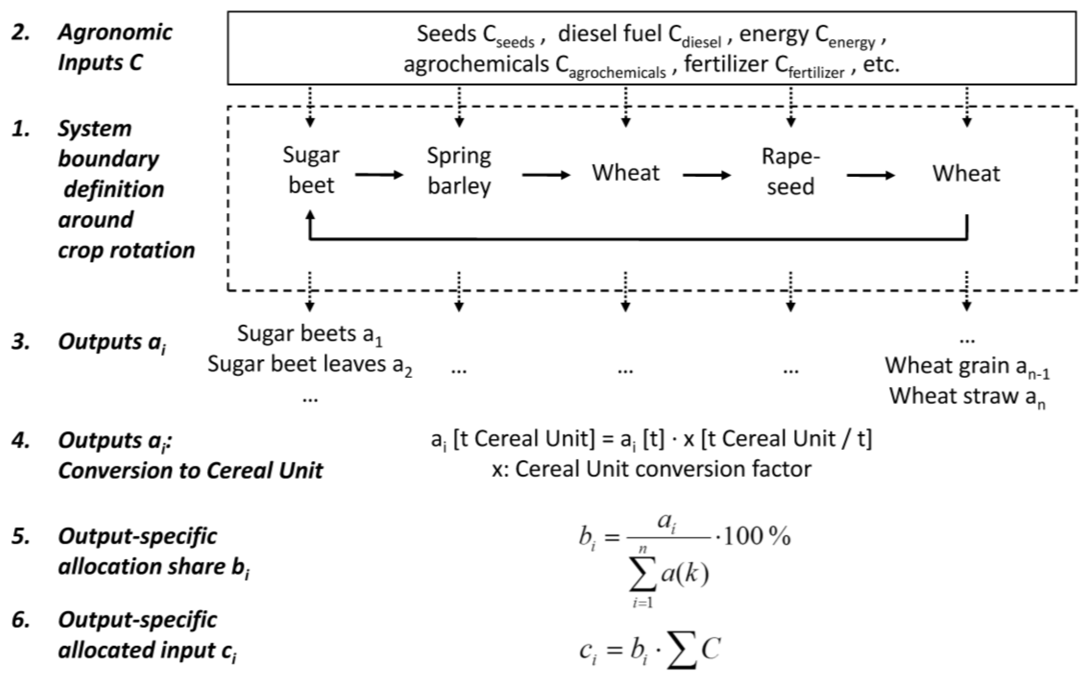

Figure 2. Calculation steps for inclusion of crop rotation effects in LCA inventory analysis

The proposed approach consists of the following steps (see also Figure 2): **First**, the assessed agricultural crop grows in a crop rotation. This crop rotation is identified and a concrete structure of this crop rotation is determined. The system boundary according to ISO 14040 is defined around this crop rotation. Hints for systematic and mathematical descriptions of crop rotations are given in the methods section and in the work from Castellazzi and colleagues (2008); examples are given in Figure 1. **Second**, all agronomic inputs (seed, diesel fuel, energy, agrochemicals, fertilizer, etc.) of the whole crop rotation cycle including all crop rotation elements are quantified. **Third**, all outputs (including products and by-products) of this crop rotation leaving the agricultural field are considered. **Fourth**, the units of all agricultural outputs are converted from metric tons into Cereal Unit tons. Necessary Cereal Unit conversion factors are available in several publications (BMELV, 2012; Brankatschk and Finkbeiner, 2014; Mönking et al., 2010). **Fifth**, allocation factors are calculated for all agricultural outputs of the whole crop rotation, using the amounts given in Cereal Units. Plausibility check: the sum of all allocation factors end up in unity or 100 %, respectively. **Sixth**, using the allocation shares, calculated in step five, the sum of each agricultural input (seed, diesel fuel, energy, agrochemicals, fertilizer, etc.) is allocated between all individual agricultural outputs.

As a result, the LCA practitioner obtains for each output a specific set of necessary inputs. Next steps of the LCA take place using these results. Further LCA steps are not affected by this approach.

4. Discussion

In current LCA practice, crop rotation effects are only partly included, because it is hardly feasible to quantify such crop rotation effects, e.g. it is enormously sophisticated to measure each nutrient flow in the soil – such data are not easily accessible and typically gathered in field experiments over decades. LCA today assesses each crop individually and not infrequently ignores these crop rotation effects, even though they are crucial for maintaining soil fertility and therefore are relevant for the sustainability of the whole system. Towards a solution for the consideration of these “hidden” nutrient flows and further hardly quantifiable crop sequence effects, we suggest a supplementation to the LCA methodology by adding an additional calculation step for the inclusion of the crop rotation effects into the Life Cycle Inventory according to ISO (2006). This supplemental approach is suitable for all agricultural LCAs and takes into account all inputs and all outputs of the crop rotation and thus includes as well inter-crop relations.

Within recent LCA-practice it is not obligatory to consider nutrient shifts from one to the subsequent crop. Hereby the fertilizing efforts are attributed to solely one crop of one vegetation period. This leads to free-rider situations for crops that consume nutrients, left by the previous crop on the field (e.g. by crop residues). In that sense, such crops do not get charged for their real nutrient-consumption, because they participate in the fertilization of the previous crop and subsequently other crops within the crop rotation carry more environmental load, than physically true. In other words, if LCA is performed for one individual crop, this crop automatically either enjoys the benefits or suffers the load of being part in a crop rotation. In this context it is worth to mention, that especially crops, leaving high amounts of nutrients in the soil might be systematically disadvantaged. This is the case, if the full amount of fertilizers, applied within their vegetation period, is accounted to them, even if they do not consume the full amount themselves and parts of their nutrients are transferred to the successor crop via their crop residues. By applying an adaption of the system boundaries to the crop rotation level, free-rider phenomena for nutrient-receiving crops and systematic disadvantages of nutrient-lending crops, can be avoided. Furthermore incentives are set for the inclusion of crops that perform nitrogen fixation into the crop rotation, because all crop rotation elements share the resulting environmental benefits.

The new approach for including crop rotation effects changes the system boundaries. Hereby all crop rotation elements and thus resulting crop rotation effects automatically are included in the LCA. This works, because nutrient flows between crop rotation elements do not cross anymore unconsidered any system boundary. Because the succeeding crop as well belongs to the same crop rotation and thus the nutrients remain inside the system boundary, their positive effect to the succeeding crop is considered. Those positive effects are not restricted to the immediately succeeding crop. As well improved conditions for further crop rotation elements throughout the whole crop rotation are included, due to the modified system boundary. This is especially relevant for phytosanitary effects that take effects over years and can be hardly directly measured. In case the complete crop rotation is assessed, less use of agrochemicals and improved yields are regarded.

The suggested alignment of the system boundary to the level of crop rotation brings LCA closer to the farmers’ perspective on crop rotation systems and his crop planning. The system boundary alignment leads to an immediate inclusion of all nutrient flows and changes in soil properties between crop rotation elements, without any need for measuring them. Furthermore the suggested method offers new capabilities to LCA to treat crops more fairly, especially for those crops that leave nutrients on the field for the succeeding crop.

The suggested approach also includes the Cereal Unit allocation approach as a relatively new allocation approach. It uses the Cereal Unit as an agriculture-specific biophysical unit that has been developed decades ago for the purpose of agricultural statistics and is being continuously updated and still used today in Germany. The Cereal Unit is mainly based on the feeding value of each agricultural product and via side calculation it is able to include even products, not directly fed to animals. By expressing all agricultural outputs of the inventory analysis in the same unit, they become comparable and computable. The Cereal Unit introduces by a common denominator to all agricultural products a comparability and computability for different agricultural outputs (Brankatschk and Finkbeiner, 2014). This allows allocating all agronomic inputs of the complete crop rotation to each individual agricultural output – independently if the output is vegetable or animal origin. In that sense it is a combination of system boundary alignment and biophysical allocation that allows a more realistic picture of agricultural coherences.

Even though changes in the system boundary are well known in LCA practice, they are not widely used in LCAs for agricultural systems. We see reason for that in the vast number of different outputs of one single system and enormous effort for handling so many diverging outputs. This is particularly the case when product-specific LCAs shall be done. The series of different agricultural products seems to be incomparable at the first glance. But the Cereal Unit as biophysical unit, that is suitable to depict all agricultural products and co-products, provides a powerful instrument to shoulder this task. The Cereal Unit allows sorting the number of different agricultural outputs – it makes different agricultural products and co-products comparable to each other and introduces computability. This serves as basis for an agricultural specific allocation approach. Within the Life Cycle Inventory, the Cereal Unit allocation approach is used to allocate all inputs uniformly to the individual outputs. Hereby, agricultural inputs that are applied in the vegetation period, but not used by the crop that was grown in the same time period to produce agricultural fruits, can be more fairly attributed to the overall crop rotation. The crop rotation elements that might be currently regarded as single players can be – by using this new approach – considered as team players and as well their interactions are taken into account.

5. Conclusion

A new methodology was proposed to supplement the established LCA methodology according to ISO 14040 series. A combination of aligning system boundaries in order to consider the whole crop rotation and the relationships between its elements and the Cereal Unit as basis for the allocation of the inputs to the individual outputs was considered to be appropriate. The new method allows to depict the agricultural system in appropriate time frames and includes fundamental agricultural coherences like crop rotation effects into the LCA methodology. Given examples were proven by agricultural coherences, that are scientifically described since hundreds of years and observed by humans since thousands of years, leading to recent agricultural production systems.

The presented method is a straightforward methodology to integrate whole crop rotations in agricultural LCAs, including crop sequence effects and establishing a performance-oriented allocation of environmental interventions to all agricultural outputs of the crop rotation. This new approach helps LCA models to draw a more realistic picture of agricultural reality and thus might lead to more credible results. The recommendations for agricultural systems derived thereof become more robust and help aiming the target of sustainable development.

ABSTRACT

Packaging preserves food quality and safety, but can determine a relevant part of the environmental impact associated with food consumption. A vegetarian burger has been selected as case study to evaluate, through LCA, the environmental performance of a food product packed with novel biobased polybutylene succinate (PBS), in comparison with traditional fossil based packaging (mainly polypropylene). The use of PBS instead of conventional plastics in primary packaging would still increase the environmental impact of the vegetarian burger. These results should, however, be considered in perspective: biobased PBS is in an early stage of development, and far from full industrial scale. Moreover, some first results from conservation and shelf life studies indicate that PBS packaging could extend the shelf life of some food products and thus presumably contribute to a reduction of food waste and associated environmental impacts.

Keywords: LCA, biobased PBS, bioplastics, shelf life, vegetarian burger

1. Introduction

Packaging plays a fundamental role in the food industry, allowing to preserve food quality and safety (Williams and Wikström, 2011). On the other hand, packaging production and disposal, in some cases, can determine a relevant share of the environmental impact associated with food consumption, and contributes to generation of waste and depletion of non renewable resources (Marsh and Bugusu, 2007). Many companies and organizations are currently developing and testing different kinds of bioplastics, in order to provide a more environmental friendly solution for packaging (Davis and Song, 2006). The SUCCIPACK project, promoted by the EU through the 7th framework programme, aims to support European industry efforts to introduce biobased polybutylene succinate (PBS) in the food packaging market (www.succipack.eu).

PBS is a semi-crystalline polyester bioplastic with 35-40% crystallinity, melting temperature of 114-115°C, glass transition temperature of -32°C, and similar properties to PET (Song et al., 2011). PBS is synthesized through polycondensation of succinic acid and 1,4-butanediol (BDO) (Rudnik, 2010) and its building blocks can be fossil based or biobased. Most of the PBS currently available on the market are fossil based or only partially biobased (Storz and Vorlop, 2013). Regarding its barrier properties, PBS is more similar to PLA than to polyolefins and can be considered as a middle oxygen barrier, and a middle/poor water barrier. Introducing PBS as a new biobased material in food packaging requires various innovations, such as optimization of its thermomechanical and gas barrier properties. In this context, the SUCCIPACK project aims at formulating entirely biobased PBS that can be flexibly applied in the food packaging sector, developing a bioplastic that is both biobased and biodegradable.

Using biomass resources as raw materials does not automatically guarantee a better environmental performance than fossil resources (Miller et al., 2007), due to, for example, environmental impacts of the agricultural phase or high energy consumption for processing, especially for new developed materials produced in small scale facilities. For this reason, life cycle assessment is applied to assess biobased PBS and PBS packaging solutions in a cradle to grave perspective, in order to avoid environmental trade-offs and contribute to the development of the bioplastic, providing ecodesign feedback through screening LCAs. LCA has allowed to identify the most critical aspects in the synthesis of biobased PBS, and to identify possible improvement options, some of which have been already implemented in the production process.

The focus of the SUCCIPACK project, along with the development of the material, is the introduction of new packaging solutions in the food packaging market; screening LCAs of existing food products have been conducted, in order to evaluate the environmental performance of new packaging solutions in comparison with existing traditional packaging. The study presented here reports the LCA results obtained for a vegetarian organic burger and its packaging; this case study is the first one selected for a more in dept evaluation of the environmental performance of the potential application of PBS packaging materials in the food sector.

2. Methods

2.1. Goal and scope, functional unit and product description

The goal of this study is to quantify the environmental impacts associated with one package of vegetarian burger, comparing its traditional fossil based packaging (baseline solution) with biobased PBS packaging (biobased solution). The attributional modeling approach has been adopted, since the main objectives of the analysis are identification of environmental hotspots and optimization of the product (ecodesign). PBS can be considered a niche product, and therefore is not expected to bring major changes in the market.

The functional unit is 1 package of vegetarian organic burger including its primary (tray, sealing film and cardboard sleeve), secondary (cardboard box) and tertiary (pallet and plastic film) packaging.

One unit of vegetarian burger contains 180 g of food product; its ingredients, in descending order of quantity are: seitan, spinach, potato, onion, sunflower oil, wheat flour, potato flakes and formulation for vegetable broth. Primary packaging is composed by a plastic tray sealed with plastic film and wrapped in a color printed white-lined chipboard sleeve. Secondary packaging is a corrugated (single wall) printed cardboard box and contains three units of primary packaging. Tertiary packaging is composed by a europallet wrapped in polyethylene film; each pallet carries 1584 units of primary packaging. The composition and weight of packaging for the two scenarios (baseline and biobased) are reported in Table 1. In the baseline solution the tray is thermoformed while in the biobased solution the tray is produced through injection molding.

Table 1. Packaging composition for one package of vegetarian burger

Packaging element		**Baseline solution**		**Biobased solution**	
		Material	**Weight (g) [a]**	**Material**	**Weight (g) [a]**
Primary	Tray	PP-EVOH-PP	15.2	80% biobased PBS + 20% talc	22.6
	Sealing film	PET-LDPE-EVOH-LDPE	1.7	Biobased PBS	2.1
	Cardboard sleeve	Coated white lined chipboard	17.5	Coated white lined chipboard	17.5
Secondary	Cardboard box	Corrugated board, single wall	17.0	Corrugated board, single wall	17.0
Tertiary	Europallet	Wood	15.8	Wood	15.8
	Film	LDPE	0.3	LDPE	0.3
Total			67.5		75.3

[a] Weight of each packaging element per functional unit.

The weights of biobased PBS packaging elements (tray and film) are calculated supposing that the volume of material employed is the same as in traditional packaging; the total weight is therefore higher for PBS packaging elements, due to a higher density of the materials.

Biobased PBS is synthesized from glucose in three main steps:

1. Fermentation of glucose to succinic acid
2. Hydrogenation of succinic acid to BDO
3. Polymerization (in molten and solid state) of succinic acid and BDO to PBS

PBS production process has been optimized taking into account technical and LCA feedbacks; further improvement of the technology is still possible, since data refer to the pilot scale. The technology currently implemented involves succinic acid production through yeast fermentation; during fermentation, succinic acid is neutralized with a ammonia and recovered through exchange over ionic resins. Sulfuric acid is used for the regeneration of the ion exchange column and ammonium sulfate is produced as co-product. Biobased BDO derives from succinic acid through catalytic hydrogenation and, finally, polymerization of succinic acid and BDO delivers biobased PBS. High molecular weight PBS is needed for most packaging applications; both melt and solid state polymerization are being applied, along with compounding of the material with additives (e.g. talc, PLA, PBSA, etc.), in order to obtain high molecular weight PBS and PBS grades suitable for target applications.

2.2. System boundaries

Vegetarian burger is produced in Italy, while packaging materials are supposed to be produced in Europe; the Italian and UCTE electricity mixes have been used accordingly. The burger has been supposed to be distributed within Italy, therefore packaging disposal reflects the Italian scenario (ISPRA, 2012). Primary data refer to 2011 and 2012.

System boundaries include production of food ingredients and packaging, raw materials, related transports, manufacturing process of food, distribution to retailers and end of life of packaging. Use phase (retail, storage and cooking) and disposal of food waste are excluded from the analysis. Furthermore, the role of packaging in preserving food quality and safety and its influence on food spoilage and loss have been, for the moment, excluded from the analysis, due to lack of data from specific conservation tests. Infrastructures have been excluded as well, except in case of database processes already containing infrastructures. A synthetic overview of system boundaries is reported in Figure 1.

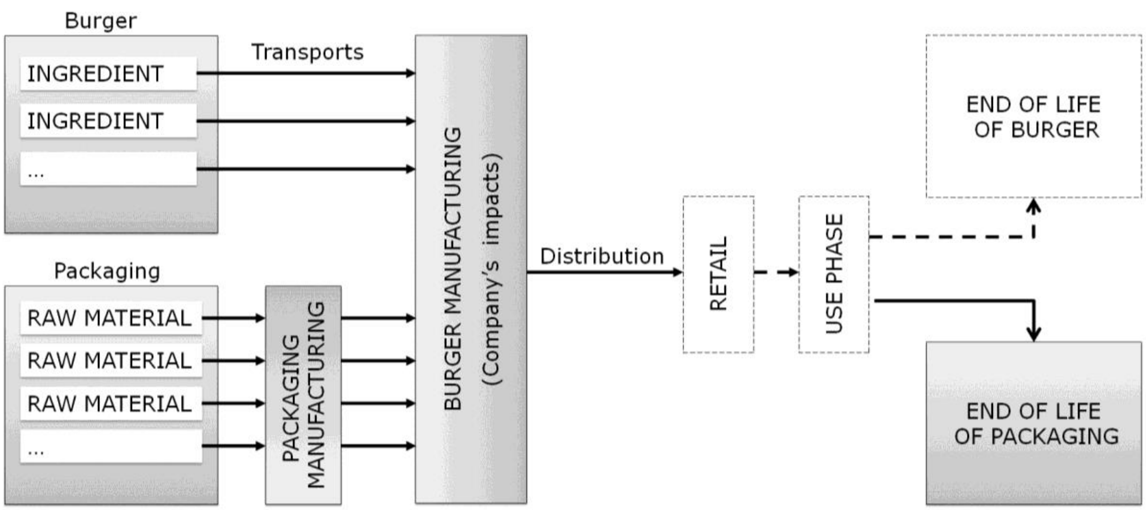

Figure 1.System boundaries. Solid lines: processes included in the system boundaries, dotted lines: processes excluded from the system boundaries.

Concerning biobased PBS granulate, inputs and outputs included in the system boundaries for each processing step are reported in Figure 2. In order to guarantee transparency, atmospheric CO_2 stored in biobased materials has been assessed neutrally, thus no CO_2 credits have been assigned to biobased PBS.

Outputs subject to recycling in the end of life phase (post-consumer), PBS not available for further processing and starch produced during burger's manufacturing, are addressed according to the cut-off approach. Therefore, the environmental impacts of the recycling process are excluded from the system boundaries. Other substances (e.g. water, H_2, N_2) are supposed to be recycled within the PBS granulate manufacturing process.

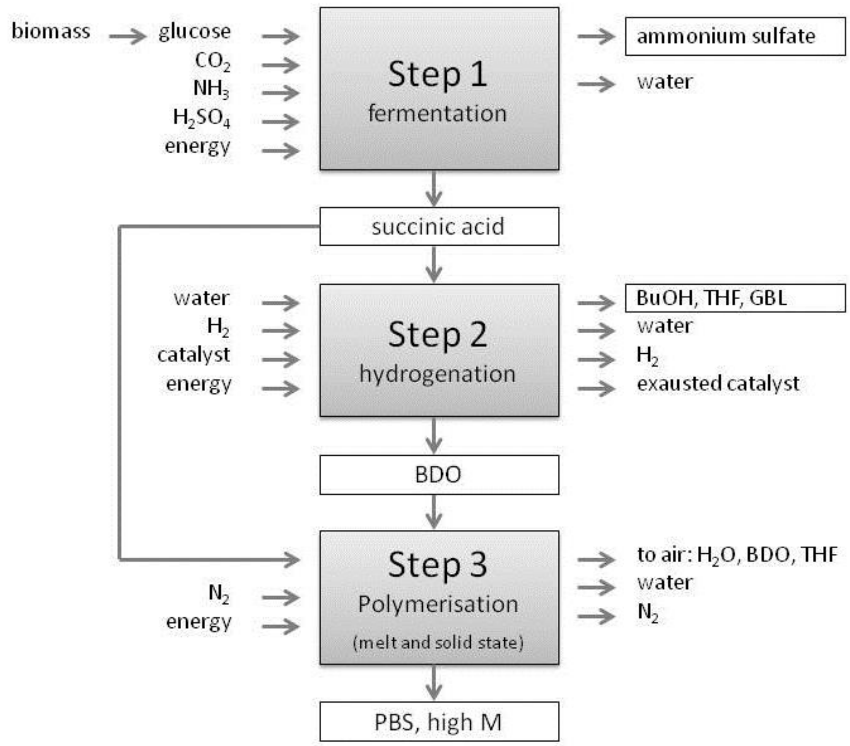

Figure 2. System boundaries: inputs and outputs for biobased PBS production; white boxes: products and co-products

2.3. Data sources and key assumptions

Data on vegetarian burger manufacturing and traditional packaging composition and weight have been provided by the burger's manufacturing company. The main focus of the study is biobased PBS, therefore, while foreground data have been collected from biobased PBS manufacturer, database processes have been used for traditional packaging materials. For the agricultural phase of both food and packaging and for glucose production (from sugar beet), database or literature data have been used (for vegetables: Stoessel et al., 2012). Database processes have been also used for packaging manufacturing (e.g. thermoforming, injection molding, etc.). All database processes derive from the ecoinvent v2.2 database (ecoinvent Centre, 2010). Data not available as foreground data or database information have been approximated; the main assumptions adopted in this study are reported below.

Concerning vegetarian organic burger's ingredients, data referring to organic agriculture have been preferred, while data on Integrated Production (IP) have been used when data on organic farming were not available. LCI data for the production of wheat, potato and sunflower derive from the ecoinvent v2.2 database, while data on vegetables (i.e. spinach, onion) derive from Stoessel et al. (2012). An additional energy consumption has been calculated for frozen ingredients and refrigerated transports, based on Masanet et al. (2008) and Stoessel et al. (2012). It has been assumed that no organic waste, except starch obtained from the manufacturing of seitan, is produced. A transport of 500 km has been assumed for burger distribution.

Data provided by biobased PBS manufacturer are mass balance of main inputs and outputs for the three steps and energy required for the production of succinic acid and melt polymerization. Missing material and energy inputs have been approximated in different ways. Mass of hydrogen and nitrogen required has been calculated based on patent EP 0881203 (Pedersen et al., 2001) and the application of the ideal gas law. Energy required for the hydrogenation step has been supposed to be the same as in the ecoinvent v2.2 process "cyclohexanol, at plant" while cooling energy employed during the polymerization step refers to PET polymerization, as reported by Van Uytvanck et al. (2014). Energy used for solid state polymerization (SSP) refers to an industrial equipment used for the SSP of PET.

In the end of life phase, direct CO_2 and CH_4 emissions deriving from the degradation of plastic materials have been assumed to be of fossil origin for conventional packaging and biogenic for biobased PBS packaging. Waste treatment processes for PBS (e.g. landfilling and incineration) have been created using an ecoinvent tool for the calculation of specific waste datasets (Doka, 2007). According to the carbon neutrality approach, biogenic CO_2 emissions do not contribute to global warming potential.

2.4. Allocation

The recovery of succinic acid from fermentation broth delivers ammonium sulfate as co-product, while the hydrogenation of succinic acid to BDO produces small amounts of n-butanol (4.6% w/w), gamma-butyrolactone (1.6% w/w) and tetrahydofuran (0.3% w/w). In case of BDO, allocation of environmental impacts among co-product has been based on physical relationship (mass), whereas for succinic acid and ammonium sulfate, due to the relatively great amount of ammonium sulfate produced (0.56 kg of ammonium sulfate for each kg of succinic acid), and the remarkable difference in price between the two substances, economic allocation has been applied, assigning 98.6 % of the environmental burden to succinic acid and 1.4% to ammonium sulfate.

For vegetable burger production, being impossible to retrieve data for specific production lines (various food products are produced in the same facility), total energy and water consumption, and waste production of the company (company's impacts) have been allocated to vegetable burger based on its economic value with respect to the overall turnover.

2.5. Life Cycle Impact assessment methods

The methods employed to carry out LCIA are CML baseline v3.01 (Guinée et al., 2002) integrated with the impact category "Land competition" (Guinée et al., 2002) and the method ReCiPe Endpoint H/A v1.10 (Goedkoop et al., 2012). Both methods comprise a set of indicators potentially useful when considering agricultural processes (e.g. euthrophication, human toxicity, ecotoxicity, land use) and allow the normalization of the results. It has been decided to apply one midpoint and one endpoint method, in order to gain a broader overview of the environmental impacts related to the product under study. ReCiPe endpoint, in particular, is applied because it provides a single score indicator, that gives an overall synthetic estimation of the environmental performance of the product. All calculations have been performed with the software SimaPro 8.0.3.

3. Results

The results obtained for the vegetarian burger for the baseline and biobased scenarios are reported in Table 2 and Figure 3 (method CML, characterization). Each impact category has been split into different aspects of the life cycle, in order to identify which processes give the most relevant contribution to the overall environmental impact. The parts of the life cycle selected are: burger ingredients, including transport to burger's production facility; company's impacts, allocated as previously explained; refrigerated distribution; packaging manufacturing, further subdivided into 1^{ry}, 2^{ry} and 3^{ry} packaging and, finally, packaging disposal.

Table 2. Impact assessment of one package of vegetable burger, for 180 grams of food including its packaging. Method CML, characterization.

Impact category	Unit	Biobased solution	Baseline solution
Abiotic depletion	mg Sb eq	0.829	0.676
Abiotic depletion (fossil fuels)	MJ	10.3	8.73
Global warming (GWP100a)	kg CO_2 eq	0.794	0.672
Ozone layer depletion (ODP)	mg CFC-11 eq	0.094	0.061
Human toxicity	kg 1,4-DB eq	0.172	0.111
Fresh water aquatic ecotox.	kg 1,4-DB eq	0.171	0.124
Marine aquatic ecotoxicity	kg 1,4-DB eq	402	262
Terrestrial ecotoxicity	g 1,4-DB eq	1.49	1.22
Photochemical oxidation	g C_2H_4 eq	0.131	0.105
Acidification	g SO_2 eq	5.93	5.24
Eutrophication	g PO^{3-}eq	4.58	4.02
Land competition	m^2a	0.591	0.561

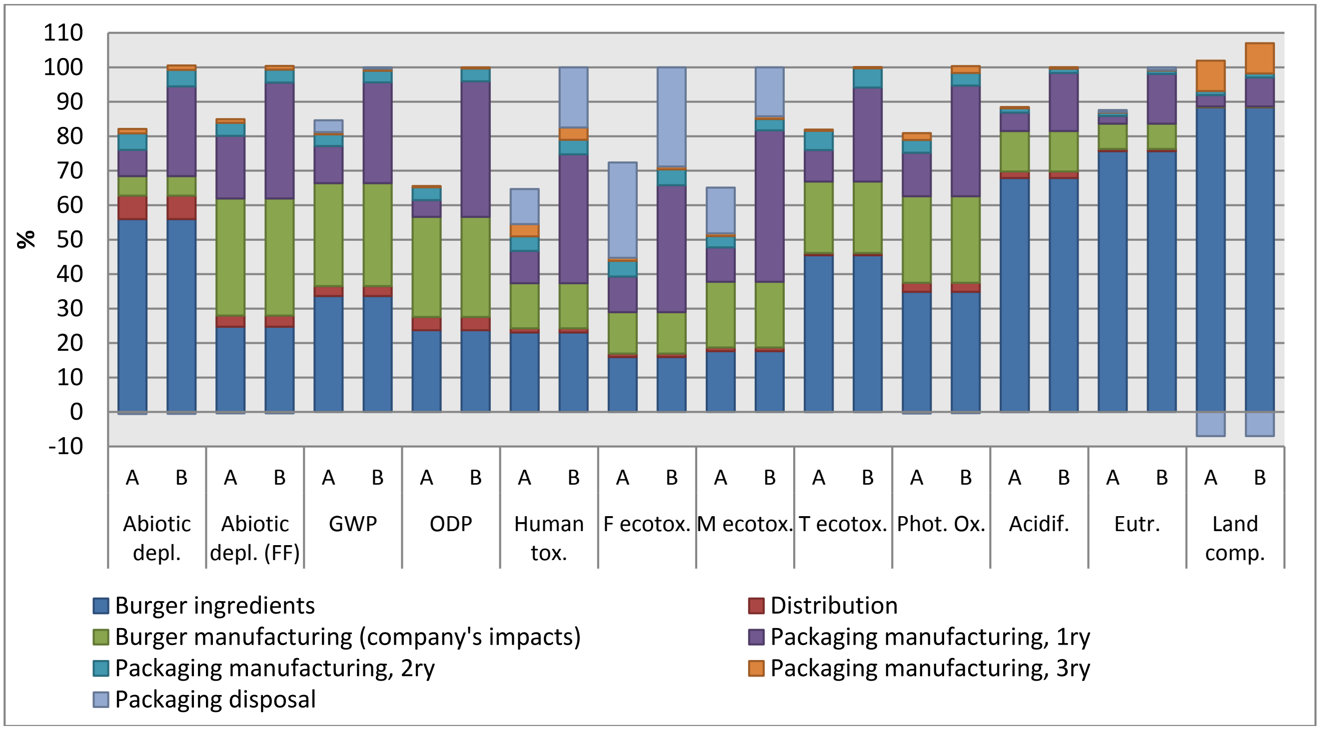

Figure 3. Impact assessment of vegetable burger. A = baseline scenario; B = biobased scenario; method CML, characterization. (FF= Fossil Fuels; ODP = Ozone Layer Depletion; F = Freshwater; M = Marine; T = Terrestrial).

Alternative B (biobased scenario) has higher impacts than alternative A (baseline scenario) for all impact categories considered. The difference between the two scenarios is among 5 % (land competition) and 35 % (human toxicity and marine ecotoxicity). As can be expected, the impact categories that vary most are those with a high contribution of packaging, namely, ozone layer depletion, human toxicity, freshwater ecotoxicity, and marine ecotoxicity. These variations are mainly due to substances emitted in relation to the manufacturing of biobased PBS, for instance, ozone depletion is connected, in particular, to the production of heat, electricity, ammonia and glucose; human toxicity to electricity and liquid carbon dioxide; freshwater and marine ecotoxicity to electricity.

It should be noticed that, since the carbon neutrality approach has been adopted, the LCI model does not account for absorption of atmospheric CO_2 in biobased materials. According to the stoichiometry of the monomer, the CO_2 embedded in biobased PBS is around 2 kg/kg of PBS. Therefore, for each package of spinach burger, approximately 40 g of CO_2 are absorbed from the atmosphere and embedded in biobased plastics (cradle to gate). Some of the carbon absorbed is released in the end of life of packaging; according to the assumptions and waste scenario adopted, biobased packaging disposal releases around 23,1 g of biogenic CO_2 and 16 mg of biogenic CH_4, with a net carbon sequestration of approximately 16.5 g CO_2 per package.

The contribution of food (including distribution) to each impact category varies among 29% (freshwater ecotoxicity, biobased scenario) and 95% (eutrophication, baseline scenario). Concerning the food product, the phases of the life cycle with the highest contributions are burger’s ingredients and company’s impacts, while distribution is less relevant. Burger’s ingredients are particularly important for the impact categories land competition, acidification, eutrophication and terrestrial ecotoxicity, mainly due to the agricultural phase of the life cycle; in case of abiotic depletion, transports give the most relevant contribution.

Concerning packaging, its manufacturing, and in particular the manufacturing of 1^{ry} packaging, has higher impacts than packaging disposal for most impact categories. The negative values in the graph (positive impacts) are due to the reuse of pallets.

The characterization results (not shown) obtained with the method ReCiPe endpoint H/A lead to similar considerations. The ReCiPe characterization results, normalized with respect to the European average, are reported in Figure 4. The impact categories with the highest values after normalization are fossil depletion (FD), agricultural land occupation (ALO), climate change (effects on human health CC/HH and on ecosystems CC/E) and particulate matter formation.

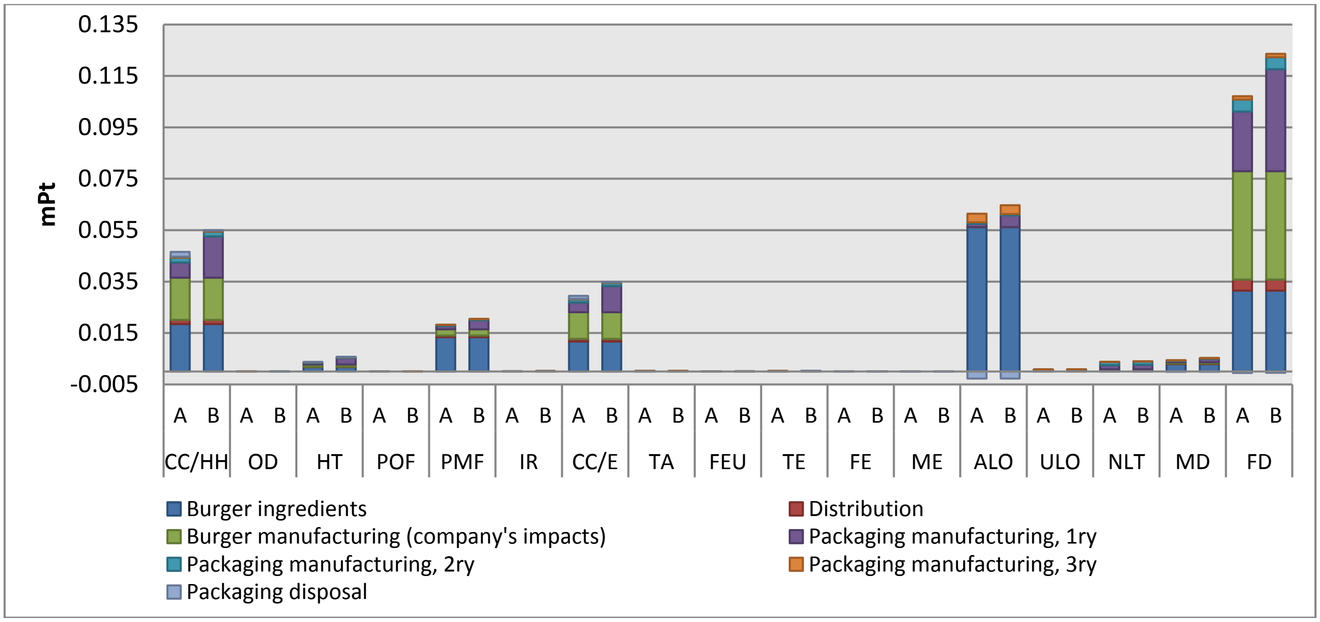

Figure 4. Impact assessment of vegetable burger. A = baseline scenario; B = biobased scenario; method ReCiPe endpoint H/A, normalization.

(CC/HH = Climate Change Human Health; CC/E = Climate Change Ecosystems; OD = Ozone Depletion; TA = Terrestrial Acidification; FEU = Freshwater eutrophication; HT = Human toxicity; POF = Photochemical oxidant formation; PMF = Particulate matter formation; TE = Terrestrial ecotoxicity; FE = Freshwater ecotoxicity; ME = Marine ecotoxicity; IR = Ionising radiation; ALO = Agricultural land occupation; ULO = Urban land occupation; NLT = Natural land transformation; MD = Metal depletion; FD = Fossil depletion).

The ReCiPe single scores values are reported in Figure 5. The biobased solution has a higher single score than the baseline solution (14%), consistently with the results previously outlined for the CML method. The food product (including distribution), has a contribution of 82% in the baseline scenario and 72% in the biobased scenario. For both scenarios, burger's ingredients give the largest contribution to the total score, followed by company's impacts and manufacturing of primary packaging. The impact categories that give the most relevant contributions to the single score indicator in the case of traditional packaging are agricultural land occupation (27%), fossil depletion (24.5%) and climate change (21.4% human health; 13.6% ecosystems), while for the biobased solution the most relevant impact category is agricultural land occupation (25%; mainly due to the agricultural phases of burger and packaging), followed by fossil depletion (24.9%) and climate change (22.2% human health; 14.1% ecosystems).

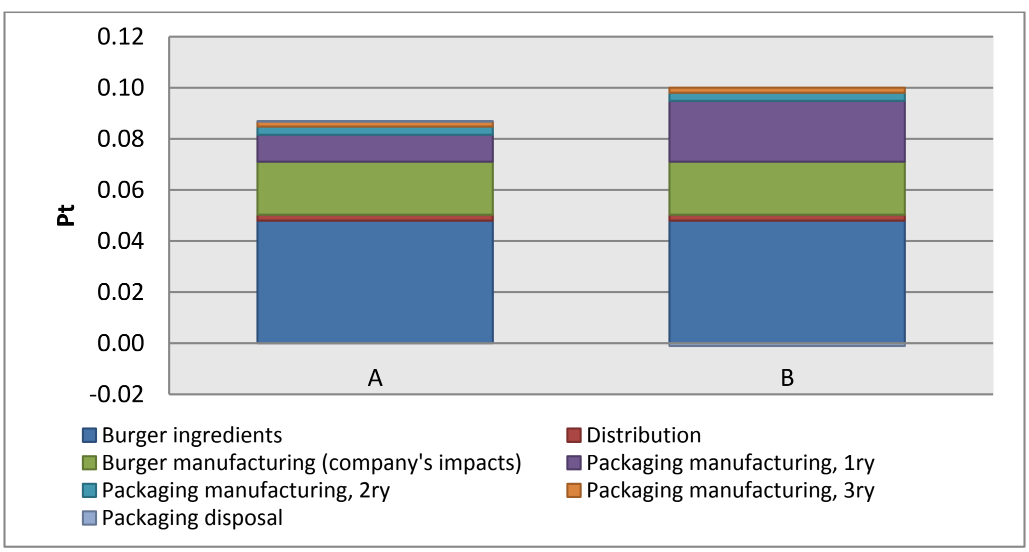

Figure 5. Impact assessment of vegetable burger. A = baseline scenario; B = biobased scenario; method ReCiPe endpoint H/A, single score.

4. Discussion

At the current scale of production (pilot scale) and state of development of the technology, the projected use of novel biobased PBS packaging in comparison to traditional fossil based packaging would increase the environmental impact of the packed vegetable burger. Currently, biobased PBS environmental impacts are higher than the ones of traditional packaging and according to the assumptions adopted a higher amount of biobased material is needed for the same amount of packed food. The environmental impacts of biobased PBS are mainly related to succinic acid production, since succinic acid is used to produce both BDO and biobased PBS. In particular, the technology currently applied for succinic acid synthesis through fermentation has a relatively high energy consumption (32 MJ/kg succinic acid). According to Cok et al. (2014), allocation of environmental burden among succinic acid and ammonium sulfate can be also relevant, economic allocation being the most conservative allocation choice, and therefore, the one with the highest overall environmental impact attributed to biobased PBS.

Another aspect that should not be underestimated in LCA, is the source of database information used; for instance, incomplete LCI (life cycle inventory) datasets could lead to lower environmental impacts than more complete datasets, due to lack of information and not to the actual environmental performance of the product (European Bioplastics, 2012). For example, the ecoinvent v2.2 record for polypropylene (PP is the main material in burger's traditional packaging), is based on inventory data from PlasticsEurope (Hischier R., 2007). These data are highly aggregated and not transparent, and this hampers the identification of possible inconsistencies between LCI and LCIA of PP and PBS.

Moreover, in the case study considered, the difference between the two packaging solutions is more evident than it would be in other applications, since the environmental impact of the vegetable burger (excluding packaging) is relatively low (i.e. GWP 2.9 kg CO_2 eq/kg) and, therefore, the packaging plays a more important role in determining the overall environmental impact.

Whereas traditional plastics are produced through well established and mature technology on industrial scale, entirely biobased PBS is in an early stage of development, and far from full industrial scale, and its environmental performance could improve moving from pilot scale to industrial scale. The main aspects to be considered in order to improve the environmental performance of biobased PBS are the energy required for the synthesis of succinic acid and the yield of the polymerization phase (e.g. reduction of the amount of PBS not available for further processing). In particular, concerning succinic acid production, alternative synthetic routes could be tested. For instance, in the analysis reported by Cok et al. (2014), succinic acid produced through low pH yeast-based fermentation followed by direct crystallization seems to have lower environmental impacts compared to the technology described in the present paper. Concerning polymerization, it seems that the application of a solid state polymerization phase in combination with melt oligomerization could reduce the environmental impact of biobased PBS in comparison to the application of melt polymerization. The applicability of this option is currently being evaluated in order to identify the most efficient solution.

Concerning the whole system (food product + packaging solution), the implementation of some improvement actions could reduce the overall environmental impact. The impact of primary packaging could be reduced by lowering its weight, especially in the case of biobased packaging. The cardboard sleeve, that is present for aesthetic reasons, could be eliminated and substituted, for instance, with a label, or its dimension could be reduced. Other aspects are the reduction of fossil energy employed by burger's manufacturing company and the use of fresh and local ingredients that would decrease the need for refrigerated long distance transports.

One of the main roles of packaging is to preserve food, reducing food spoilage and food waste. This aspect was not yet considered in the present study, but the effects of food loss on the overall environmental impact of the vegetarian burger will be the subject for further evaluations. In particular, some first results from conservation and shelf life studies indicate that PBS packaging could extend the shelf life of some food products and thus presumably contribute to a reduction of food waste and associated environmental impacts. LCA analyses of packaging solutions, therefore, should be focused not only on packaging reduction, but also on enhancing packaging's ability to preserve food and reduce food waste; in some cases, an increase of the environmental impact of packaging could be necessary in order to improve the overall environmental performance of the system, if food loss is included in the system boundaries (Williams and Wikström, 2011).

5. Conclusion

In this case study, LCA has been applied to an existing food product in order to evaluate its environmental impacts and to assess the potential outcomes of the introduction of new biobased PBS packaging materials in the food market. The application of LCA has allowed to identify the critical aspects and improvement options for the vegetarian burger and its packaging, and to provide ecodesign feedback for the development of biobased PBS.

At the current state of development of the technology, the use of biobased PBS instead of conventional fossil based plastics for primary packaging would increase the overall environmental impact of the food product under study. These results should, however, be considered in perspective: while traditional plastics are produced through well established and mature technology, biobased PBS is in an early stage of development, and far from full industrial scale. Moreover, the weight of analyzed PBS packaging is higher than the one of traditional packaging, due to higher density of PBS-based materials. In general, biobased PBS seems to be an interesting material for packaging applications but its environmental performance should be further improved. The increase of the environmental impact of packaging could be justified if this increase could result in a lower rate of food waste, reducing the overall environmental impact of the packaged food product.

ABSTRACT

Australian agricultural industries contribute approximately 14.6% of net annual national greenhouse gas (GHG) emissions, with N_2O emissions from agricultural soils the second greatest source of these emissions. Given that 25 M ha of land in Australia is cropped, the technical potential for GHG emissions reduction in Australian grain production systems is substantial. The New South Wales Department of Primary Industries (NSW DPI) has developed research capacity in Life Cycle Assessment (LCA) to assess this mitigation potential. In this paper we provide insights into the regionally-specific approach that we are taking, not only to provide credible management options at a grain grower level and ensure that detailed data are available for analysis by participants in the downstream supply chain, but also to provide data which, in an aggregated form, will underpin market access and inform national policy development. We report on initial NSW DPI studies and discuss a new project, funded by the Grains Research and Development Corporation (GRDC), to determine emissions reduction opportunities for each of Australia's agro-ecological zones. Initial studies show total emissions from wheat production in the order of 200 kg CO_2-e per tonne, with values ranging down to 140 kg CO_2-e per tonne. In one study, replacing synthetic nitrogenous fertiliser with biologically fixed N reduced emissions to 33% of prior values. The new project is particularly concerned with developing accurate foreground data by triangulating several sources of published literature (including official statistics) and conducting 'ground-truthing' through panels of regionally-based advisors to increase data specificity. The LCAs and associated mitigation strategies will be underpinned by a median and relevant distribution of values for inputs, practices and yields, with system assumptions clearly documented.

Keywords: cropping, grain production, mitigation, agriculture, emissions

1. Introduction

It can be said with 95% certainty that anthropogenic emissions of the greenhouse gases (GHG) CO_2, N_2O and CH_4 are the primary driver of climate change (IPCC 2013). Australian agriculture industries contributed approximately 79.5 Mt CO_2-e or 14.6% of net annual national greenhouse gas (GHG) emissions in 2010, with N_2O emissions from agricultural soils the second greatest source of emissions after those from livestock methane (Australian Government 2013).With approximately 25 M ha of Australian farming land cropped, the technical potential for GHG emissions reductions in grain production systems in Australia is substantial. All industries have a responsibility to contribute to the reduction of emissions to minimise the impacts of climate change, including agriculture.

The application of Life Cycle Assessment (LCA) to agricultural systems is now relatively widespread (Roy *et al*. 2009) and country-specific life cycle inventories are being developed to increase the applicability of LCAs, e.g. The Australian Agricultural Life Cycle Inventory (Eady *et al*. 2013). Australia has considerable intra- and inter-regional variation in landscape and climate, aspects which determine the most profitable functional production unit. This variation, coupled with methodological issues associated with attributing emissions accurately and accounting for the flow-on effects arising as a consequence of recommended practice changes, creates challenges for LCA practitioners. Also, data gaps exist when attempting to apply published regionally-specific Emissions Factors (EFs). In this paper, we discuss existing studies by the NSW Department of Primary Industries (NSW DPI) and a new project, which we will lead, to explore mitigation options for grain production across Australia.

2. Australian cropping systems

Australia is a relatively large landmass, with climatic zones ranging from wet tropics to temperate semi-arid plains (Williams *et al*. 2002). Australia also has high seasonal climatic variability driven in South-eastern Australia by the El Nino - Southern Oscillation and the Indian Ocean Dipole (Cai *et al*. 2011). Grain cropping is a major agricultural land use occupying approximately 25 Mha, with an estimated annual production of approximately 44 Mt (ABARES 2013). The Grains Research and Development Corporation (GRDC) has determined agro-ecological zones for their industry by using a similar framework to Williams *et al*. (2002), who considered climatic, agronomic and ecological factors. The GRDC's agro-ecological zones have been fine-tuned for relevance to regional grain growing systems and the geographical constraints of those systems (Figure 1), providing suitable biophysical boundaries for LCA studies. The GRDC is one of the primary providers of research funding for the Australian grains industry, raising funds through grower levies and federal government co-contributions.

Grains cropping in Australia primarily occurs where rainfall is < 650 mm, although can occur in high (> 650 mm) rainfall areas. Winter crops such as wheat, barley, oats and canola, with smaller areas of legumes (*e.g.* lupins, peas and vetch), are primarily grown in regions with a typical winter dominant rainfall pattern (*i.e.* southern Western Australia (WA), South Australia (SA), some parts of Victoria and southern New South Wales (NSW)) (ABS 2013). Whilst winter grain crops are also grown in northern NSW and southern Queensland (Qld), summer grain crops, such as chickpeas, sorghum and sunflowers are also grown, to capitalise upon high levels of sub-soil moisture during mid-spring and a greater proportion of rainfall in summer. In tropical zones (*e.g.* WA Ord and Central and Far North Qld) sugarcane dominates, with grain crops grown in rotation as a break crop for disease control. Where irrigation is available, systems are modified to meet market demand, with crop production primarily limited by the capital infrastructure of the enterprise.

Australian agriculture is supported by an effective financial assistance of 0.15% of national gross domestic product (GDP), which is relatively small compared to the European Union (0.73%) and the USA (1%) (OECD 2013). Cropping, sheep and cattle enterprises are aggregated for Australian national economic reporting purposes and receive approximately a third of this assistance (Productivity Commission 2013).

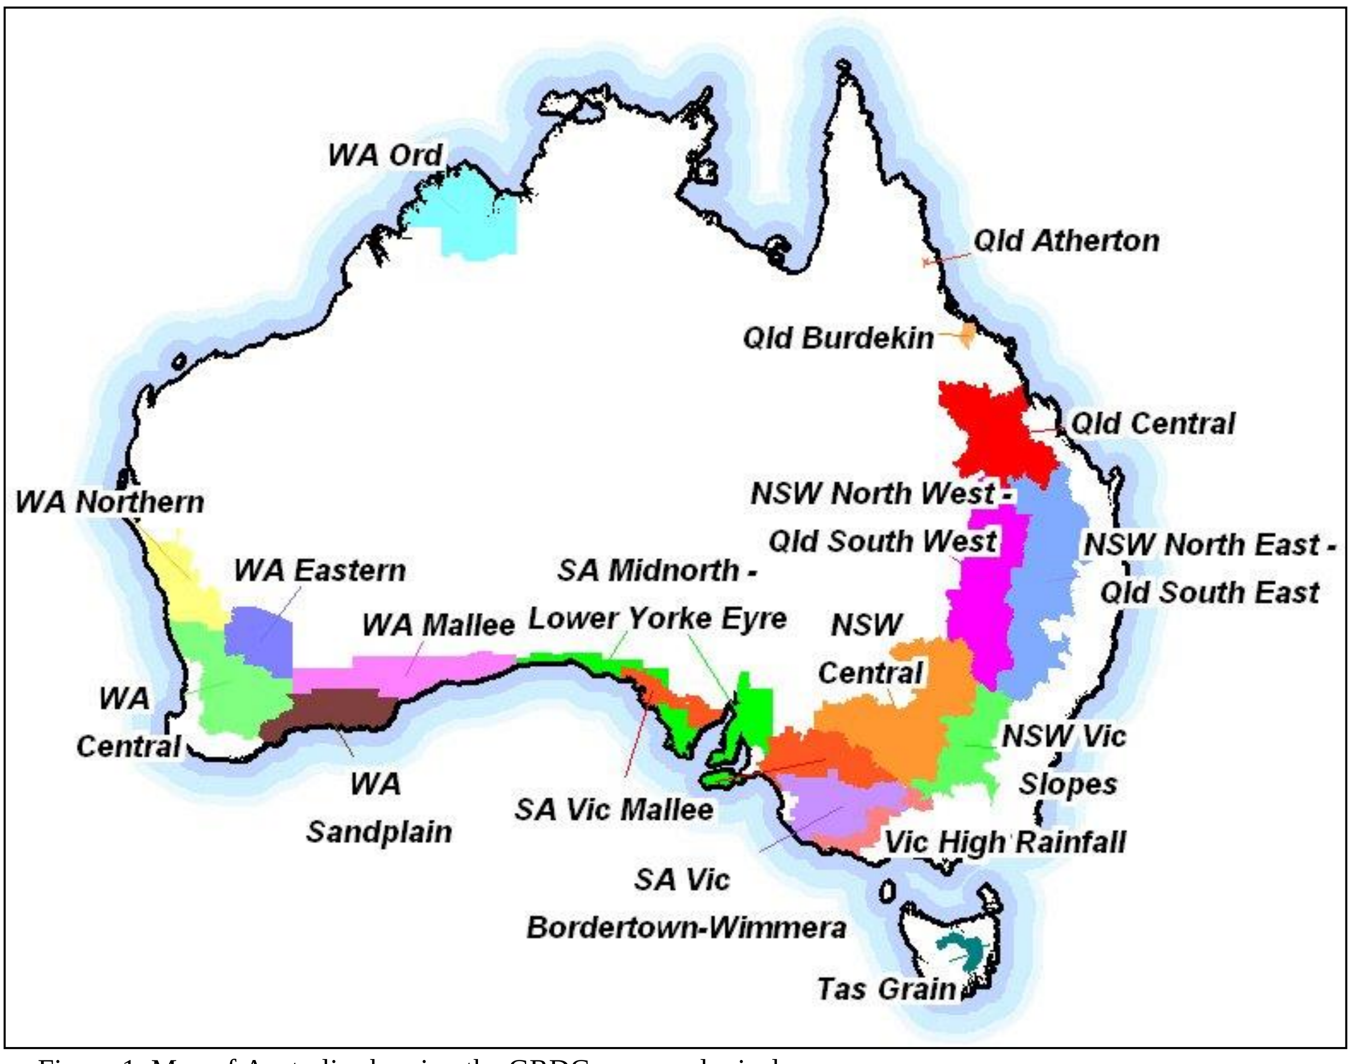

Figure 1. Map of Australia showing the GRDC agro-ecological zones.

The scale of enterprise varies between regions (Table 1) with larger grain growing holdings in WA, compared with other States and Territories of Australia. Scale plays an important role, with larger farms generally more profitable due to economies of scale in purchasing inputs, machinery size and labor costs.

Table 1. Holding area, numbers of holdings and average holding area of cropping properties in the States and Territories of Australia (ABS 2013).

State	Area of holding (ha)	Number of holdings	Average area of holdings (ha)
WA	8 543 799	8 112	1053
SA	4 048 970	9 384	431
NSW	6 931 906	18 069	383
Vic	3 818 961	12 448	306
Qld	2 898 356	11 596	249
Tas	70 581	1 415	49
NT	11 084	238	46

3. Data sources and quality

As with any modeling approach, the quality of input data is a key determinant of the quality of an LCA. In terms of foreground data, LCA research being conducted by NSW DPI takes the approach of triangulating several sources of published literature and then conducting ‘ground-truthing’ with advisors, primarily agronomists and economists. Official statistics, such as from ABS (2013) and ABARE (2013) are included, for attributes for which they are available, along with State-specific official crop statistics reports which provide total tonnages aligned with area sown. However, these data are often not collected at a sufficiently fine scale, do not cover all attributes necessary to conduct LCA and do not universally provide enterprise-specific ranges to enable sensitivity testing. Another key source of data has been annual gross margins, published by NSW DPI, which forecast yield and profit for given inputs and management actions. However, modifications to these data have also been necessary to account for long-term trends.

A new project, funded by GRDC, has a specific budget allowance for panels of regionally-based advisors to fine-tune data and by involving them in the LCA process, they will be well informed to extend findings to their grain grower clients. These advisors have a large client base with approximately half of all grain growers employing advisors in some areas. We are confident that their client data and production knowledge is strongly representative of common practice. Regionally-specific data will be made available for attributes such as the quantities of fertilizer, diesel and herbicide used. The LCAs and associated mitigation strategies will be underpinned by a median and relevant distribution of values for inputs, practices and yields, with system assumptions clearly documented. Sensitivity analysis is then conducted and individual attributes which show significant variation, due to biophysical or management differences, further investigated. For example, we are currently testing the effect of different assumptions about tractor engine capacity, source of inputs, such as herbicides, and use of lime and fertiliser. Whilst larger engines consume more diesel, they enable faster completion of farm practices. Also, biophysical modelling could be beneficial to account for differences in denitrification for a given quantity of N applied, in a specific climatic zone, on different soil types. The degree of interdependence varies between attributes, so we have tested variables independently across a representative range and then discussed linkages.

Emissions from biological processes within agricultural systems have been calculated using EFs obtained preferentially from published field measurements (Schwenke *et al*. 2012), then tier 2 data e.g. from the National Inventory Report (Australian Government 2013) and then tier 1 data (Eggleston *et al*. 2006). The approach of adopting published data where they are more specific than default EFs is consistent with the National Inventory Report (Australian Government 2013). However, Australian coverage of data from published field measurement is not complete, so where emission reduction strategies are being tested through comparative LCA, some standardisation of factors is necessary. Background emissions data about the manufacture and transport of agricultural inputs have been preferentially sourced from the Australasian LCI database (Life Cycle Strategies Pty Ltd 2013) which has been adjusted for Australian conditions, followed by data from Ecoinvent (Hischier *et al*. 2009).

4. The application of LCA to Australian cropping systems

Several LCA studies have been completed for cropping systems in the State of NSW, *e.g.* Brock *et al*. (2012a). Some of these studies and a new funded project are discussed below.

4.1. Aims

The purpose of NSW DPI's LCA studies is to develop an understanding of the various components of emissions profiles for a given functional unit and through comparative LCA, identify practice changes that will target emissions reduction hotspots. For example, the substantial contribution of emissions from both manufacture and use synthetic nitrogenous fertilisers led to testing of the effects of supplying crop N requirements from biologically-fixed N (Brock *et al*. 2012b), resulting in emissions reduction to 33% of prior values.

4.2. Methods

Cradle-to-gate attributional LCAs for wheat production in Central Zone (East) NSW (Brock *et al*. 2012a), and wheat-wheat, canola-wheat and chickpea-wheat rotations in North-East (NE) NSW and North-West (NW) NSW (Muir *et al* 2013), have been developed using SimaPro v7.3.3 (Goedkoop *et al*. 2008). Input data were sourced as per Section 3 above. Pre-farm emissions data were included for the production and transport of all inputs, with the exception of wetting agents, as their contribution to overall emissions profiles were considered to be negligible. On-farm, direct N_2O emissions from the use of synthetic nitrogenous fertilizers were included, as were indirect emissions from the re-deposition of volatilized N as NH_3. N_2O from leaching and runoff of nitrogenous fertilisers were not included as these processes were deemed not to occur, due to soil type and climate, for consistency with the National Inventory Report (NIR) (Australian Government 2013). Direct CO_2 emissions from the hydrolysis of urea were included, as were CO_2 emissions from the dissolution of lime.

Whilst emissions from herbicides used during the pre-crop fallow were included, N_2O and CH_4 emissions from the decomposition of stubble were only included post-crop, as this is when they are attributable to the functional unit. However, residue emissions were excluded where they could result in double-counting with experimental field chamber data, with field-based N_2O EF as high as 0.45%, compared to the current Australian default value of 0.3%. Following our decision rule (consistent with the NIR), to adopt local published values, ahead of NIR data, ahead of IPCC data, it will be necessary to include low EF values obtained from soil with a low clay content in WA, in the future work discussed in Section 4.4 of this paper.

Given that consideration is being given to lowering the Australian default value of 0.3%, for WA or on a wider basis, the 0.3% value is a better estimate for Australia than the 1% IPCC default value. The 0.3% value is in between the 0.45% that has been adopted for some existing studies in NSW and a lower value that will be included for future studies for WA, so will provide a useful standardised value if we wish to hold this attribute constant during comparison of other variables. However, if the next NIR (Australian Government) includes a lower value for Australia, then we will adjust our assumptions accordingly. Stubble burning is not considered common practice in these regions, so was also excluded. All above- and below-ground sequestered carbon (C), remaining after harvest, was considered to be re-emitted through decomposition of crop residues, with soil C flux in a steady state. Emissions from combustion of diesel in tractors for cultivation, sowing and spraying of farm chemicals were included, as were emissions from harvesting and on-farm cartage.

4.3. Results

The emission intensity for one tonne of wheat grown in Central Zone (East) NSW and yielding 3.5 t ha^{-1}, was calculated as 200 kg CO_2-e (Brock *et al*. 2012a). The largest contributors to emissions were the production of fertilizer and lime, and N_2O and CO_2 emissions from these inputs (Figure 2). Opportunities to modify the emissions profile through changes to inputs and practices were discussed, ranging from improved fertiliser management to replacing cultivation with herbicide application.

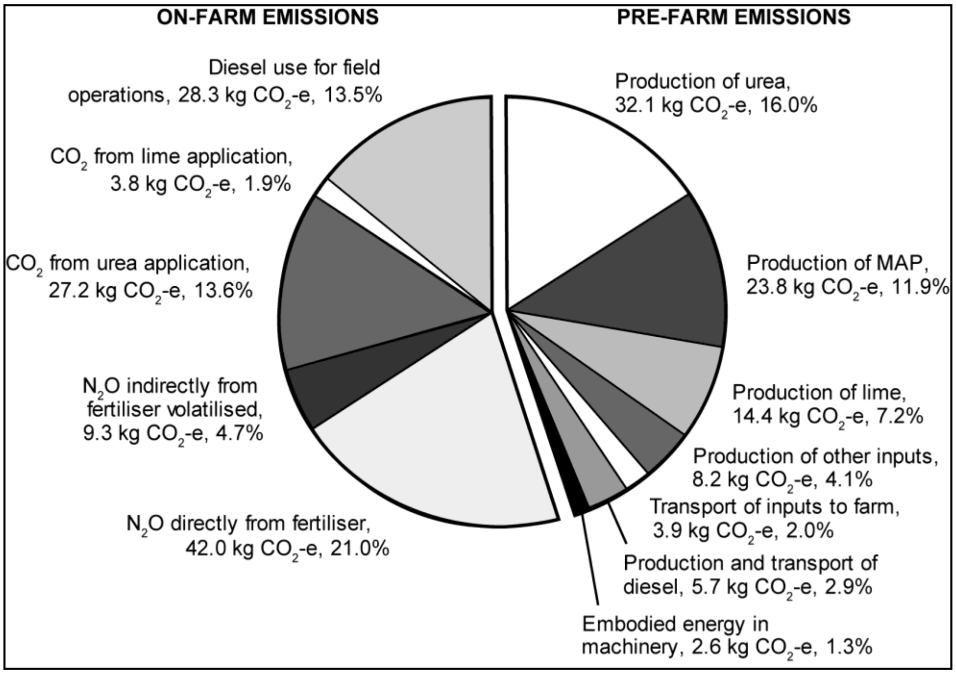

Figure 2. On-farm and pre-farm GHG emissions (CO_2-e) for a tonne of wheat from cradle-to-gate in Central Zone (East) NSW.

Similar studies by NSW DPI, funded by the GRDC (Muir *et al*. 2013), have provided estimated emissions intensities of short fallow wheat production in North East (NE) NSW following wheat (at 218.9 kg CO_2-e), following canola (at 185.3 kg CO_2-e) and following chickpea (at 139.1 kg CO_2-e per tonne of wheat), with 130, 130 and 80 kg N ha^{-1}, respectively. A tonne of wheat grown after chickpeas had an intensity that was approximately 80 kg CO_2-e lower than that grown after wheat. These reductions were primarily driven by the lower quantity of synthetic nitrogenous fertiliser applied (Figure 3). Similar impacts were found for the North West (NW) NSW where a tonne of short fallow wheat grown after chickpeas (at 140.7 kg CO_2-e) was calculated to have an emissions intensity that was approximately 50 kg CO_2-e lower than wheat grown after a wheat crop (at 192.5 kg CO_2-e) (Figure 4). The reduction of emissions intensity of approximately 30 kg CO_2-e/t for wheat following canola for both districts was the result of higher crop yields, given the same fertiliser inputs as wheat following wheat, with a total for one tonne of wheat following canola in NW NSW of 166.1 kg CO_2-e.

When long fallow wheat after sorghum was considered for NE NSW, emissions were found to be 143.4 kg CO_2-e per tonne of wheat (Muir *et al*. 2014a). These emissions are similar to wheat from short fallow after chickpeas but, despite 106 kg N/ha applied, the emissions intensity was much reduced by the higher yield (3.5 t/ha) obtained, compared with 3 t/ha in the short fallow. Emissions were 139 CO_2-e/t for long fallow wheat grown in more arid NW NSW and planted with a total of 32 kg N/ha (Muir *et al*. 2014b). Again a combination of lower N fertiliser application and greater grain yield of 2.4 t/ha reduced the emissions intensity compared with short fallow wheat (1.7-2 t/ha). LCAs are currently being finalised for the pre-crop, grown in rotation with the cereal, and as the product is usually marketed for human consumption, rather than used within the same production system, its emissions profile will be reported separately. This approach is discussed further in Section 5.1 below.

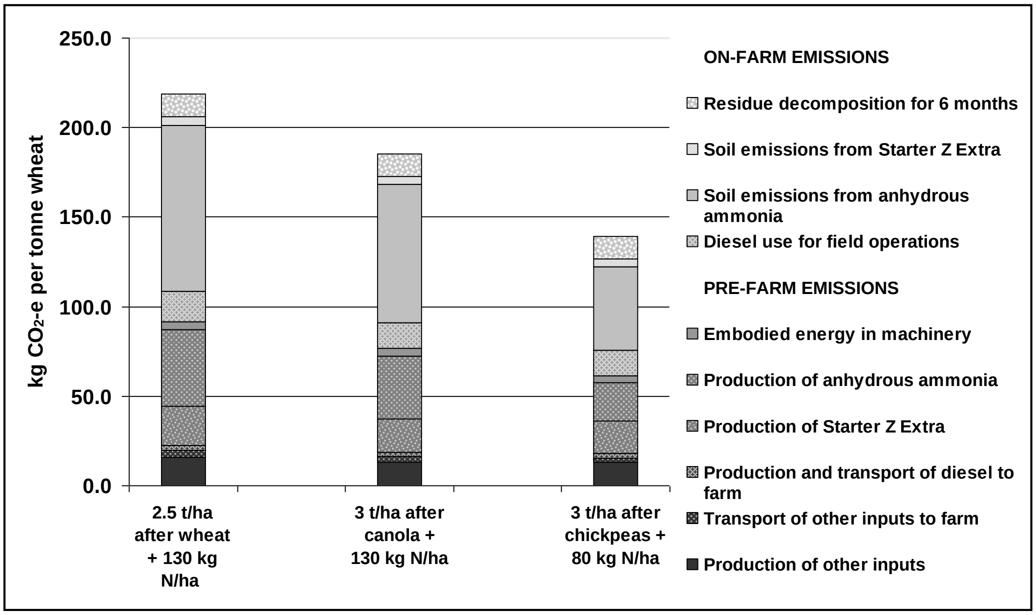

Figure 3. Characterization of GHG emissions for a tonne of short fallow wheat grown in NE NSW in either a wheat-wheat, canola-wheat or chickpea-wheat rotation, with 130, 130 and 80 kg N ha^{-1} applied respectively as combined anhydrous ammonia and Starter Z Extra. Crop yields used in calculations are stated for each rotation.

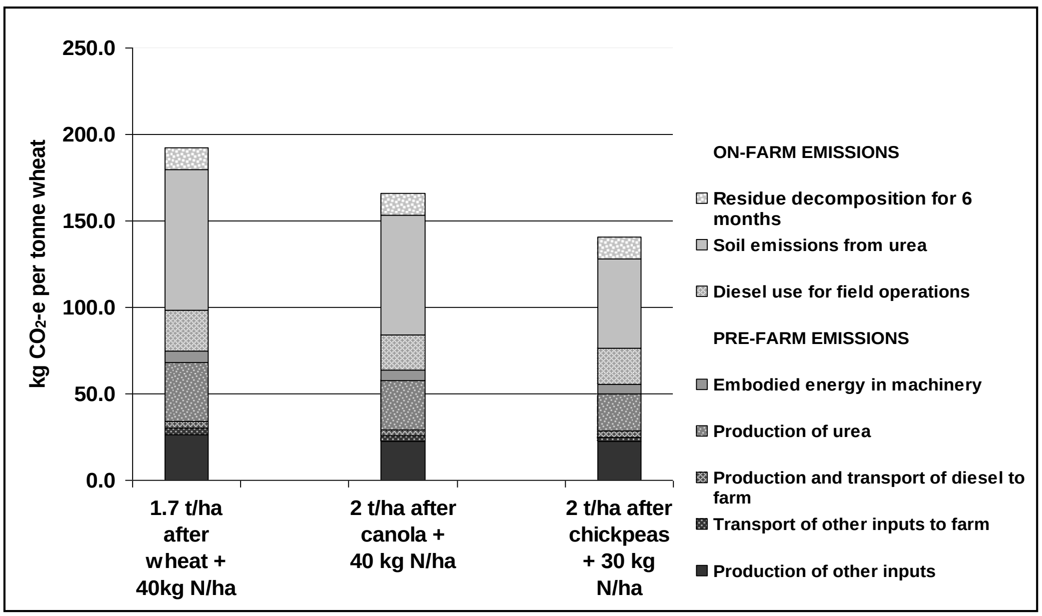

Figure 4. Characterization of GHG emissions for a tonne of short fallow wheat grown in NW NSW in either a wheat-wheat, canola-wheat or chickpea-wheat rotation, with 40, 40 and 30 kg N ha^{-1} as urea respectively. Crop yields used in calculations are stated for each rotation.

4.4. Future work

The GRDC has funded NSW DPI to develop GHG emissions mitigation strategies for the Australian grains industry. This project will involve determining the emissions intensity for a functional unit of the primary grains crop grown in each GRDC agro-ecological zone and for a crop grown in rotation with the primary crop. LCA will be applied to determine emissions intensities and also explore alternative systems and practices that will result in emissions reduction for the same functional unit. It is anticipated that GHG emissions reduction strategies will focus on reducing emissions from the manufacture and use of nitrogenous fertilizers. A possible strategy to achieve this will be by increasing legume rotations into cropping systems to biologically fix N, through rhizobial activity. Emissions reductions may also be achieved by managing excess nitrates in the soil available for denitrification. Possible strategies to achieve this may include splitting fertilizer applications to tailor N availability to crop requirements, using variable rate fertilizer applications to match N application to yield potential and sowing cover crops during the traditional fallow period to 'tie-up' soil nitrates. The effect of different N_2O EFs on this analysis is discussed in Section 5.1 below. The potential to gain minor emissions savings from reductions in fossil fuel use in farm machinery and more energy efficient production of inputs will be examined. The work will also provide a framework for testing future management practice recommendations from an emissions perspective.

Life Cycle Strategies will build non-GHG impact categories, such as land use, water use, eutrophication and ecotoxicity into the LCAs, so that NSW DPI can test for potential unintended consequences of recommended practice changes. The Commonwealth Scientific and Industrial Research Organization (CSIRO) will contribute by developing an impact category to examine the effect of LCA scenarios on soil health. Development of the impact category has commenced and Life Cycle Strategies Pty Ltd will integrate this impact category into the Australian Agricultural Life Cycle Inventory.

Cotton production systems in northern NSW and southern Qld include cereal and legume crops in their rotations and cotton seed is itself a grain. Initial LCA work (Tan *et al*. 2013) has established preliminary emissions profiles for Australian cotton lint and seed production, with separate funding secured by NSW DPI to continue this work. Studies into rice production are also underway (Suenaga *et al*. 2014).

5. Application of results

5.1. On-farm constraints and trade signals

Abovementioned practice change recommendations identified, to date, by NSW DPI researchers include incorporating legumes into cropping rotations, using split fertiliser applications, using nitrogenous fertilisers that have lower emissions potential, growing cover crops during traditional fallow periods, using variable rate fertiliser technology to manage excess nitrates in soils and exploring potential reductions in diesel use. Also, measures to improve productivity tend to provide a net reduction in emissions intensity. Whilst there is some uncertainty about N_2O EFs, with some published factors based on short-term trials, we believe that there are sufficient emerging Australian data from which to test practice change options. NSW DPI has adopted published N_2O EFs, including 0.45% (Schwenke *et al*. 2012) and 0.3% (Australian Government 2013) and will adopt lower published values for WA, where clay content and in some instances rainfall is lower. Current EFs are adequately representative for determining the relative benefit of different practice change options. Values for the absolute benefit can then be refined over time, with emerging data and potential revision to the NIR default values. In the meantime, we will continue to discuss the consequence of choosing different factors, as per Brock *et al*. (2012a) where the sensitivity of the emissions profile to choice of EF was discussed.

In particular, use of biologically-fixed N has the potential to reduce N_2O emissions, primarily through reduced emissions from the manufacture and use of nitrogenous fertilisers. The practical application of these findings by Australian farmers is, however, somewhat constrained. Farmers tend to tailor their systems to manage economic and agronomic risks to maximise profit and current enterprise mix reflects a robust consideration of these factors. Growing legumes (such as chickpeas, peas and lentils) poses different agronomic risks than growing cereals. Sowing time is more critical for legumes, to minimize the risk of frost damage and heat stress, and legumes are more susceptible to fungal diseases. However, adoption may increase with improvements in skill and technology, and will be driven by increased prices for synthetic fertilisers and market pressures for low-emissions intensity products.

The availability of markets is less of a constraint on practice change. Whilst prices for legumes are variable, Australia has established markets for both premium grade legumes for human consumption and legumes for stock feed. The legumes are targeted towards the human consumption market, with the stock feed market providing a lower value market if human consumption quality is not achieved. These markets are able to absorb additional production, increasing the chance of meeting the technical potential for mitigation through the adoption of legumes. However, impacts on price may occur, reducing the level of risk that growers will be willing to accept. Issues of leakage may also arise, from foregone cereal production, requiring augmentation elsewhere and reduced demand for legume production by other nations. Use for stock feed is often not within the same farm boundary but where it is, there will be associated livestock emissions, livestock co-products and displacement of other sources of protein as a feed source. These factors increase the need for consequential LCA. We include grain legumes as an additional product to the cereal, in a two-product system. We have trialled substitution of the legumes to focus on emissions from cereal production, attributing emissions from biological fixed N in lieu of those from synthetic fertilisers, with N treated as a legume co-product. However, it was not possible to be certain about market substitution and we now focus on reporting on the two products, with relative economic benefits and find this approach beneficial, especially when contrasting different production systems in comparative LCA.

Economic risk associated with changing aspects of a system such as those discussed here is generally determined by whether the marginal cost is equal to the marginal benefit. Even without a need to acquire capital assets, the marginal benefit and cost will vary between farm enterprise as a result of holding area, climate and soil type. They will also fluctuate from year to year based on factors such as commodity prices and climatic forecasts. In addition, the status of an Australian GHG emissions reduction policy framework is currently evolving. This is resulting in uncertainty which may constrain practice change, especially when coupled with uncertainty about the potential scope of international import penalties and restrictions between specific countries and requirements for Environmental Product Declarations. LCA is being increasingly adopted to underpin market access, for example for canola importation into European Union markets.

5.2. Policy

As discussed by Plevin *et al*. (2013), attributional LCA has limitations when used for policy development. This is because it does not take into account how a system shock, such as a reduction in demand for the nitrogenous fertilizers, due to increased use of biologically fixed N, would affect the demand for and use of these commodities within the entire agricultural sector under different market conditions. A reduction in demand for nitrogenous fertilizers in cropping enterprises may see fertilizer use, and GHG emissions, increase in other enterprises, such as those associated with livestock production. Alternatively, if the relative advantage of biologically fixed N is reduced, due to lower fertiliser prices and/or expected high cereal prices, then opportunistic farmers may increase fertiliser rates to stimulate yields and/or quality. In these cases, consequential rather than attributional LCA becomes important.

Attributional LCA is useful for policy development within a specific industry sector where internal policies will not necessarily have to consider impacts outside the industry. Further, data generated by attributional LCA models may also be indirectly used to develop government policy by providing input data for computer generated equilibrium or partial equilibrium models which aim to inform policy by modeling the impact of system shocks (*e.g.* C price) on the wider economy. In general terms, attributional LCA provides a useful starting point, especially when conducting paired comparisons and understanding likely emissions reduction ‘hot spots’, but needs to be augmented with consequential assessment when considering broader system boundaries, investigating leakage or making final practice change recommendations.

6. Conclusion

Researchers at NSW DPI have demonstrated the ability to use LCA as a tool to estimate emissions intensity from the production of grains crops under different management actions, particularly at a regionally-relevant scale. The information which has been generated is intended to be useful for farmers who wish to change their management practices to minimise GHG emissions for environmental stewardship or in response to policies, such as emissions trading schemes, where those who do not reduce emissions may be disadvantaged. The information is also intended to play a role to inform decision-making in the post farm-gate supply chain where the environmental credentials of products is increasingly being deemed important. Although this information has only received limited use in policy formulation in Australia, so far, LCA is a tool that has the potential to guide long-term management change in agricultural systems, whether by strengthening market signals or informing direct government intervention.

ABSTRACT

Organic residues from agriculture and waste and wastewater treatment can be used as organic fertilizers or soil amendments due to their nutrient and organic matter contents. In order to replace mineral fertilizers by organic residues at equivalent nutrient and fertilizer values, the mineral fertilizer equivalent (MFE) of the organic residue must be known. A simple Excel-tool was developed that allowed determination of the nitrogen MFE of organic residues based on their nitrogen content and composition, and nitrogen emissions from field application of the organic residue. Nitrogen field emissions were estimated using simple models and average climate and soil conditions. A global sensitivity analysis revealed that the application method, determining the extent of incorporation into the soil, contributed 66% to the variability of the calculated nitrogen MFE for application of raw pig slurry.

Keywords: agricultural valorization, organic residues, mineral fertilizer equivalent, sensitivity, substitution

1. Introduction

Many organic residues from agriculture as well as waste and wastewater treatment are suitable for an agricultural valorization as organic fertilizer or soil amendment due to their nutrient and organic matter contents. Application of organic fertilizers can replace the use of mineral fertilizers resulting in a financial advantage for the farmer. Furthermore, if organic residues are applied instead of mineral fertilizers and not in addition to, nitrogen (N) and phosphorus (P) emissions will be reduced due to decreased N and P application to farmland. Organic fertilizers have, however, a lower fertilizing value than mineral fertilizers, because nitrogen is present in both mineral and organic forms. Organic nitrogen is only plant available after mineralization by soil microorganisms. For replacing mineral fertilizers by organic residues at equivalent nutrient and fertilizer values, the mineral fertilizer equivalent (MFE) of the organic residues must be known. So far, MFE values reported in literature were typically used when manures or sewage sludge were substituted for mineral fertilizers in life cycle assessment (LCA) studies (e.g. Bayo et al. 2012; De Vries et al. 2012; Johansson et al. 2008; Linderholm et al. 2012) (see Hélias and Brockmann (2014) for a review). Although simple methods for estimating the MFE of organic residues from their composition have been reported (Delin et al. 2012; Water Environment Federation 2005), they have not yet been applied in LCA studies. A decision support tool (MANNER-NPK) for determination of plant available nitrogen from manure has been developed by Nicholson et al. (2013). The decision support tool was designed for the use by farmers to calculate for a specific manure application the plant available nitrogen for the year of application and the following year. Quantification of the plant available nitrogen was based on organic nitrogen mineralization curves and a sophisticated calculation of nitrogen losses considering site specific climate (e.g. temperature, rainfall, wind speed) and soil conditions (e.g. moisture, temperature) (Nicholson et al. 2013).

The aim of this study was to develop a simple Excel-tool designated for the use in LCA studies that allows for determining the nitrogen MFE of organic residues. The nitrogen MFE is calculated based on the nitrogen content and composition of the organic residue, and nitrogen emissions from field application of the organic residues, which are estimated for average climate and soil conditions.

2. Methods

2.1. Nitrogen MFE calculation

We based the nitrogen MFE calculation on the plant available nitrogen (PAN) calculation presented by the Water Environment Federation (2005) for biosolids. But in contrast to Water Environment Federation (2005), we take into account all nitrogen emissions from field application of the residue instead of only NH_3 emissions. In general, the nitrogen MFE calculation is based on the nitrogen content and composition of the residue (ammonium-N, nitrate-N, organic nitrogen), a mineralization rate for organic nitrogen, and estimated nitrogen emissions from field application of the organic residue (Eq. 1).

$$PAN = N_{org} \cdot k_{min} + NH_4\text{-}N + NO_3\text{-}N - N_{emissions} \qquad \text{Eq. 1}$$

where N_{org} is the organic nitrogen content of the fertilizer/amendment [kg $_{Norg}$/kg N_{tot}], $NH_4\text{-}N$ is the ammonium nitrogen content [kg NH_4-N/kg N_{tot}], $NO_3\text{-}N$ is the nitrate nitrogen content [kg NO_3-N/kg N_{tot}], k_{min} is the organic nitrogen mineralization rate factor [-], and $N_{emissions}$ is the sum of all nitrogen emissions from fertilizer application (NH_3, NO_3^-, N_2O and NO_x) [kg N/kg $N_{applied}$]. Organic nitrogen mineralization rate factors for different organic residues are given in Table 1. Nitrogen emissions from fertilizer application are calculated with equations given in section 2.2.

Table 1. Organic mineralization rate factors for different organic residues.

	Mineralization rate factors		
Organic residue	**Year of application**	**Long-term**	**Source**
Dairy cattle or other livestock			
Lagoon water (< 1% DM)	0.40	0.77	Sullivan (2008)
Thin slurry (1 to 5% DM)	0.40	0.77	Sullivan (2008)
Thick slurry (5 to 10% DM)	0.30	0.67	Sullivan (2008)
Solid (> 10% DM)	0.30	0.67	Sullivan (2008)
Separated dairy solids or horse manure[a]	0.10	0.35	Sullivan (2008)
Compost	0.10	0.35	Sullivan (2008)
Solid poultry (> 10% DM)	0.50	0.87	Sullivan (2008)
Activated sludge (biosolids)	0.40	0.75	Water Environment Federation (2005)
Supernatant[b]	0.40	0.75	Water Environment Federation (2005)

[a] dairy solids from a mechanical separator.
[b] from activated sludge processes.

2.2. Calculating nitrogen emissions from field application

Ammonia emissions from field application of organic fertilizers and amendments were calculated with the AGRAMMON model (Nemecek and Schnetzer 2012), which takes into account application method, time of incorporation after application, and weather conditions during application, among others.

$$NH_3 - N = TAN \cdot \left(EF + c_{app}\right) \cdot c_x \qquad \text{Eq. 2}$$

where $NH_3\text{-}N$ is the emission of ammonia [kg NH_3-N], *TAN* is the total ammonium nitrogen [kg N], *EF* is the emission factor [%TAN/100], c_{app} is a correction factor influencing the emission factor (applies only for liquid manure; [-]), and c_x is a correction factor taking into account impacts of application method and time [-]. Correction factors were taken from Agrammon Group (2013b). Emission factors for a range of organic residues are given in Table 2.

Table 2. Ammonia emission factors for different organic residues.

Organic residue	Emission factor [%TAN]	Source
Cattle manure, liquid	50	Agrammon Group (2013b)
Cattle manure, solid	80	Agrammon Group (2013b)
Pig manure, liquid	35	Agrammon Group (2013b)
Pig manure, solid	60	Agrammon Group (2013b)
Poultry manure, liquid and solid	40	Agrammon Group (2013b)
Horse, sheep, goat manure	70	Agrammon Group (2013b)
Compost, solid digestate	80	Agrammon Group (2013b)
Liquid digestate	60	Agrammon Group (2013a)
Activated sludge (biosolids)	50	Water Environment Federation (2005)
Supernatant[a]	50	assumed to be the same as for biosolids

[a] from activated sludge processes.

Nitrate emissions were estimated with the Smaling (1993) model, proposed by Roy et al. (2003), because the model enables to discriminate between nitrate emissions originating from organic residue application and background nitrate emissions from soil organic matter nitrogen.

$$NO_3 - N = \left(N_{min,soil} + N_{fert}\right) \cdot \left(0.021 \cdot P_{prec+irr} - 3.9\right)/100, \quad \text{for } c < 35\% \qquad \text{Eq. 3}$$
$$NO_3 - N = \left(N_{min,soil} + N_{fert}\right) \cdot \left(0.014 \cdot P_{prec+irr} + 0.71\right)/100, \quad \text{for } 35\% < c < 55\% \qquad \text{Eq. 4}$$
$$NO_3 - N = \left(N_{min,soil} + N_{fert}\right) \cdot \left(0.0071 \cdot P_{prec+irr} + 5.4\right)/100, \quad \text{for } c > 55\% \qquad \text{Eq. 5}$$

NO_3-N is the amount of N leached to groundwater [kg N], $N_{min,soil}$ is the amount of mineralized N in the upper 20 cm of the soil [kg N], N_{fert} is the amount of N applied with organic residues [kg N], $P_{prec+irr}$ is the sum of precipitation and irrigation [mm/year], and c is the clay content of the soil [%]. To obtain only nitrate emissions directly related to organic residue application, $N_{min,soil}$ was set to zero.

Nitrous oxide emissions were calculated with the IPCC method (IPCC 2006) following the equation given in Nemecek and Schnetzer (2012).

$$N_2O = 44/28 \cdot \left(0.01 \cdot \left(N_{fert} + N_{cr}\right) + 0.01 \cdot NH_3 - N + 0.0075 \cdot NO_3 - N\right) \qquad \text{Eq. 6}$$

where N_2O is the emission of nitrous oxide [kg N_2O], N_{cr} is the nitrogen contained in crop residues [kg N], and *NH_3-N* and *NO_3-N* are the ammonia and nitrate emissions calculated with equations given above.

Nitrogen oxide emissions were estimated according to Nemecek and Schnetzer (2012) based on nitrous oxide emissions. NO_x and N_2O are given in kg NO_x and kg N_2O, respectively.

$$NO_x = 0.21 \cdot N_2O \qquad \text{Eq. 7}$$

2.3. Determination of mean soil and climate conditions

Estimation of nitrate emissions from organic residue application required information on annual precipitation and irrigation, as well as on the clay content of the soil. Mean climate and soil conditions have been determined for five European countries: Denmark, France, Germany, The Netherlands, and Poland (Table 3).

Table 3. Mean soil and climate conditions used.

Country	Precipitation (mm/year)	Irrigation[a] (mm/year)	Agricultural surface area with clay content < 35%	Agricultural surface area with clay content 35-55%	Agricultural surface area with clay content > 55%
Denmark	718[b]	1.7[d]	100.0%[i]	0.0%[i]	0.0%[i]
France	700[b]	15.0[e]	93.3%[j]	6.7%[j]	0.0%[j]
Germany	757[b]	1.6[f]	100.0%[k]	0.0%[k]	0.0%[k]
Netherlands	854[b]	7.4[g]	92.5%[l]	7.5%[l]	0.0%[l]
Poland	595[c]	0.6[h]	99.0%[m]	1.0%[m]	0.0%[m]

2.4. Sensitivity analysis

We carried out a global sensitivity analysis to evaluate the impact of different parameters on the calculated nitrogen MFE value of a selected organic residue (raw pig slurry). Parameters included in the analysis and their ranges and discrete values, respectively, are given in Table 4. Based on the clay contents of agricultural soils in the five European countries considered (see Table 3), it was assumed that agricultural soils do not have a clay content > 55%. The variance-based extended Fourier amplitude sensitivity test (extended FAST) was applied, which allows for estimating the contribution of individual input parameters to the variance of the output variable (Saltelli et al. 2000). First-order sensitivity indices (S_i) provide the fractional contribution of individual parameters to the variance of the output. Total sensitivity indices (S_{Ti}) estimate the contribution of individual parameters including interaction effects between parameters, and are defined as the sum of sensitivity indices involving parameter *i*. Sample generation and calculation of sensitivity indices was carried out using Simlab 2.2 (European Commission and IPSC 2004).

Table 4. Parameter values and ranges used in the global sensitivity analysis

Parameter	Symbol	Values/range	Distribution	Source
Application method (correction factor)	c_{Method}	0.2; 0.3; 0.5; 0.7; 1.0	Discrete	Agrammon Group (2013b)
Season of application (correction factor)	c_{Season}	0.95; 1.00; 1.15	Discrete	Agrammon Group (2013b)
Daytime of application (correction factor)	$c_{Daytime}$	0.8; 1.0	Discrete	Agrammon Group (2013b)
Application on unseasonably warm day (correction factor)	c_{Warm_day}	0.96; 0.98; 1.00; 1.05	Discrete	Agrammon Group (2013b)
NH_3 emission factor (for raw pig slurry)	EF	0.35-0.75	Uniform	this study
Mineralization rate factor for organic nitrogen	k_{min}	0.4-0.8	Uniform	this study (first-year vs. long-term mineralization rate)
Annual precipitation and irrigation [mm/year]	$P_{prec+irr}$	600-850	Uniform	this study
Agricultural surface area with clay content < 35%	clay1	0-1	Uniform	this study
Agricultural surface are with clay content 35-55%	clay2	1-clay1	Relation	this study

3. Results

The developed Excel-tool requires as input information on nitrogen content and composition of the organic residue, type/nature of organic residue, application method and time of field application, and geographical location (for climate and soil conditions). First, field emissions of NH_3, NO_3^-, N_2O and NO_x during organic residue application are calculated. Then, the nitrogen MFE for the first year and for the long-term are calculated. Figure 1 shows nitrogen MFEs calculated for field application of raw pig slurry with 4 kg N_{tot}/m^3, 2.5 kg NH_4-N/m^3, 1.5 kg N_{org}/m^3, different application methods and different geographical locations. Nitrogen MFEs calculated for Danish and French climate and soil conditions were very similar. Total annual precipitation and irrigation differed only slightly (5 mm/year) between Denmark and France, but in contrast to Denmark, 6.7% of the French agricultural surface area had a clay content between 35 and 55% (Table 3). The lowest nitrogen MFEs were calculated for Dutch soil and climate conditions, while the highest MFEs were obtained for Poland. Poland had the lowest annual precipitation and irrigation, whereas the Netherlands had the highest annual precipitation and irrigation. For the same application method, the MFE increased by about 30% when the long-term mineralization rate factor for organic nitrogen was used instead of the mineralization rate factor for the year of application. For the same mineralization rate factor, nitrogen MFEs increased for application methods that allowed for better incorporation of the applied fertilizer into the soil, because burying the applied organic residue decreases NH_3 volatilization.

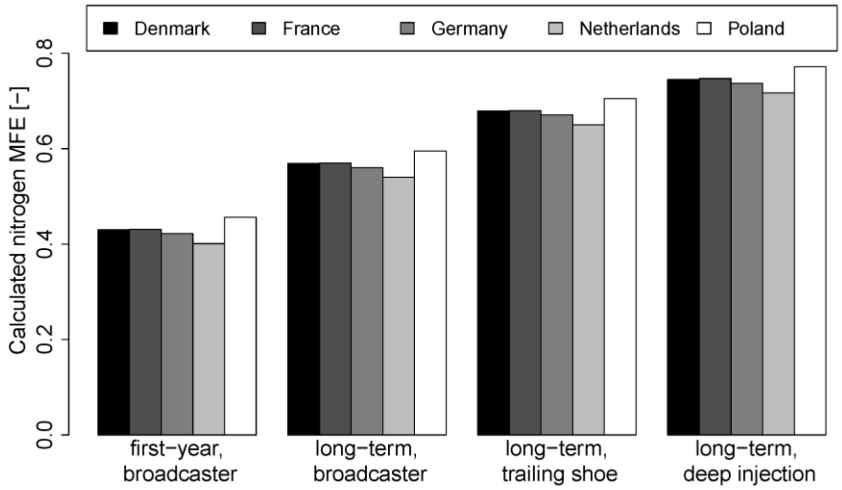

Figure 1. Calculated nitrogen MFE values for different application methods and geographical locations

Nitrogen MFE values calculated for the same application method did not vary much between the selected countries. The variations were mainly due to differences in annual precipitation and irrigation, as the soil types (clay content) were very similar for the different countries. To evaluate the impact of more extreme soil and climate conditions not covered by the selected countries, the clay content of the soil was assumed to be either <35%, between 35% and 55%, or >55%, and the annual precipitation and irrigation was assumed to be 250, 500, 750 or 1000 mm/year. First-year nitrogen MFE values calculated for broadcaster application and different soil and climate conditions are given in Figure 2. Nitrogen MFE values differed most for varying annual precipitation and irrigation for a clay content of the soil <35%. The differences in calculated nitrogen MFE values due to varying precipitation and irrigation decreased with increasing clay content of the soil. Independent of the clay content of the soil, nitrogen MFE values were higher for lower precipitation and irrigation due to lower nitrogen emissions. For low annual precipitation and irrigation (250 mm/year), nitrogen MFE values were higher for low clay contents, while for high annual precipitation and irrigation (1000 mm/year), nitrogen MFE values were higher for higher clay contents.

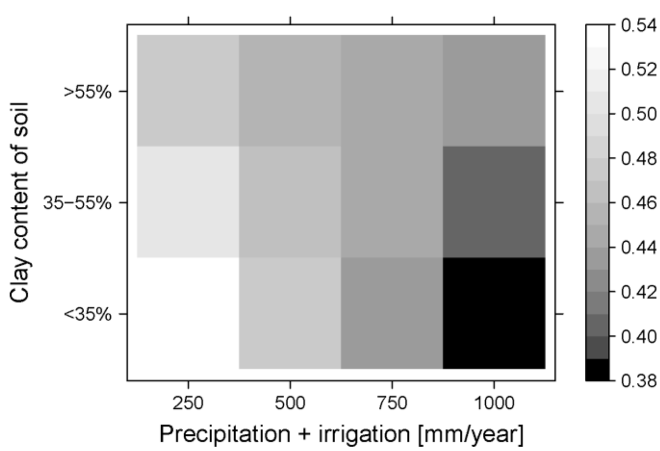

Figure 2. Calculated first-year nitrogen MFE values for broadcast application for different clay contents of soil and different annual precipitation + irrigation.

Calculated nitrogen MFEs presented above showed that application method, mineralization rate factor for organic nitrogen, amount of annual precipitation and irrigation, and clay content of the soil affected the calculated nitrogen MFEs. In order to quantify the impact of the different parameters on the variance of the MFE, a global sensitivity analysis using the extended FAST method was carried out. Figure 3 a) shows the large variability in the nitrogen MFE as a result of the variability in the model parameters. The contribution of individual parameters to the variance of the nitrogen MFE is presented in Figure 3 b). The type of application method chosen had clearly the largest impact on the calculated MFE followed by the NH_3 emission factor (*EF*) and the mineralization rate for organic carbon (k_{min}). The variability in the application method contributed 66.4% to the uncertainty in the calculated MFE based on the first-order sensitivity index and 73.1% based on the total sensitivity index. Contributions of the NH_3 emission factor and the mineralization rate factor for organic nitrogen to the variance of the MFE were very similar with 10.3% and 11.1% (first-order sensitivity index), respectively. All other parameters had only a minor impact (< 5%) on the calculated MFE.

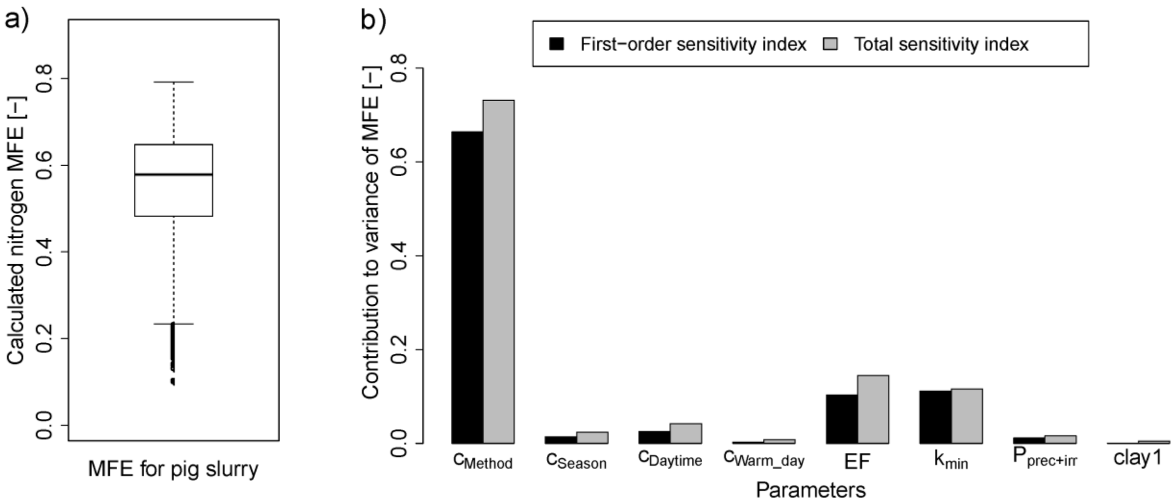

Figure 3. Uncertainty and sensitivity analysis results: a) Box-Whisker plot of the calculated nitrogen MFEs for raw pig slurry. The boundaries of the box mark the 25th and 75th percentile, and the line within the box marks the median. Whiskers above and below the box indicate the furthest points that are within 1.5 times the interquartile range (box length) from the end of the box; b) Contribution of the individual parameters to the variance of the calculated nitrogen MFE based on the first-order and total sensitivity indices calculated with the extended FAST method.

4. Discussion

The developed Excel-tool was based on simple models describing emissions from field application of organic residues. The model for estimating NH_3 volatilization losses accounted only indirectly for climate conditions through different correction factors. In contrast, Nicholson et al. (2013) considered in their decision support tool the impact of soil moisture content, wind speed, land use, and rainfall after spreading on the volatilization of NH_3. But it is difficult to say how much climatic conditions influence NH_3 emissions. Webb et al. (2012) showed that the measuring method and the incorporation of manure (vs. no incorporation) had significant effects on NH_3 emissions. The latter agrees with our results from the sensitivity analysis. When fixing the application method (or the extent of fertilizer incorporation) to broadcaster application without incorporation, the variability in the ammonia emission factor had the largest impact (55%) on the variance of the nitrogen MFE (data not shown). Thus, reducing the variability of the ammonia emission factor by determining, for example, a standard measurement method for ammonia field emissions, would significantly decrease the variability in the estimated nitrogen MFE.

In the calculation of the nitrogen MFE, we did not differentiate between different soil types when applying organic nitrogen mineralization rates. Shah et al. (2013) observed, however, that mineralization rates of organic nitrogen from organic residues vary widely with soil types. But the sensitivity analysis carried out in this study showed that the variation of the mineralization rate factor for organic nitrogen in the range of 0.4-0.8 contributed only 11% to the variation in the nitrogen MFE. Even for a fixed application method (broadcaster application), the contribution of k_{min} to the variance of the nitrogen MFE increased only slightly to 16% (data not shown). As a consequence, reducing the variability in k_{min} by considering the soil type would result only in a minor decrease in the variability of the nitrogen MFE. Thus, the simplification of not differentiating between soils considered to be acceptable.

Our goal was to develop a tool that is easy to apply and does not require many inputs. We think that using simple models and average climate and soil conditions for estimating the nitrogen MFE is reasonable for LCA studies, because LCA studies are often based on a regional or national level. Nonetheless, applying site specific soil and climate conditions and mineralization rates for organic nitrogen may reduce the uncertainty of the calculated nitrogen MFE for a specific case.

5. Conclusion

An Excel-tool was developed that allows for fast and easy determination of the nitrogen MFE of organic residues valorized as organic fertilizers or soil amendments. The nitrogen MFE is needed for calculating the amount of substituted mineral fertilizers. The tool also calculated nitrogen field emissions from organic residue application. The nitrogen MFE was estimated using simple models and average climate and soil conditions for estimation of nitrogen field emissions. A global sensitivity analysis using the extended FAST method was used to quantify the contribution of individual parameters to the uncertainty in the calculated nitrogen MFE. For the case of raw pig slurry application, the type of application method selected (determining the extent of incorporation into the soil) contributed most (66.4%) to the variability of the nitrogen MFE, followed by the NH_3 emission factor and the mineralization rate for organic carbon. It is, therefore, essential to determine the nitrogen MFE for a specific application method to reduce the uncertainty in the calculated nitrogen MFE and with it the uncertainty in the amount of replaced mineral fertilizers. The Excel-tool is available from the authors upon request.

Developing Environmental Footprint, Cost, and Nutrient Database of the US Animal Feed Ingredients

ABSTRACT
The main objective of the US Animal Feed Database was to develop a robust nutrient, economic, and environmental footprint database in one location. The database will be integrated into the US Pig Production Environmental Footprint Calculator (PPEFC). This paper provides an overview of 180 animal feed prices, climate change impacts, water consumption, and land use inventory. The environmental footprint data was based on life cycle assessment (LCA) ReCiPe impact method. The cost and environmental footprint results were analyzed in the context of a single baseline swine diet to evaluate the effect cost and environmental footprint of each feed ingredient based on its inclusion rate. The database potential is seen within the PPEFC calculator where the farmers would be able to model diets beyond the baseline diets. In addition, this database will be used to project least cost and environmental footprint diet formulations which would also be integrated within the PPEFC calculator.

Keywords: animal feed database, environmental footprint calculator, swine diet, feed cost.

1. Introduction

Pork producers are committed to protecting their resources (water, land, and air) and are searching for production strategies of minimum cost to comply with an array of federal, state, and local environmental regulations. In 2011, the US National Pork Board, supported by the USDA Climate Change Mitigation and Adaptation in Agriculture grant, launched a project to develop a science-based decision tool called Pig Production Environmental Footprint Calculator (PPEFC). The PPEFC has the ability to calculate impact to climate change, costs, land use, and water consumption across the pork production chain, including feed formulation and crop production. The combined analysis of all of these factors allows identification of potential ecologically and economically feasible production practices for pork producers.

One of the goals of the PPEFC project is developing an environmental footprint, cost, and nutrient database of the US animal feed ingredients and integrating it with the calculator. The PPEFC is built upon cradle-to-farm-gate life-cycle assessment (LCA) of pork production combined with the US National Resource Council (NRC) swine nutrient requirements models (NRC 2012), farm operation inputs, and animal feed database. Farm operation inputs include: barn characteristic, utilities, manure management, dead animal disposal, and farm operation costs. The animal feeds database includes: environmental footprint, feed prices, and nutrient composition, as seen in Figure 1.

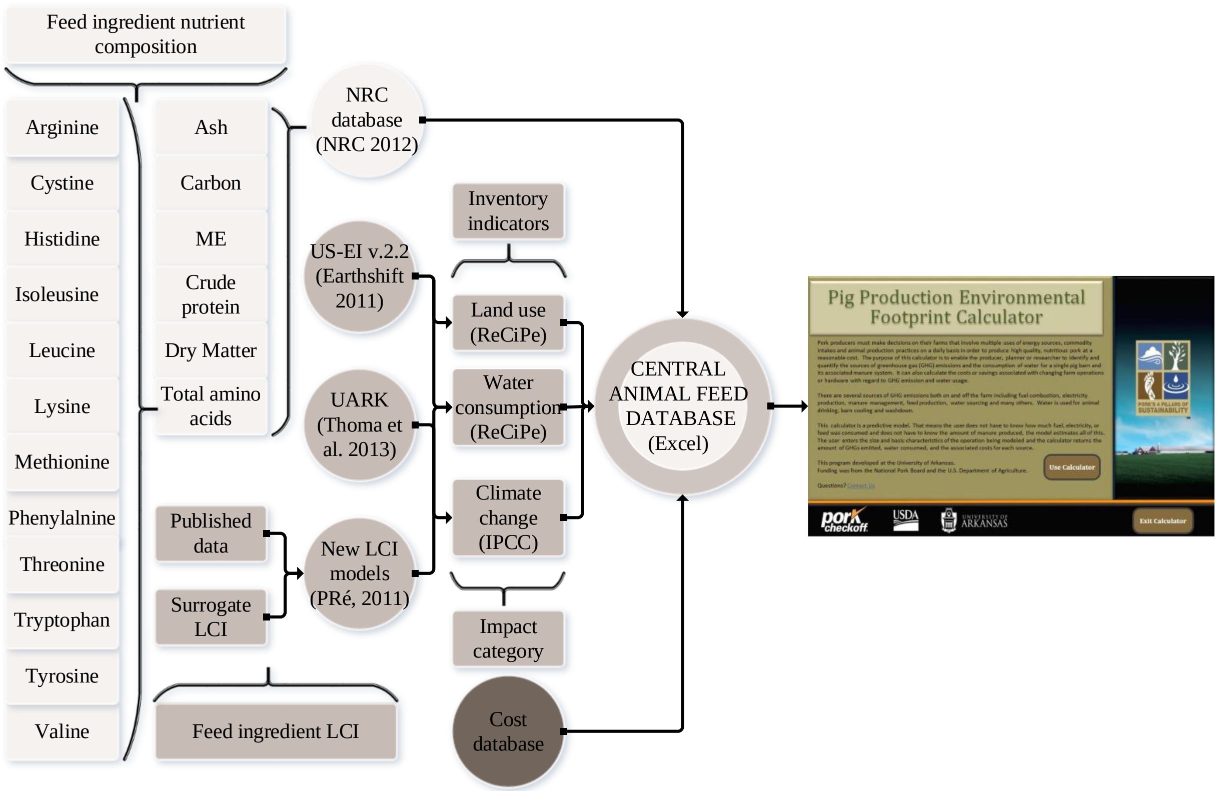

Figure 1. Animal feed ingredient nutrient content, cost, land use, water consumption, and climate change impact database structure and integration into pig production environmental footprint calculator.

This paper analyzes environmental footprint and cost data for swine feed ingredients. Feed ingredients used in swine diet are numerous and of various origins: production of grains and protein crops specifically to feed livestock (e.g., corn grain); by-product feeds from the production of human food and biofuel (e.g., corn meal and Dried Distillers Grains with Solubles (DDGS)); and minerals, vitamins, and other additives from chemical production. According to the NRC (2012), there are more than 180 feeds that could be part of the swine diet in the US. In addition, the US animal feed database contains ingredients that are part of pork production management practices: phytase, ractopamine, and antibiotics.

2. Methods

2.1. Data sources of animal feed nutrient, cost, and environmental footprint

The system boundaries for collection of animal feed ingredients are defined in Figure 2. The main animal feed nutrient content data were obtained from the NRC (2012). Feed ingredient prices were collected from various feed market data sources, including Feedstuffs (2014), a weekly newspaper for agribusiness as well as from feed mills, pork industry representative and firms engaged in the production of feed additives. The animal feed cost values were provided from the Department of Agricultural Economics & Agribusiness at the University of Arkansas (Popp 2014). The main environmental footprint data (40%) for swine feeds was obtained from the US agricultural and product LCA models built in SimaPro 7.3.3 (PRé Consultants 2011). These models are a result of several years of work on fluid milk, poultry, cheese, peanuts, and swine LCA projects at the University of Arkansas (Van Loo et al. 2011; Mccarty et al. 2012; Thoma et al. 2013b; Kim et al. 2013; Adom et al. 2013; Nutter et al. 2013; Thoma et al. 2013a; Thoma et al. 2013c; Thoma et al. 2013d). Standard LCI databases were used (4%): US-EI v2.2 (EarthShift 2011) and US Input-Output database (Mongelli et al. 2005). Direct LCIA results from published papers (Tan et al.; Nielsen and Wenzel 2007; Mosnier et al. 2011) represent less than 10% of data sources. Approximately 7% of data uses surrogate LCI which are used to bridge data gaps for animal feed ingredients.

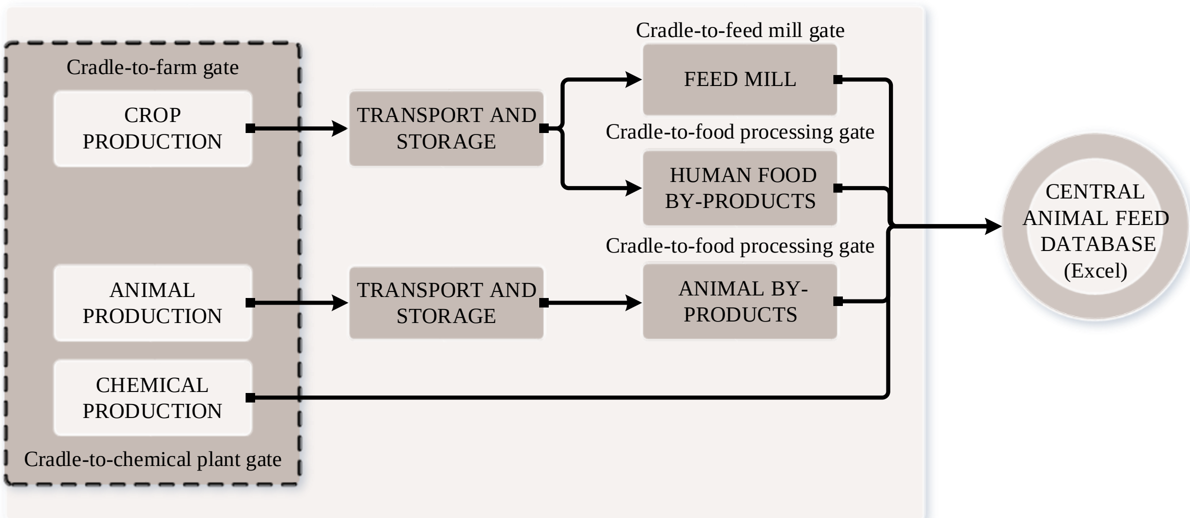

Figure 2. System boundary for feed ingredient production.

2.2. Limitations of the animal feed database

Potential limitations of the Animal Feed Database include the use of different LCI databases, direct LCIA results, multiple, surrogate, and incomplete models. The US-EI v2. 2 (EarthShift 2011) represents the largest database source of swine feed nutrients. The US-EI database (EarthShift 2011) is used to bridge the current gap in the USLCI database (NREL 2012) and applies US electrical conditions to the Ecoinvent database (Ecoinvent, 2010). Input-output databases are based on national economic and environmental statistics. The main disadvantage of this approach is that processes are relatively aggregated and models don’t include water consumption. Sometimes, for similar feeds the same models were used multiple times based on product group. For example, the animal and marine fats and oils model (Mongelli et al. 2005) can be used for animal oils, grease, tallow, bones, fish, and animal meal processing plants. Animal and marine fats and oils model is an input-output model based on market value of the product. The distinction between the environmental footprint of animal and fish processing by-products stems from individual feed prices. Multiple, surrogate, and incomplete models may lead to overestimation or underestimation of the results depending on the relative environmental footprint and percent inclusion of feed in a swine diet. For example, feed ingredient of different origin was used to represent one or multiple feeds. It is important to note that the percent of current use of these feeds in practice is assumed low because production and availability of those feeds in the US is not high. Also, average soybean meal production LCI was used to represent different soybean meal production practices. Direct LCIA results are limited in the number of environmental footprint categories presented (e.g., only GHG emissions available) and published results may have used different LCIA method to calculate the environmental footprint. The results presented in this paper are not final, as the project is still ongoing. With new databases such as ecoinvent 3 database (Weidema et al. 2013) and Agri-footprint v1.0 database (Blonk Consultants 2014) we the US feed database we should be able to avoid the use direct LCIA results.

2.3. Environmental footprint method

The environmental footprint in this context relates to: climate change impact based on 100 year Global Warming Potential (GWP) (Solomon et al. 2007) and inventories of water consumption and land use (Goedkoop et al. 2009). Water consumption and land use denote the ecological footprint of key resource consumption indicators. According to Goedkoop et al. (2009), the consumed water (m^3) refers to a fraction of water that is evaporated or exported to another location from the watershed or released to a different watershed. Land use (m^2a) is described as an inventory of agricultural and urban land occupation (Goedkoop et al. 2009). Climate change impact also deals with resource use (e.g., fossil fuel), but it’s focused strictly on the greenhouse gas (GHG) emissions. The majority of feeds have been converted from external data sources to SimaPro 7.3.3 (PRé Consultants 2011). Thus, it is possible to obtain results for other impact categories, but this analysis is out of scope of the project.

3. Results

The animal feed costs ($/kg dry feed) and environmental footprint results of all 180 feeds are shown in Figure 3, 4, 5, 6. The costs of animal feeds vary greatly by region. The prices in the Figure 3 represent 2013 US national averages (Popp 2014). The units for environmental footprint are CO_2e, m^3, and m^2a per 1 kg dry feed. To avoid over cluttering and to enable highlighting of different feed ingredients, we have separated feeds into 3 columns. The first and second columns contain feeds that are the most often used in US swine production; the third column shows results for feeds that are rarely used. This selection was based on discussions with swine producers and nutritionists in Arkansas, so it should not be taken to be representative for the whole US. In addition, the color scheme links up ingredients to specific feed category (e.g., corn and corn by-products).

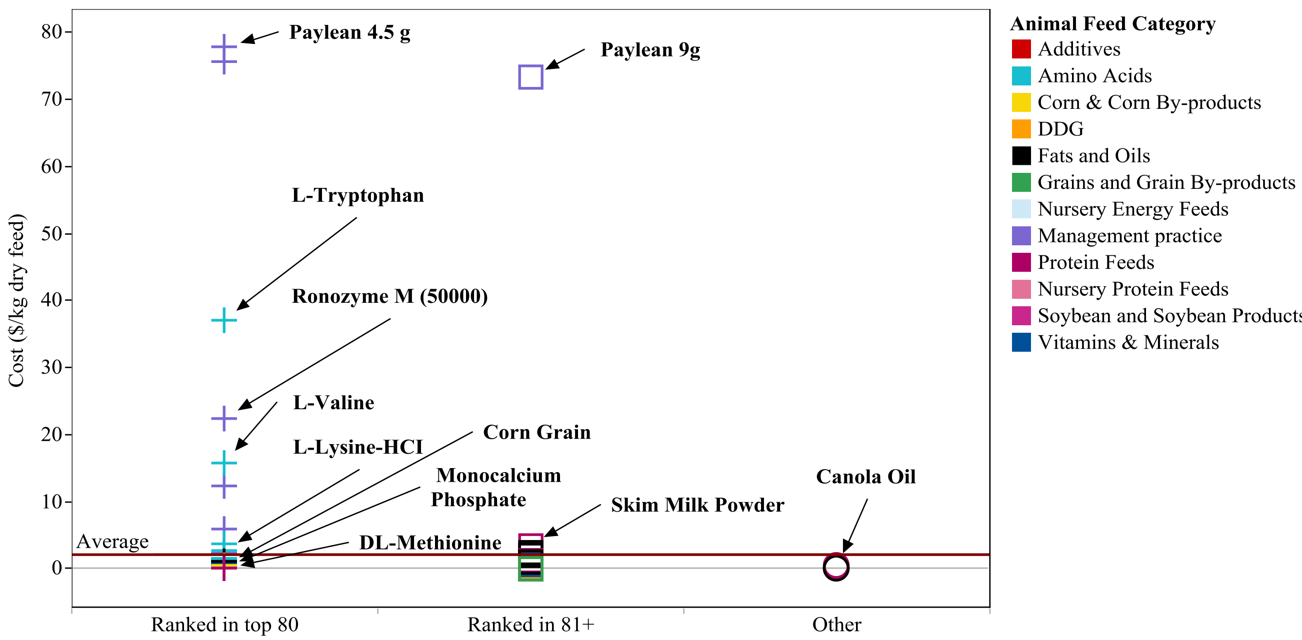

Figure 3. Animal feed cost ($/kg dry feed).

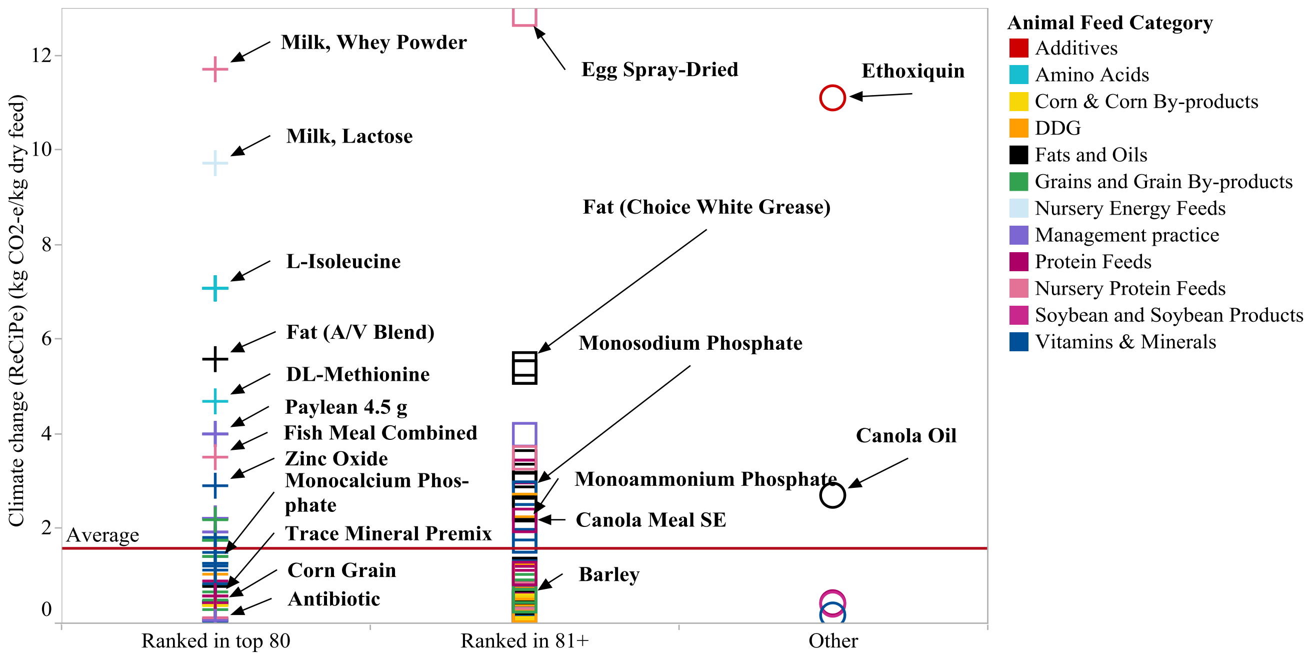

Figure 4. Animal feed climate change impact (kg CO_2e/kg dry feed).

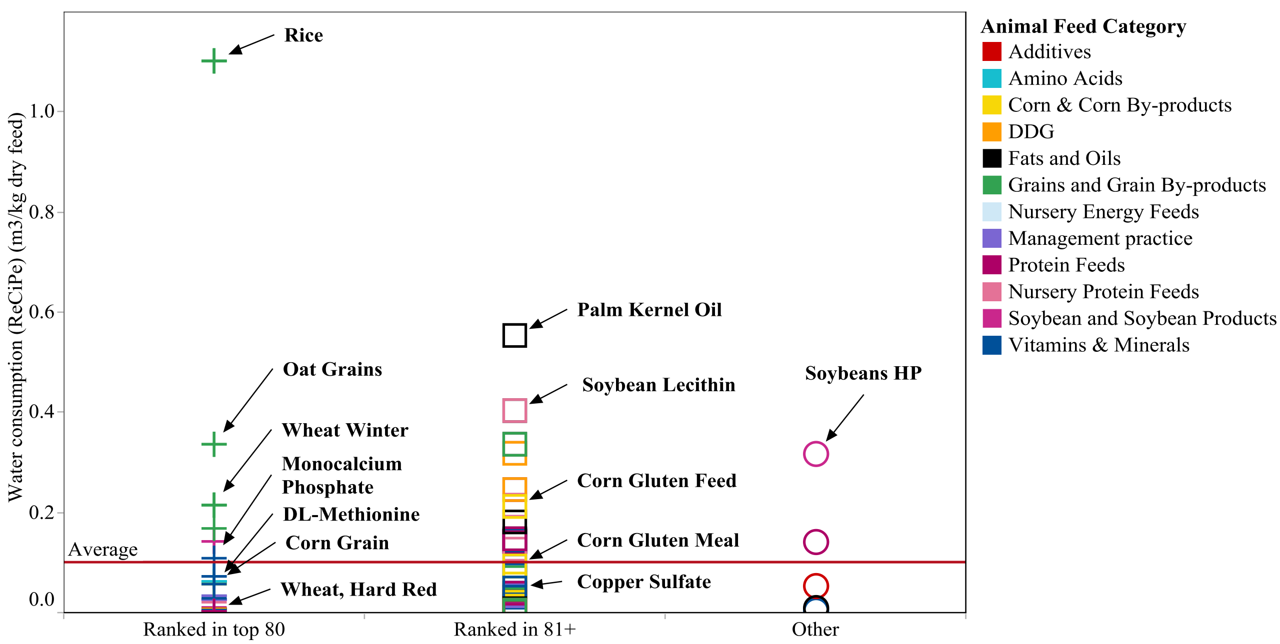

Figure 5. Animal feed water consumption (m^3/kg dry feed).

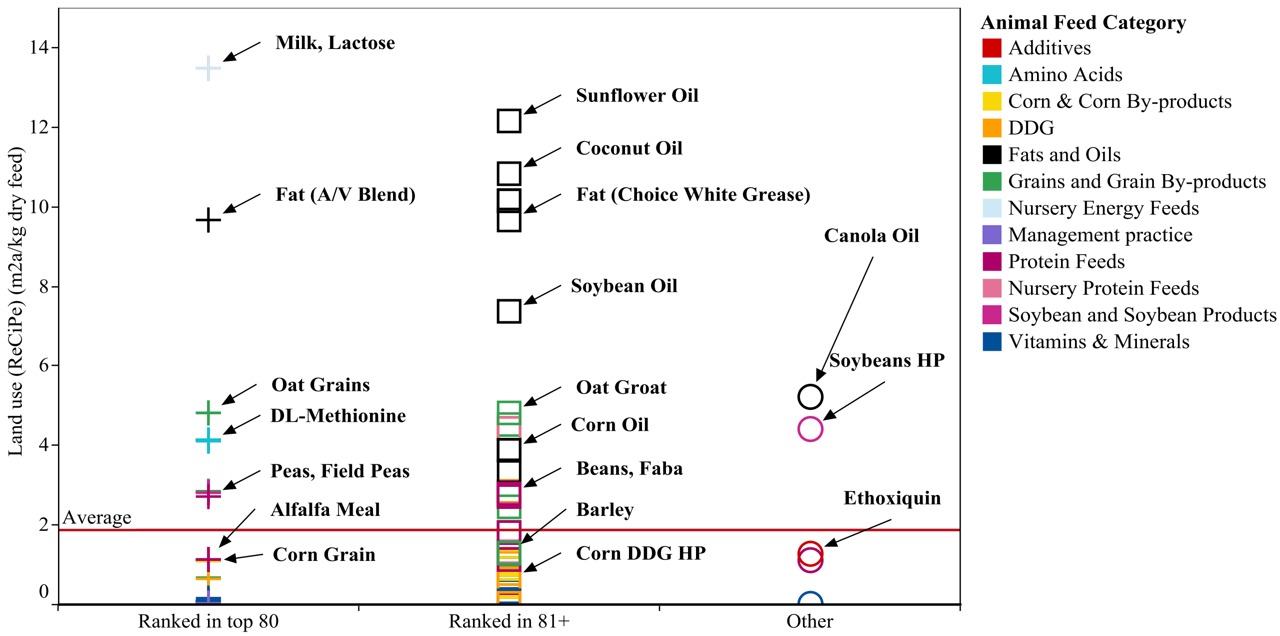

Figure 6. Animal feed land use (m^2a/kg dry feed).

The environmental footprint and feed costs were analyzed against the 7 phase swine diet (nursery-finish), as seen in Figure 7. The reference unit for each phase was defined as \$, kg CO_2-e, m^3, and m^2a per 1 kg of dry feed mix. Formulating swine diets depends on many factors: including but not limited to nutrient requirements, price, feeding limitations, and availability of feeds on the market. Thus, diet is a critical component in modeling environmental footprint and cost. In collaboration with swine producers and nutrition experts in Arkansas, a seven-phase swine diet (nursery, grow to finish) was proposed to serve as a baseline model in PPEFC (Table 2). This diet was used to estimate the environmental footprint of one kilogram of feed mix against the environmental footprint of 1 kg of dried feed.

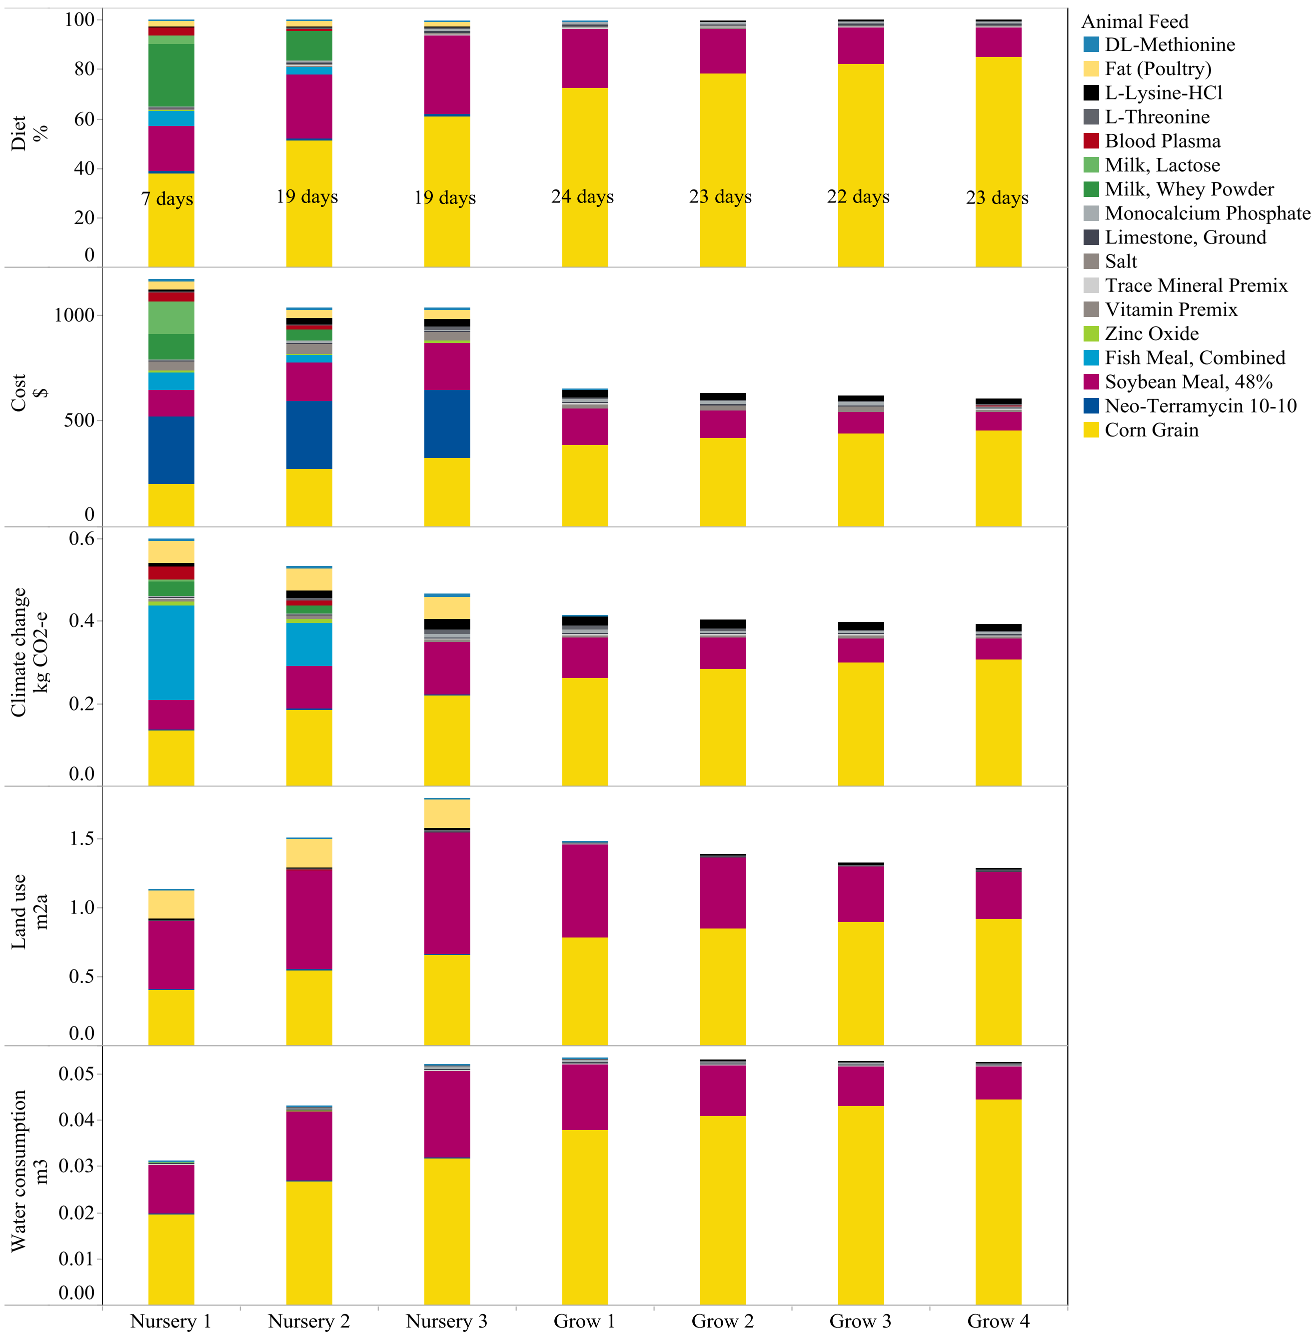

Figure 7. Diet, cost (\$), climate change impact (CO_2e), water consumption (m^3), and land use (m^2a) results of nursery-finish 7 phase swine diet (per 1 kg of dry feed mix).

4. Discussion

Readers should use caution when interpreting results shown in Figures 3, 4, 5, 6 since this is not a direct comparison of values for one feed against another due to different data sources, level of data available, and database limitations. Figures 3, 4, 5, 6 show that the US Animal Feed Database includes a comprehensive collection of animal feed ingredients' environmental footprint, and national average cost results, which will enable farmers using PPEFC to build a variety of swine diets.

There is a distribution of values on an interval for all indicators and one impact category with average values clustered at the bottom range of the interval (e.g., cost). Feeds can have a relatively large contribution to one indicator or impact category and relatively small to another (e.g., sunflower oil). Categories of feeds may show similar results for a specific indicator (amino acids in cost, vitamins and minerals in climate change impact).

Figure 7 shows results for seven-phase swine diet. Large inclusion rates set corn grain and soybean meal as the main contributors for all environmental footprint. Fishmeal use in nursery phase 1 (6.5%) and 2 (3%) is the largest contributor to climate change impact due to higher CO_2-e value per kg of dry fishmeal (note: no water consumption and land use data were available). Inclusion of whey and blood plasma in nursery contributes to climate change impact and for poultry fat to climate change impact and land use inventory. Small inclusion rate of DL-methionine contributes to climate change impact.

5. Conclusion

The importance of the US Animal Feed Database is to compile environmental, economic, and nutrient content in a single location and integrate it into a US LCA - economic model of swine operations. The information from this database will be used as a starting point for identifying potential mitigation options in diet formulation and integration of a linear programming algorithm into the environmental calculator to achieve the necessary nutrient composition under the constraint of least cost and least environmental footprint. During the duration of this project the database will be improved as new information becomes available, such as information gathered from Agri-footprint® (Blonk Consultants 2014). In addition, an explanatory data analysis (EDA) will be performed on the database background results using a graph and network analysis open source tool Gephi (Bastian and Heymann 2009). This analysis should maximize insight into data sets and uncover the underlying structure of the feed database for driving processes and substance. The EDA should help identify outliers and with that, ensure overall quality of the environmental footprint results as well as help to interpret and improve robustness of the results.

Challenges of comparing food and feed products from different countries of origin

Maria Bystricky*, Thomas Nemecek, Martina Alig, Gérard Gaillard

Life Cycle Assessment Group, Institute for Sustainability Sciences, Agroscope, Zurich, Switzerland
* Corresponding author. E-mail: *maria.bystricky@agroscope.admin.ch*

ABSTRACT

The environmental impacts of home-produced food and feed products as compared to imported products is a widely discussed subject. Within regions such as Central Europe, production systems are comparatively similar. Therefore, inventories representing average production in different countries have to be modeled using detailed agronomic information. In this paper, we describe our approach for compiling life cycle inventories for food and feed products from Switzerland and other European countries. For illustration we present LCA results and their most important drivers. Our results showed that following our approach permits to create inventories for different countries with comparable results, even if data availability is different. The production systems for cereals within Central Europe led to relatively similar LCA results, while the results for potatoes clearly depicted the greater intensity of cultivation in the Netherlands. Transport distances from the production site to Switzerland were decisive only for potatoes.

Keywords: domestic production vs. import, inventories, cereals, potatoes

1. Introduction

The preferability of home-produced compared to imported food and feed products is currently widely discussed in society and politics, especially with regard to the environmental implications. In order to assess the influence of origin on the environmental burdens along the value chain of products, it is necessary to compare agricultural production in different countries. However, within regions such as Central Europe, production systems are comparatively similar. Therefore, for a life cycle assessment of food products, detailed agronomic data from national surveys and other local sources are needed, rather than using rough estimates or data from international sources such as FAOSTAT or FADN, in order to obtain results that depict relevant differences between the countries realistically. However, each country has its own data collection system with its own level of detail. The challenge lies in analyzing those elements that are decisive for differences in the environmental impacts, and in securing the equivalence of systems in a comparative study according to the requirements in ISO (2006). Furthermore, the risk of introducing differences in results as a consequence of different methodologies must be minimized.

We developed an approach for compiling inventories for crops from various European countries processed in Switzerland whose results should be comparable among each other. Those inventories were then used to compare home-produced to imported products via LCA at two levels: 1. At the farm gate: wheat and barley from Switzerland, Germany, and France; potatoes from the same countries and the Netherlands, and 2. at the point of sale in Switzerland: wheat bread, feed barley, and table potatoes. The functional units were 1 kg of product at the farm gate, and 1 kg wheat bread, feed barley, or fresh table potatoes at the point of sale. In this paper, we present our approach to creating comparable inventories of food and feed products using different data sources for each country of origin. We then show LCA results for the products mentioned above, illustrating the feasibility of our approach.

2. Methods

2.1. General approach to create comparable inventories

For all countries of origin, new inventories were created, so as to be able to calculate direct field emissions and the ensuing environmental impacts for all systems with the same tool, ensuring comparability of all inventories. As an example, we compiled our own inventories for crop cultivation in France using raw data from the AGRIBALYSE database (Koch & Salou, 2013) rather than using the AGRIBALYSE inventories themselves. All calculations were done using the SALCA tools (Swiss Agricultural Life Cycle Assessment, Nemecek et al., 2010). SALCA contains a life cycle inventory database for agriculture, models for direct and indirect field emissions, a selection of methods for impact assessment, calculation tools for farm and crop inventories, an evaluation concept, and a communication concept for the results. SALCA requires a set of input data groups to calculate direct and indirect emissions for the inventories: climate and soil properties, yields and information on the crop rotation, fertilization, pesticide use, water use, and field work processes. For every data group, data were available from separate data sources with varying degrees of exactness and specificity in the countries investigated.

In order to secure geographic representativeness as well as comparability for input data, in our approach we suggest a succession of priorities: Priority 1: Data representative for the whole country are to be used if available. Priority 2: If no such data are available, data from the most important production region within the country according to their importance for the total production are to be used. Priority 3: if no country-specific data are available, data from the country with the most similar production system should be used, determining "similar" countries with information from more unspecific data sources such as FAOSTAT for each input data group. Priority 4: Data with little effect on the environmental impacts can also be taken from the SALCA default values, representative for Swiss lowlands, if the effort to collect country-specific data is deemed disproportionately great.

Regarding sources of country-specific data, or data quality, we also followed a set of rules in order to secure comparability between the countries and to ensure, at the same time, representativeness of data for the actual production in the countries: If there were reliable international sources with a quality at the same level or surpassing national data sources, which would cover several of the countries or products under investigation, we used those rather than separate country-specific data. Otherwise we looked for data from national surveys and statistics. If no such data were available, we tried to find other empirical data, or, as the last option, we made assumptions based on national recommendations, e.g. for fertilization.

2.2. System boundaries, allocation, and impact categories

Figure 1 shows the system boundaries for crop production and downstream stages (transport, processing and storage) assumed in this study. Crop production included all processes and inputs occurring on the field plus transport to the farm. Storage and processing was different for each crop: Whereas cereals were first stored at a local place of collection in the countries of origin and then again in Switzerland, potatoes were transported to Switzerland directly. Processing of wheat and barley grains took place in Switzerland. The point of sale for bread and potatoes was a supermarket; feed barley was sold directly at the feed mill.

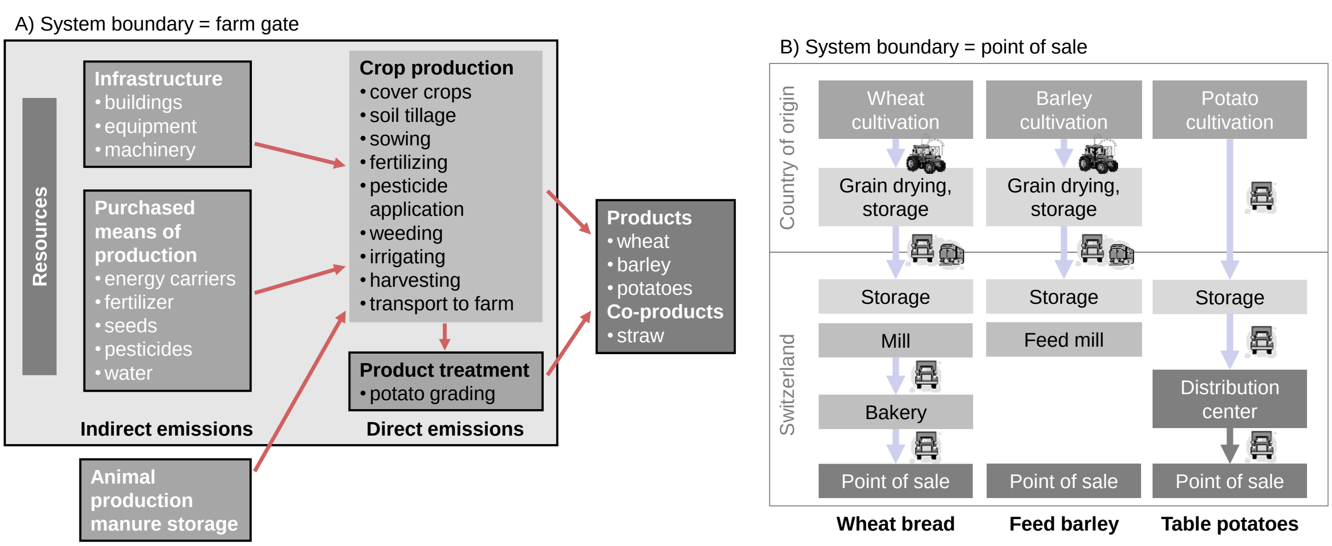

Figure 1. System boundaries for A) crop production and B) food and feed products at the point of sale.

For cereals, the environmental impacts had to be divided between the co-products grain and straw. This was done via economic allocation based on prices (average of three years).

In this paper, we show results for the impact categories energy demand, global warming potential, land competition, water use (weighted with the water stress index, WSI, described in Pfister et al., 2009), aquatic eutrophication N and P, and terrestrial and aquatic ecotoxicity.

2.3. Modelling of crop production

Precipitation and soil data were defined applying priority 2 of our approach: Precipitation data were taken from national climate observation institutions for the major production regions. For clay and humus content, values fitting results from national soil surveys were selected. Other soil data had only minor effects on the emission models; for those we used the SALCA default values which are representative for Swiss lowlands (priority 4). Yields (see table 1) and the share of crop groups in the crop rotation were available from national agricultural statistics, priority 1 being applicable.

Table 1. Crop yields in dt ha^{-1}.

	Switzerland[1)]		**Germany[2)]**	**France[3)]**	**Netherlands[4)]**
	non-extenso	**extenso**			
Winter wheat	66.0	54.7	74.9	71.0	
Winter barley	70.7	52.7	64.8	67.2	
Potatoes	389.4		413.7	449.2	469.0

Data sources: [1)]Farm accountancy data network (Agroscope), AGIS (Federal office for agriculture); [2)]DESTATIS (2012); [3)]raw data for the AGRIBALYSE database (Koch & Salou, 2013); [4)]CBS Statistics Netherlands (2013).

No statistical data were available quantifying the actual amount of fertilizer used in specific crops. Assumptions about nutrient requirement had to be made according to each country's official fertilizing recommendations in accordance with priority 1. These partly led to considerable differences in the overall nutrient requirements of the crops, mostly because the recommendations take account of soil nutrient content in different ways. Likewise, official statistics on the use of manure were lacking. For Switzerland, we had data on manure use in wheat, barley and potatoes from a group of farms which had been investigated in a previous project (Hersener et al., 2011). For France, we used raw data for the AGRIBALYSE database (Koch & Salou, 2013) which contains inventories representing average wheat, barley and potato cultivation based on statistical data and expert estimates. According to FAO (2013), livestock density and farming structures in Germany and the Netherlands were comparatively similar to France and different to Switzerland. Following priority 3, we estimated organic fertilization in Germany and the Netherlands by extrapolating manure use from the French inventories according to livestock density. Likewise, the amount of straw removed from the wheat and barley fields was assumed to be the same in Germany as in France. Table 2 shows our assumptions for fertilization.

Table 2. Assumptions for nutrient requirement and manure use in Switzerland, Germany, France, and the Netherlands.

		Switzerland[1)]		**Germany[2)]**	**France[3)]**	**Netherlands[4)]**
		non-extenso	**extenso**

	Solid manure (cattle, pigs, poultry) (t ha^{-1})	4.7		6.2	4.9	17.7

Data sources for nutrient requirement: [1)]Flisch et al. (2009); [2)]KTBL (2012); [3)]raw data for the AGRIBALYSE database (Koch & Salou, 2013); [4)]WUR (2012).

For pesticide use, we could use data from national survey programs (priority 1). However, these were collected with very different levels of detail and in different time periods in the countries investigated. Swiss data were collected by Agroscope in 2009-2010 at 70-260 field plots, depending on the crop. Data on pesticide use in Germany originated from 37-825 field plots in the years 2007-2011 and were provided by the Julius Kühn-Institut. For France, we used raw data from the AGRIBALYSE database, while the Dutch statistical office provided us with results on pesticide use from 6'822 potato-growing farms in the Netherlands in 2008. In each case, we removed from the input list active ingredients which were only used on a small fraction of the fields so as to avoid distortions of results caused by rarely used and therefore non-representative pesticides. Likewise, we removed active ingredients which were no longer permitted in 2013, according to each country's register of authorized pesticides. Those removed active ingredients were then included into the inventories as "pesticide, unspecified", using average toxicity characterization factors.

Following priority 1, assumptions for the type and number of field work processes were based on national marginal return calculation resources (Boessinger et al., 2011, KTBL, 2012, WUR, 2012), and from the raw data for the French AGRIBALYSE database. The AGRIBALYSE database also contains inventories of field work processes, composed of machinery and diesel consumption adapted to agricultural structures in France. At the same time, the SALCA database contains field work process inventories representing Swiss structures, i.e. smaller machines and higher diesel consumption per hectare due to smaller fields. We worked with the SALCA inventories for Switzerland, while at the other countries we worked with the AGRIBALYSE inventories (priority 3). Lastly, data on water use came from Pfister et al. (2011), who estimated average water consumption for a multitude of crops and countries. We used the "blue water deficit", which is derived by multiplying the theoretical water requirement of the crops by the percentage of surface under irrigation for each country and crop.

2.4. Modelling of transport, processing, and storage

Table 3 gives an overview of the means of transport and the transport distances we used in our calculations. Grain storage was assumed to be six months, half of which took place in the country of origin, the other half at the mill in Switzerland. We used ecoinvent inventories for storage, changing the electricity mix to cover the two storage locations. Grain milling (bread wheat and feed barley) was modelled by adapting the inventory "barley, at feed mill" from the ecoinvent database with expert estimates on electricity, gas, and water use. Processing in the bakery was modelled using inventories from the Danish LCA Food database (Dalgaard et al., 2004).

Potatoes from all countries were assumed to be stored with cooling, in Switzerland for 125 days. The ecoinvent inventory for seed potato storage was used, adapting electricity use according to expert estimates.

Table 3. Means of transport and transport distances for wheat, barley and potatoes from the investigated countries of origin.

Crop	Transport route	Means of transport	Transport distance (km) for crops produced in			
			Switzerland	Germany	France	Netherlands
Wheat[1)]	Farm – local storage	Tractor and trailer	10	25	25

3. Results

In general, the agricultural phase dominated most of the environmental impacts. Key factors in the comparison were therefore mostly to be found in the differences between agricultural production in Switzerland and abroad. In a few cases, however, there were also major differences in the downstream stages, particularly with regard to energy demand and global warming potential.

Regarding wheat cultivation, most of the environmental impacts of Swiss wheat were comparable to those of German wheat, but compared to French wheat it was to be rated less favorably regarding many impact categories. Figure 2 shows results for wheat cultivation. In Switzerland, only water use was considerably lower and hence more favorable than in the other countries. Energy demand and global warming potential were higher due to higher machinery input and lower yields in Switzerland as compared to Germany and France. Yield differences were also decisive for land competition. Dates for fertilizer application and differences in the amount of rainfall in winter accounted for slight differences in aquatic eutrophication through N. French wheat caused lower aquatic eutrophication through P because of the low P fertilizer requirement in France. Terrestrial and aquatic ecotoxicity were largely influenced by pesticide use, with very few active ingredients causing most of the impact.

The assessment of bread at the point of sale was consistent with that of wheat cultivation. Although in most instances processing the wheat to bread failed to change the ranking of the countries, the percentage differences between the countries decreased. Transportation had a slightly adverse effect in imported wheat in terms of energy demand and global warming potential.

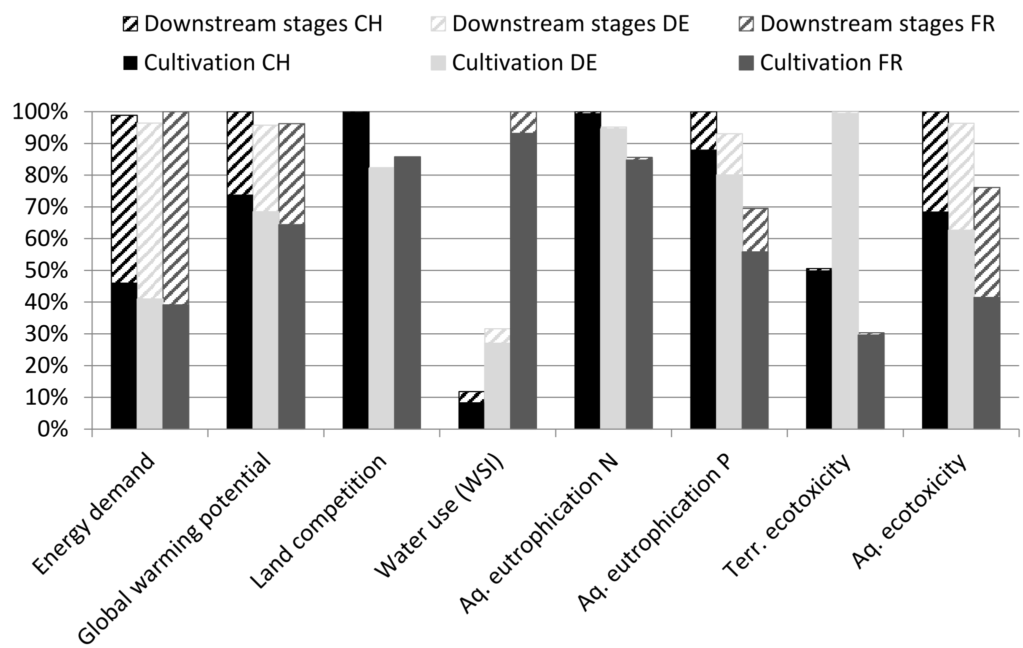

Figure 2. Comparison of the environmental impacts of bread produced from Swiss (CH), German (DE) and French (FR) wheat, at the point of sale in Switzerland. WSI: water stress index.

Results for barley cultivation were comparable to those for wheat cultivation. Nevertheless, Swiss barley was assessed more favorably than Swiss wheat compared to Germany and France, as yield differences between the countries were smaller. Barley from Switzerland required less water than imported barley and had lower ecotoxicity results than French barley (Figure 3). Regarding the remaining impact categories, however, French barley in particular frequently scored more favorably, while German barley was for the most part comparable to Swiss barley. The impact of machinery on energy demand and global warming potential was lower in Germany and France than in Switzerland, which was partly counterbalanced by higher energy demand for irrigation and fertilizer production. Lower P fertilizing requirement in France caused lower aquatic eutrophication P. The use of specific pesticide active ingredients caused differences in ecotoxicity, but fertilizer input, machine usage, and electricity use for irrigation played a role, too. At the point of sale, the country ranking was largely the same as at cultivation level. Shifts in the ranking, for example in energy demand and global warming potential, were caused by different transport distances but were not rated as significant. The share of downstream stages in the environmental impacts of the overall chain was considerably lower for feed barley than for wheat bread, as processing into feed is less complex than bread production.

In potato cultivation, notable differences between Switzerland and Germany were found only in a few environmental impacts (Figure 4). Slightly higher inputs per hectare were offset by higher yields in Germany. Several environmental impacts of cultivation in France were assessed more favorably than in Switzerland, but still both countries were not markedly different for the most part. In France, yields were also higher than in Switzerland, and there was less use of machinery per kilogram of potatoes. Dutch potatoes, in contrast, tended to score worse than those from other countries, particularly regarding nutrient-related environmental impacts. Higher N input, higher organic fertilization, and pesticide use had adverse effects for Dutch potatoes. A better rating could be achieved in aquatic eutrophication P because of the low P fertilization requirement. However, high environmental impacts per hectare were partly offset by higher yields in the Netherlands. At the point of sale the downstream processes, particularly transportation, had a major influence on many environmental impacts. Compared to cereals, this was mainly due to considerably lower environmental impacts per kilogram of produce at the farm gate level. Consequently, regarding the transport dominated impact categories (energy demand, global warming potential, acidification potential), Swiss potatoes rated considerably more advantageously than imported potatoes. In other impact categories, potatoes at the point of sale still followed the rating of the cultivation stage.

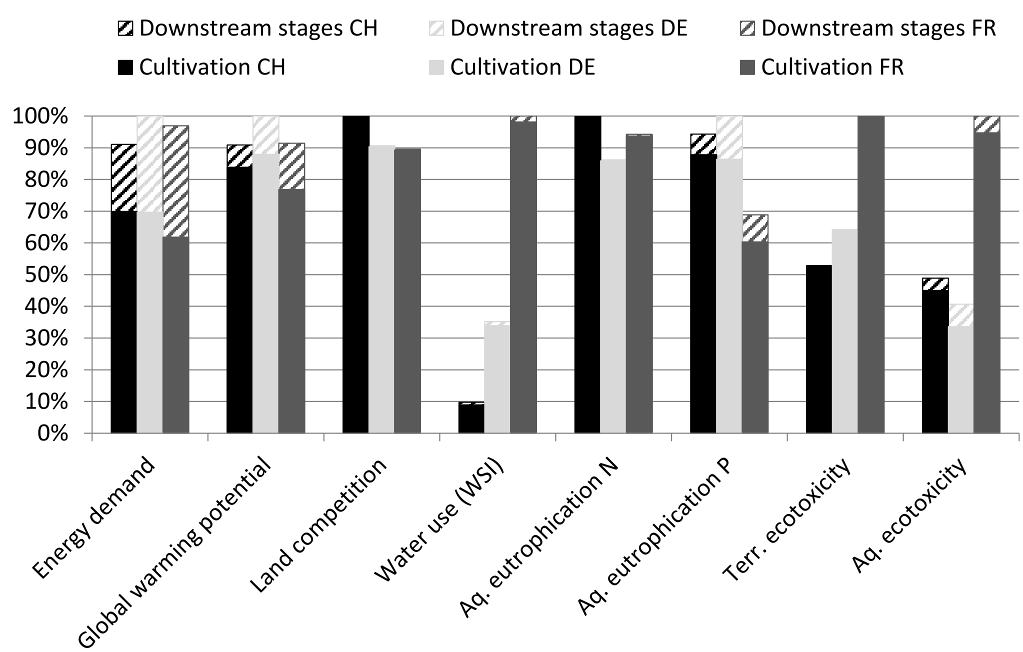

Figure 3. Comparison of the environmental impacts of feed barley from Switzerland (CH), Germany (DE) and France (FR), at the point of sale in Switzerland. WSI: water stress index.

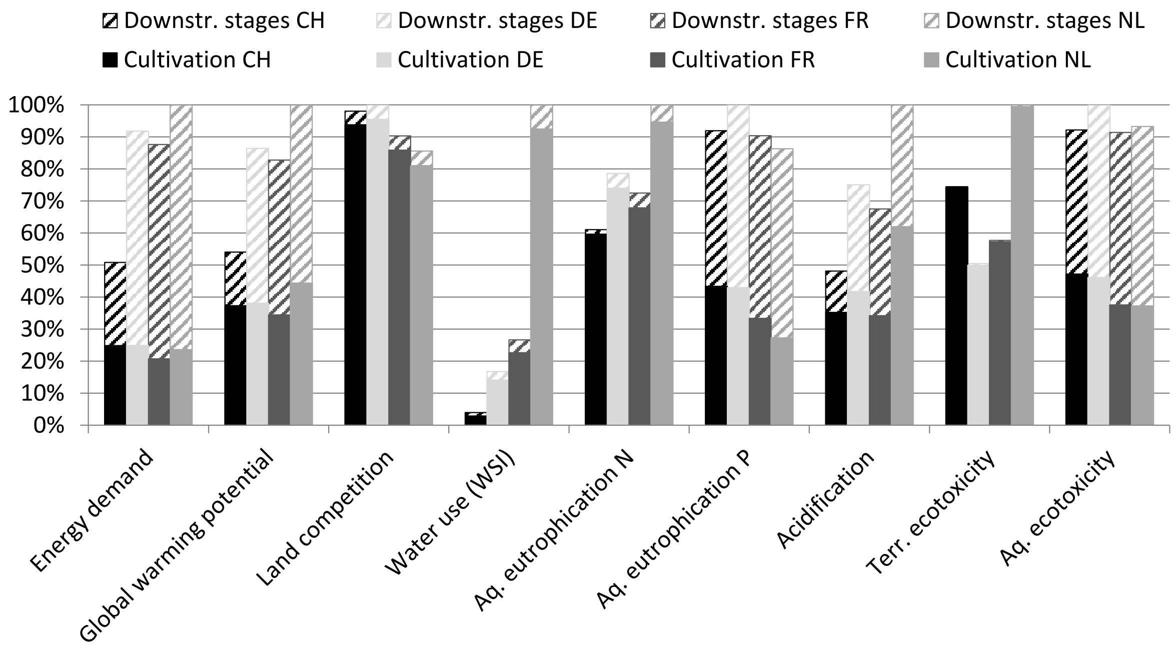

Figure 4. Comparison of the environmental impacts of table potatoes from Switzerland (CH), Germany (DE), France (FR) and the Netherlands (NL), at the point of sale in Switzerland. WSI: water stress index.

4. Discussion

Transport distances can give domestic products a systematic advantage, or at least shift results slightly in their favor, leading to a better rating of home-grown potatoes as compared to imported potatoes. The cultivation stage, however, had a decisive influence on the country rating order in most impact categories, especially for wheat bread and feed barley.

Several major drivers for the evaluation of the cropping stage became apparent. Among these were machine use and fuel consumption. We assumed that in Switzerland fields as well as machines were smaller than in other European countries, which lead to higher impacts of machine use in Swiss production. Indeed, Switzerland ranks among the countries with the highest degrees of mechanization worldwide (Roches et al., 2010), which is clearly reflected by our results.

Water use was the only impact where Swiss production had a systematic advantage compared to the other countries. In addition, irrigation water consumption can have a decisive impact on energy consumption, e.g. for potatoes grown in Switzerland or the Netherlands. The figures we used for irrigation in this study were all taken from the same source, presenting a good basis for a valid comparison between countries. Still they are only estimates that may not always be consistent with water use in reality. Data on irrigation from empirical studies and international statistics (Weber & Schild, 2007, DESTATIS, 2010, FAO, 2013) which were available only for some of the investigated crops and countries point into the same direction that irrigation in Switzerland tends to be lower than in Germany, France, or the Netherlands.

The amount of mineral and organic fertilization affected several environmental impacts significantly. The production of mineral fertilizers and the height of nutrient requirement influenced energy demand, resource use P and K, aquatic eutrophication with P, aquatic ecotoxicity and, partly, human toxicity, while the amount and type of organic fertilizer accounted for differences in terrestrial eutrophication and acidification potential. Using the same type of data source for fertilizer requirement in each country lead to systematic differences, as the national recommendations were based on different assumptions regarding soil nutrient content and requirements per kg crop yield. Thus, P and K requirement was considerably lower in France and in the Netherlands than in Switzerland or Germany. According to EC (2013), phosphorous surplus in soils is particularly high in Switzerland as well as in the Netherlands. If nutrient content of soils would be considered in a uniform manner for all countries, the results of some impact categories could shift. Furthermore, farmers do not always follow fertilization recommendations. In reality the amount of fertilization may differ considerably from the recommendations, leading to different results for the corresponding impact categories. Modelling country averages, the recommendations do already lead to country-specific differences, but investigating data from a farm network would produce more realistic results that could probably vary even more.

For toxicity results, the pesticides applied played a major role. Rather than the overall amount of pesticides, single active ingredients were decisive for the results. Crop-specific data from national surveys were available in all countries, though the scope of those surveys was very divers, leading to great gaps in data quality. We adjusted those differences between the countries by excluding active ingredients which were used only on small proportions of the land or which were not permitted to be used any more in 2013, thus reaching a good level of comparability. Still results might differ from our findings if comprehensive, nationwide surveys were available for all countries.

Lastly, crop yield in the investigated countries was an important parameter for many results. Yield differences between the countries were biggest for potatoes. Negative effects of the input-intensive potato cultivation in the Netherlands were largely offset by higher yields. Yield data were based on resilient data sources which provide great security for this part of the calculations.

5. Conclusion

Our results showed that if our suggested set of priorities for compiling inventories are followed it is possible to create inventories for different countries with comparable results, even if data availability in the countries is quite different. The production systems for cereals within Central Europe led to similar LCA results, while the results for potatoes clearly depicted the greater intensity of cultivation in the Netherlands (higher yields, more organic and more N fertilizer). Furthermore, transport distances were decisive for potatoes. In order to achieve results that are comparable on the one hand and appropriately reflect differences for countries with similar crop production systems on the other hand, it is necessary to treat each group of input data in detail.

With this study we could also point out the importance of high data quality for a systematic and correct comparison between countries. In spite of considerable effort to obtain valid data, we still had to make a lot of assumptions. To increase data quality as well as representativeness of data for the countries, a comprehensive European network of farms would be necessary to collect detailed agronomical data using the same methodology.

ABSTRACT

Poor cattle health reduces productivity, increases mortalities and reduces welfare. These impacts have economic costs, but also increase environmental impacts per unit output. We report the first application of systems-based life cycle assessment (LCA) to modelling the impacts of ten endemic conditions in the UK and their control on GHGE per unit output.

The worst within-herd impacts for milk and beef were Salmonella, bovine viral diarrhoea (BVD), and Johne's disease, increasing GHGE by up to 25% above the healthy baseline. For all conditions, the reductions in GHGE enabled by intervention leading towards recovery were greater than the additional GHGE burdens of implementation. The greatest within-herd reductions were for Johne's, Salmonella and BVD, which may show reductions of up to 20%, while mastitis and lameness are more difficult to treat effectively and thus reduce emissions. Sensitivity analysis showed that effectiveness of interventions was a significant factor in GHGE reductions.

Keywords: cattle health; greenhouse gas emissions; welfare, endemic diseases, systems-modelling

1. Introduction

Poor cattle health reduces productivity, increases mortalities and reduces welfare. These impacts have both economic costs and thus incentives for improvement (Bennett, 2003). However, the environmental impacts of these losses have received little consideration (Stott et al., 2010), although there are expectations for reducing greenhouse gas emissions (GHGE) from cattle production (e.g. GHG Action Plan for England). Reduced productivity can adversely affect greenhouse gas (GHG) emissions (GHGE) per unit output. Veterinary or managerial interventions to mitigate the ill-effects of poor health may themselves cause additional GHGE, e.g. production and delivery of medicine or civil engineering methods to improve welfare. This paper addresses the impacts of ten endemic cattle diseases or conditions on GHGE per unit output, as well as the net benefits of interventions to reduce the impacts of these conditions, using a life cycle assessment perspective and drawing on both statistical and expert veterinary experience. It was part of a wider project, in which the economics of abating GHGE through improved cattle health were evaluated, aiming to understand whether emissions can be reduced in the UK national cattle sector in a cost-effective way by implementing measures to control endemic diseases or conditions.

2. Methods

Expert surveillance and practice veterinarians used statistical and published data, and expert judgement to quantify impacts on productivity, morbidity and mortality. These were translated into parameters to enhance the Cranfield Agricultural Systems-LCA model (Williams et al., 2006). The systems-based nature of the model enabled these impacts to be applied as individual parameters, including increases in mortality rates, reductions in milk yield, daily liveweight gain (DLWG), and fecundity, and increases in feed requirements. A baseline case for healthy cattle was also established, against which the impacts of the conditions could be quantified. This still allowed for mortalities from accidents or other factors, e.g. during calving as well as normal biological variability. These were developed with much veterinary input and the main features were resolved, as shown in Table 1. These represent performance that is above that of the average recorded activity data for UK cattle, as these would be expected to be affected by the ten endemic conditions as well as others outwith this study, e.g. ketosis or tuberculosis. The structure of the LCA model is such that animal production is split by system and age of animal, thus enabling the impacts of diseases to be applied to individual parts of a system or age group. For example, mastitis impacts can be applied purely to the dairy herd, while replacement heifers or beef calves are unaffected and can be modelled as such.

Table 1**.** Main features of cows in the healthy cattle scenario

System	Feature	Values
Dairy	Mortality	1%
	Number of lactations	6
	Lactation yield,	7875
Beef	Mortality	1%
	Number of lactations	8

A set of interventions or mitigation measures was compiled by the veterinarians and the effectiveness of each measure in treating a disease was estimated. These interventions ranged from veterinary, e.g. vaccination or antibiotics; management e.g. better oestrus detection or biosecurity; to engineering, e.g. limestone cow tracks, improved housing ventilation, or pasture drainage. These were applied in the LCA model to calculate the GHGE associated with implementing each intervention. For example, estimates were made as to the number of veterinary visits and treatments that may be required for a given condition, and quantities of raw materials such as ground limestone or sand bedding to improve conditions such as lameness and mastitis were derived. The effectiveness of each measure in treating a disease was estimated to calculate the extent of potential recovery for an infected animal or herd to be returned to the healthy baseline case.

The conditions have different impacts, which thus require different approaches. Reduced growth rate reduces intake commensurately and more time is needed to reach the same end point, so increasing the proportion of energy used for maintenance. Reduced milk yield is more complex. While reduced (e.g. through lameness), energy demand is reduced, but after recovery, the overall lactation yield also depends on management choices. Increased mortality rates were carefully assessed and the model enhanced to allow for more time-critical specification, e.g. higher calf mortality rates increase the number of calf births needed for herd replacements. These tend to occur at a lower age, rather than randomly. So fewer resources are wasted and lower GHGE are incurred than if a random age at death is assumed. Reduced fertility was represented by increasing the calving interval (and increasing AI servicing in dairy cattle). This was based on a stochastic analysis of conception rates. Fighting infection through mounting an immune response demands more energy and effectively increases the maintenance demand for metabolisable energy (ME). There is a lack of evidence on the quantification of ME needs for fighting infection. Conservative estimates were thus made of the expected current levels in commercial herds and how much could be expected for each condition. It must be noted that these ME needs can be high over a relatively short time scale, but are very unlikely to affect, for example, a beef suckler cow for all her life.

3. Results

The GHGE from healthy dairy cows were 0.89 kg CO_2e per kg energy and fat corrected milk. The current national herd performance is 6% higher at 0.94 kg CO_2e. The overall results (ranked by impacts of each single condition) cause increases in the GHGE per unit milk of up to 24%, i.e. for Johne's disease (Figure 1). The maximum impacts for Salmonella, BVD and infertility were also high at 16 to 20%. Liver fluke, IBR, Lameness and Mastitis have more moderate impacts in the range 7 to 10%. Calf diarrhea and pneumonia only affect herd replacements and so have a relatively small impact on GHGE from milk production. These values are the maximum impact for a herd and do not account for prevalence rates, which would reduce the impact nationally. They do, however, indicate clearly how herds can be adversely affected by these conditions and highlights the need for interventions for both welfare and environmental reasons. Of the three highest impacting conditions, infertility is probably most affected by normal management factors, e.g. identifying oestrus in early lactation.

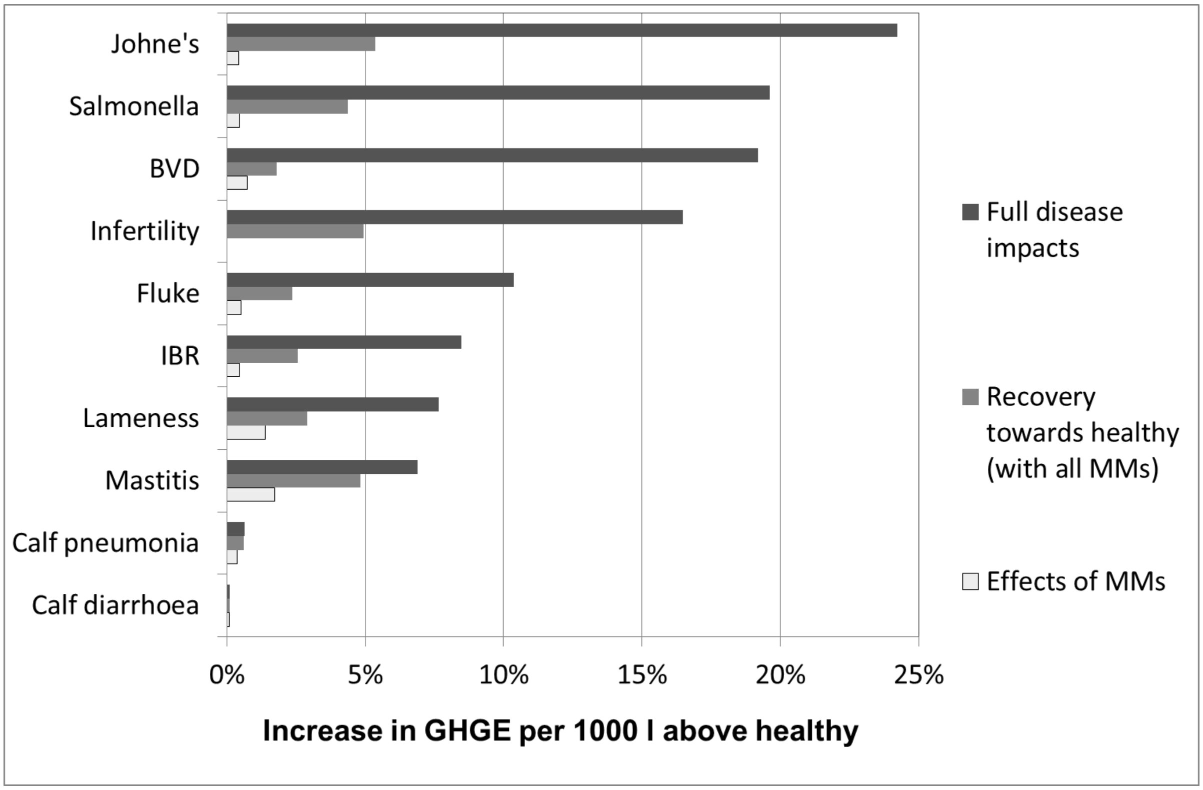

Figure 1. Results for dairy showing percentage increase in GHGE per 1000 l milk above a healthy baseline.

For suckler beef, the GHGE for 1000 kg beef carcass from a healthy herd was estimated to be 17.1 t CO_2e. The current national herd performance is 6.6% higher at 18.2 t CO_2e. The overall results (ranked by impacts of each single condition) cause increases in the GHGE per unit beef carcass of up to 113%, for BVD (Figure 2). This is followed by Johne’s (at 40%), Salmonella, infertility and IBR (at 20% above healthy). Again, these are the maximum farm-level impacts and do not include between-herd prevalence. As with milk, the combined interventions obtained substantial benefits for most conditions. The effectiveness was varied and, for most, reduced the impacts by about 70% of the increase above healthy. Dairy beef results were significantly lower as the breeding phase is accounted for in milk production. BVD remained the worst condition, increasing GHGE by 14% of the healthy baseline for dairy beef production.

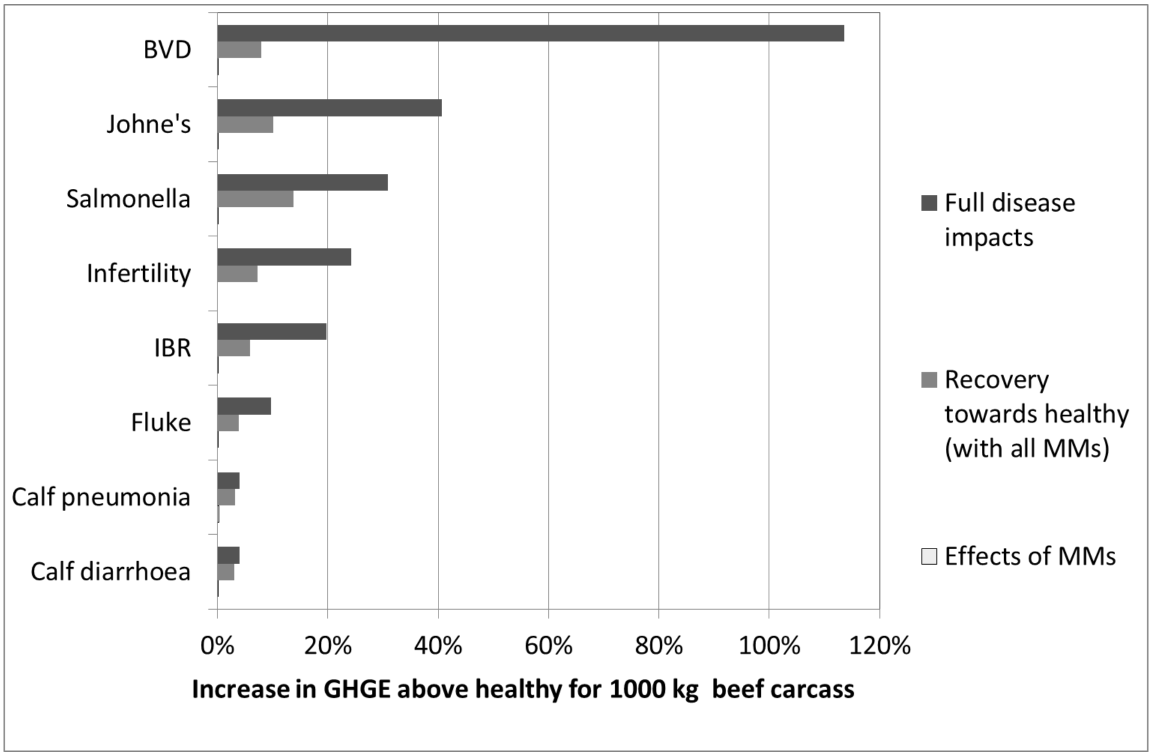

Figure 2: Results of the maximum effects of conditions on GHG emissions from suckler beef production together with the maximum recovery from interventions and the impacts of those interventions themselves.

4. Discussion

The combined interventions clearly produced substantial benefits for top eight conditions and reduced the increase in GHGE caused by the conditions in the range 2% to 5%. Apart from the two low-impacting calf conditions, mastitis is the most difficult to treat effectively and BVD is the least. This does not address economic cost: only the technical feasibility of veterinary, managerial and engineering interventions.

The sensitivity of individual disease impacts on GHG emissions per functional unit were tested by varying the value of one selected parameter in turn by ±10%. For dairy, GHGE per unit milk increased by varying amounts from 0.02% (cow mortality) to 6.2% (extending the calving interval). For beef the effect of increasing metabolisable energy requirement (MER) for both suckler cows and calves have the most substantial effects on GHGE.

A sub-set of mitigation measures were investigated for sensitivity of response. The results ranged from a 0.1% increase in GHGE for veterinary visits to 0.45% for more daily sand use in cow cubicles to reduce the incidence of mastitis. Increasing building replacement rate fell between these measures at 0.13%. Although the environmental investment in a new building is large *per se*, the lifespan is relatively long, at an assumed 25 years, so that the impacts per animal are relatively small.

The systems-based LCA model relies on the disease impact data and expert judgement on the extent to which treatments temper this. In order to provide these estimates, the concept of a healthy animal was used as a reference point and the veterinary experts in the team populated the parameters for each state – healthy, diseased and treated. These data are necessarily informed estimates and do not reflect the considerable variability that would be seen in each of these states on farms. The ambition was to provide a reasonable central estimate which can be modelled to provide high-level analysis of GHGE between conditions.

While previous research has indicated that lameness and mastitis are among the most economically significant endemic cattle diseases, notably in the UK dairy herd, limited GHGE abatement is offered from the controls considered in this study. This owes much to the modest change in productivity parameters which drive GHGE, notably mortality and yield; there is a reasonable degree of additional uptake of controls for these conditions (around 10%).

The key opportunities in terms of GHGE abatement available appears to be with IBR, liver fluke and Johne's disease. These rely on levels of uptake of the controls combined with moderate to high disease impacts on GHGE, while BVD, Salmonella, infertility and some mastitis controls offer moderate abatement levels, combined with moderate to high levels of control uptake.

5. Conclusion

The use of systems-based LCA allowed the effect of individual disease impacts to be quantified and presents scope for application to further diseases (and species). There is further scope to extend the model to consider the interactions between conditions and also between intervention, which would require significant veterinary input and investigation. The findings show the added value in improving cattle health in terms of both productivity and reducing GHGE. The potential to improve animal health and welfare is considerable and is a good example of sustainably increasing production.

ABSTRACT

Eco-labels serve as a means to narrow the information gap between producers and consumers with regard to the environmental impact of consumer choices. Whether they are successful is open to debate because of credibility issues, one of which is the specificity of the label: is the label specific to the particular item labelled (e.g. a cut of meat from a specific cow, milk from a particular farm) or the class of items (e.g. beef produced in a country in general, milk from a co-op). Most eco-labels do not provide consumers with information about the specific food products they choose because tactical and operational management decision are not captured in the life cycle inventory collection process, and are usually a historical snapshot from a time in the past. This paper reviews the spatial and temporal aspects of current eco-labels, and assesses the potential to decrease the producer-consumer information gap as farm ICT is developed as part of routing farm management.

Keywords: Eco-label, credibility, ICT, LCA

1. Introduction

In recent decades consumers have started to demand more information about the environmental impact of food products, especially in developed countries represented by organisations such as OECD. Consumers are increasingly willing to buy “environmentally friendly” food products, even if they are more expensive than the market norm (Brécard et al. 2009). At the same time, national policies are driving producers to reduce environmental impacts. Together these have driven demand for informative labelling. Early studies on “environmental labelling” found a wide range of labels with very different meanings and validity (OECD 1991). In 1993, the General Agreement on Tariffs and Trade (GATT) Secretariat differentiated between ‘environmental labelling’ that reflected any type of claim and ‘eco-labelling’ that used life cycle methods (GATT. 1993). Eco-labels are usually voluntary and convey information to consumers about the full life cycle environmental implications of their choices, but the specificity in terms of impact, product and geography can be unclear.

Life Cycle Assessment (LCA) is a tool to assess the potential environmental impacts and resources used throughout a product lifecycle, i.e., from raw material acquisition, via production and use phases, to waste management (ISO14040:2006). As a comprehensive assessment, LCA considers all attributes or aspects of natural environment, human health, and resources (ISO14040:2006), and avoids problem-shifting. There are an increasing number of eco-labels using life cycle methods, though many of them do not follow the LCA standards (ISO 14040/14044). For these eco-labels, the spatial and temporal scale over which they apply is not clear, as is the case for many LCA studies. This can be important in terms of both the impacts and the activity data.

Emerging EU research on deployment of Information and Communication technology (ICT) for agriculture is investigating whether massed sensor technology combined with cloud data sources (sometimes known as the “Internet of Things”, IoT) can provide real-time data for decision making to optimize profit, environmental impact and welfare (for example the ERA-net, Agri-ICT project ‘Sustainable Integrated Livestock Farming’, SILF). SILF is evaluating the concept of using data from sensors with a high spatial and temporal resolution, combined with national databases and life cycle methods to define algorithms for real-time decision support based on the environmental impact of the decision. As such technology develops from concept to application, the question arises whether eco-labelling convey appropriate spatial and temporal information about the specific product being labelled.

This study investigated the how spatial and temporal scale is considered by current eco-labels and evaluated whether integrating the ICT systems and life cycle assessment at farm level may have implications for future eco-labels and the information they convey.

2. Methods

The investigation used three evaluations: (i) review of eco-label types and assessment of scale specificity at the macro level, (ii) evaluation of some example labels commonly used in Europe, and (iii) evaluation of an example farm system, low-cost, grass-based, rotational milk production, for scale specificity and the potential of IoT to permit more specific label information.

2.1. Review of label types

The current status of eco-labels was reviewed. There are three types of eco-labels defined: Type I, Type II and Type III. A comparison with respect to criteria, metrics, standards, verification processes, and spatial and temporal considerations was undertaken. Key issues were identified.

2.2. Evaluation of example eco-labels

Three Type I eco-labels used for food and agricultural products in OECD countries and the Type III international EPD system were evaluated. The selected labels claim to contribute to improved agricultural sustainability. The labels used were:

a) the ***Carbon Reduction label*** was developed by the Carbon Trust, based on the PAS2050 standard and Footprint Expert(TM). The certification uses life cycle assessment including production, use and disposal. The certification must be undertaken every two years and prove that real reductions have been made.
b) the ***MK*** (the abbreviation for Milieukeur) label, was developed in 1995 by Stichting Milieukeur (SMK) using a credit system with points to reward some actions and penalize others. To be eligible to use the MK label, a producer is obliged to have a positive score at the end of the season, both for the company and for each product. The label is based on life cycle methods but not LCA as such.
c) the ***KRAV*** label was first used in 1985 based on IFOAM (International Federation of Organic Agriculture Movements) Basic Standards to fulfil EU regulation (EC) No 834/2007. It is based on life cycle thinking, including environmental impacts and energy consumption.
d) an ***EPD*** (Environmental Product Declaration) is a Type III environmental declaration in accordance with ISO 14025. The EPD system is international, compatible with all types of goods and services, third party verified and a flexible source of information. It is LCA based with defined Product Category Rules (PCR) defined for classes of products that can then be used for the LCA modelling of a specific product.

2.3. Farm system example

Low-cost, grass-based, rotational milk production was taken as an example of a farming system in which tactical and operational decision can have significant influence on the environmental impacts that occur. The system diagram from (Casey & Holden 2005) was evaluated with respect to spatial and temporal specificity.

3. Results

3.1. Label types

Type I labels refer to the environmental quality of a product compared with similar products (or production process) and are meant to encourage a switch towards more environmentally friendly consumption habits. These labels are the result of third party certification programs (usually government supported), and are voluntary. The guiding principles for eco-labels follow ISO 14024, which has more specific requirements than ISO 14020 (ISO14024:1999). Type I labels need to include all stage of the life cycle from resource through extraction, production, distribution and use phase to disposal. Spatial and temporal requirements are not specified in detail, but consideration of relevant local, regional, and global environmental issues when establishing defining criteria and revision period must be specified. ISO 14024 indicates that the ranges and variability of the data obtained for specific products should be analysed to ensure that the selected product environmental criteria are adequate and reflect the differences among and between products. This means that a minimum spatial and temporal resolution should be specified for data quality. Common examples of Type I eco-labels include Nordic Swan and Blue Angle in Europe, but these do not include a specific agriculture or food product category.

Type II labels are self-declarations made by the manufacturers, importers or distributors and refer to specific attributes of the products (like "CFC free", recyclability, degradability and so on). Since these labels are without third party verification, some assurance of reliability is essential. In addition to the requirements of ISO14021, the Type II labels should also follow the principles set out in ISO 14020. ISO 14021 requires Type II labels to take into consideration all aspects of the product life cycle in order to identify the potential for problem shifting. This does not necessarily mean that a life cycle assessment must be undertaken. There are no clear guidelines with respect to spatial and temporal other than stating that the area should correspond to the expected environmental impact and that for comparative claims the calculation should cover an appropriate period such as 12 months (ISO14021:1999). Common examples of Type II labels include Energy Star and WaterSense.

Type III labels are voluntary programs that provide quantified environmental data about a product, under preset categories of parameters set by a qualified third party, based on life cycle assessment, and verified by users or a qualified third party. A typical example is Environmental Product Declarations (EPD). Type III labels are primarily intended for use in business-to-business communication, but under certain conditions, they can be used for business-to-consumer communication (ISO14025:2006). They specifically use the ISO 14040 series of standards either following a complete LCA including goal and scope, inventory analysis (LCI); impact assessment (LCIA) and interpretation or incomplete LCA restricted to goal and scope, LCI and interpretation. There is no clear requirement for spatial and temporal scale to be addressed except to clarify the scope and to define limits, for example, to a certain geographical area. Since Type III labels are based on LCA, the requirement for spatial and temporal specificity should be applied as in ISO 14040/14044. Any lack of spatial and temporal specificity in the LCI introduces uncertainty in the LCIA results. For example, in a milk production system, changes to animal management or fertiliser and slurry application timing can lead to significant change in impact (as discussed later). Currently, the number of Type III label in market is still small. Use in Europe is increasing through the EPD system.

At present, Eco-labels are poorly specified in terms of spatial and temporal detail (Table 1), but recent ICT advances leading to the concept of the IoT might change this. Traceability and sell-by information for specific packaged items are offered to consumers as reliable information so it should also be technically possible for more specific environmental information to be conveyed on labelling.

Table 1. Comparison of the labels types

	Type I	Type II	Type III
Criteria metrics	Multiple	Single	Multiple
Extent of life cycle	Life cycle considered but need not be complete	Life cycle considered but need not be complete	Life cycle assessment, usually complete
Third party verification	Yes	No	Yes
ISO Standard	ISO14024	ISO14021	ISO14025
Spatial aspects	General product characteristics, not specific to the labelled package	Area of environmental impact not specific to the labelled package	Same requirement in ISO 14044
Temporal aspects	General product characteristics not specific to the labelled package	No clear requirement	Same requirement in ISO 14044

A further consideration is that most eco-labels are designed for a specific region or country, which means for example that eco-labels for the China market can be quite different to eco-labels for Europe (UNOPS 2009). (Cohen & Vandenbergh 2012) suggest that the entire life cycle of a product being labelled should be described according to an international standard for measurement and reporting and that once a product meets set criteria, producers can use the eco-label logo for a fixed period of time. Knowledge gained through use of ICT and IoT is increasingly revealing that management and production process change, thus making the label inaccurate. As the technology exists to capture space and time specific data about food products (from precision agriculture technology, activity reporting for regulators and increased ICT use on farms) this weaknesses of eco-labels should be overcome by developing systems to capture real-time data and link it to mass flow during processing.

3.2. Specific examples

The characteristics of the selected eco-labels (Table 2) indicate that all have a relatively loose consideration of spatial and temporal scale that reflects historical technological competence. EPD, which uses ISO 14044 requires specific consideration of spatial and temporal differentiation of the characterization model relating the LCI results to the category indicator and consistency of the spatial and temporal scales of the environmental mechanism and the reference value, but is not specific with regard to the activity data. The Carbon Reduction label that use PAS 2050 requires the time of coverage (age of data and collection period) and geographical specificity (location of collection) to be specified, but this result is then applied to the class of products rather than being product specific.

Table 2. Characteristics of selected Eco-labels

Name of label	Country	Spatial Scale	Temporal Scale	LCA based
KRAV	Sweden	From regional to national	Production phase, historical	LC perspective
Carbon reduction label	International	Product type	Specific to product, historical	LCA
MK	South Africa/EU	National scale, specific to company and product type	Production phase, historical	LC perspective
EPD	International	Same as LCA	Same as LCA, historical	LCA

The life cycle thinking labels (KRAV and MK), do not use LCA but should covers all aspects of production from raw material extraction to production, distribution, use phase and disposal. Spatial and temporal considerations are not clearly stated other than to specify location of production for food categories. MK relies on national data, but for KRAV spatial scale depends on product category. The temporal scale in KRAV and MK only considers the growth stage of products and is historical. Farm ICT and IoT has the potential to improve the information conveyed by the Carbon Reduction label by providing time and location specific data for modelling and labelling. Similar possibilities arise for KRAV and MK. Real time data from sensing, ICT and IoT can be specific to an item within a product class or can be temporally current for classes of product, thus bringing better information to the consumer.

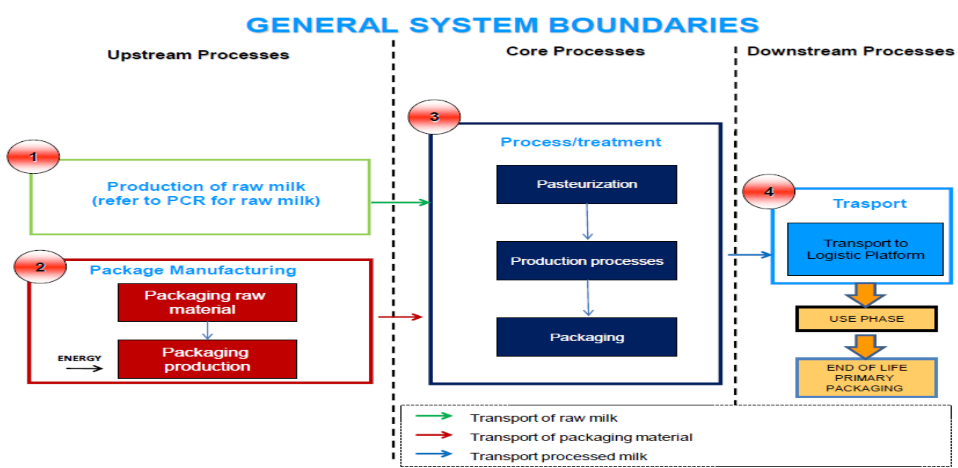

Figure 1. System boundary for Product category rules (PCR) of processed liquid milk and cream

Taking diary products as an example of an EPD, the life cycle has two distinct stages, cradle-to-farm-gate and farm-gate-to-consumer (EPD 2014) (Figure 1). As for many food products, the raw product (in this case milk) production is the main contributor to environmental impacts. The spatial specificity will be limited to the contributing farms, or a sample of the types of farms, while the temporal specificity will be historical, but the sampling period can be of various. A label derived from this system boundary will be spatially specific and historical for packaging and processing, but only the most general information can be included in the downstream processes because a label cannot reflect specific consumer behaviours. It should be made clear however what population the downstream data are derived from as shopping behaviour, transport distances and usage patterns will influence the outcome for this stage.

3.3. Farm system example

The avarage Irish milk production system from “gradle to farm gate” (Figure 2) describes a low-cost, grass-based, rotational dairy system (Casey and Holden, 2005). This system is assumed to be composed of five units: (i) concentrate feed, (ii) fertiliser, (iii) livestock, (iv) manure management and (v) energy. There are different spatial scales using in each part of the system diagram.

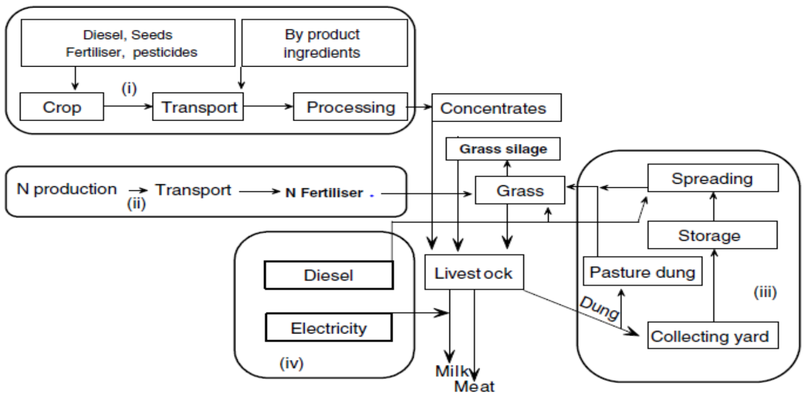

Figure 2. A flowchart of the ‘‘cradle to farm-gate’’ milk production system representing the processes included for describing a typical Irish dairy unit. Where (i) is concentrate feed related, (ii) is fertiliser related, (iii) is manure management related and (iv) relates to electricity and diesel usage (Casey and Holden, 2005).

For concentrate feed, the data will generally be global, using national yield data and management data, and the detail is completely different from that applied in the livestock unit and manure management units. Despite 60% of concentrate feed used in Ireland being imported these data are considered background, yet it is clear that differences in concentrate use will be reposnsible for significant differences between farms. The production of ingredients for concentrated feed accounts for nearly 12% of GWP in this milk production system, and for grass-based systems is likely to be decreased by reducing concentrate feed. Month-by-month, and season-by-season the management of concentrate feed can vary between unprocessed rotations of locally-sourced products to purchased mixes of imported feed. This information cannot currently be conveyed on eco-labels but with modern precision feeding systems it should be possible to collate data at least at farm scale to label milk products. For example, farm ICT can sense the health status of cows for precision feeding to decide the quatity and quantity of supplementary feed. In the context of labels based on EPD (Figure 1), it should be possible to weight contributions from suppliers to dairy processors to link the farm phase to the final product rather than relying on arbitrary historical data.

For the feritiliser unit the impact comes from the decision about which fertiliser to use, when to spread it and how much is used. Fertiliser production accounts for a significant part of the carbon footprint of a farm (14% from prodcution and transportation, 8% from application) therefore tactical and operational management decisions have the potential to siginficantly change the environmental footprint of livestock products. Efficient N management can not only reduce the GWP, but also some local impact categories, like acidification and eutrophication. Modern farm management software and regulatory requirements for N management reporting in Europe (and elsewhere) suggest that more temporally specific data could be associated with products at the farm gate, and then integrated at the processing stage. Modern farm manegement sofatware can use forecasts of polluting losses to support decisions about the best time to carry out slurry application therefore eco-labels should reflect the quality of these decisions in the information they carry.

For the livestock unit, the most important contributor to carbon footprint is CH_4 from enternic fermentation. According to Casey and Holden (2005), a 10% reduction in enteric fermentation from all stock would cause a 5% reduction in kg CO_2 eq $_{ECM}$ (energy collected milk) at the farm gate. It is possible to use known animal attributes collated in livestock registers and known milk production to estimate livestock emissions at the farm scale. As a farmer manages the herd to optimise production this could be reflected in an eco-label because the necessary data are already collected, but are not tagged to the physical product as it goes for processing. At present spatial averages are used on a regional or national scale rather that spatially and temporally specific data.

Farm ICT can identify the breed and age of animals and link to related databases to get the unique animal attributes for estimating the CH_4 emission.

The manure management unit is perhaps less important as its contribution to carbon footprint was estimated at around 7%, thus small changes in management will have relatively little impact, but contribution to acidification and eutrophication is unclear. There is relatively little currently available technology to monitor organic nutrient resources so these are less likely to be considered in the first instance, but as they are the subject of wide ranging regulation this situation might change. It is possible to apply ICT systems on farm for monitoring the emission from manure management (especially storage) and thus real time data collected by ICT could improve the spatial and temporal resolution of the data about manure management phase greatly.

The energy unit includes diesel and electricity consumption. Spatial and temporal specificity could be achieved by using modern farm accounting software to identify consumption from costs, or by using monitoring systems. As this is a relatively small contributor it is less likely to be an immediate focus. The electricity generation for farm can affect its environmental performance in an insignificant way, unless a more energy efficient means of milk preservation is introduced.

4. Discussion

Spatial scale of LCA can be very important for environmental impact assessment. According to (Hauschild 2006), there are three levels of spatial differentiation in LCA, but these tend to relate more to the assumed impact than the detail of the system being modelled.

Site-generic modelling takes all sources considered to contribute to the same generic receiving environment. In this case, we do not have to consider spatial differentiation between sources and subsequent receiving environments. From the analysis of label types, example labels and the example dairy system is it clear that there is the possibility of an over-emphasis on site-generic activity data for food products for pragmatic reasons. While precision may be lost, accuracy may be assured. IoT has the potential to permit eco-labelling systems to move from a reliance on site-generic activity data as it becomes more common in food production systems.

Site-dependent modelling considered some spatial differentiation to distinguish between classes of sources to determine the receiving environment. Source categories are typically defined at the level of countries or regions within countries (scale 50–500 km). The receiving environment is typically defined at high spatial resolution (scale at maximum 150 km, but often down to a few kilometres). With respect to activity data for eco-labelling, some specificity is typical, such as inventory of data for specific suppliers or types of supplier. Again, IoT has the potential to radically enhance the information conveyed on eco-labels so that the data are more focused on the actual suppliers at a specific time.

Site-specific modelling requires large volumes of data to build models for specific locations to evaluate the environmental impacts that are very close to the source. This typically involves local knowledge about the conditions of specific ecosystems that are exposed to the emitted pollutants. This level of spatial differentiation modelling is rare for more than a few processes in a product system. The development of IoT on farms will permit eco-labelling to migrate towards site-specific data and more sophisticated modelling.

Agricultural production systems have different resource consumption (energy, water, natural resource) and emission characteristics depending on the local natural resources, specific management decisions and weather. When compared between different regions or countries eco-labels should reflect these differences, but to date there has been little focus differences between farms and years. A label with site-generic spatial information cannot reflect the true impact of a food product. Farm ICT and sensing has the potential to permit eco-label awarding organizations to demand site-specific data in the near future. Taking dairy farming as an example, the calculation of CH_4 emission from livestock, feed management and fertilizer management should all be possible to ensure products are labelled with information that is specific to the mass flow of product and no more than 12 months old. This improvement of data capture will greatly increase the reliability of information conveyed on eco-labels.

Temporal scale also plays a significant role in the accuracy of LCA, which is generally poor at accounting for time and temporal information (ISO 2006a). The temporal specificity of impact is limited for two reasons. Firstly in the LCI phase aggregated emission data from all the unit processes dispersed through space and time, are typically used (Finnveden et al. 2009, Heijungs & Suh 2002), and secondly during the LCIA phase the potential impacts of the aggregated emissions are assessed using characterization factors based on a fixed time horizon (de

Haes et al. 2002). The temporal specificity of activity data is critical because of internal annual variation in management and changes in technology during the life of the product. For example, the timing of slurry application is very important for GHG emission. N_2O emissions from early time (April) spreading may be 10 times greater than later time (July) spreading (Chadwick et al. 2000), but prolonged storage over the summer period would offset any advantage from late spreading. In addition, the method of application can have a great impact on volatilization losses (Søgaard et al. 2002). When farm ICT can record the time and amount of slurry application the related emissions can be calculated more accurately.

5. Conclusion

This study investigated how spatial and temporal scale is considered by current Eco-label schemes and evaluated whether integrating the ICT systems and life cycle assessment at farm level may have implications for future eco-labels. Considering the extent of application of life cycle assessment to eco-labels for food and agricultural products, it may be premature to talk about consumer attitude towards spatial and temporal scale in eco-labels, but based on the result of this analysis, it will be technically feasibly in the near future to address this matter. If consumers pay more attention to the environmental impacts of their choices they are likely to become more aware of the importance of spatial and temporal scale. The increased popularity of 'local food' suggests that a consumer understanding of scale is now emerging. A label with better-specified spatial and temporal information might be more transparent, thus improving credibility.

Life cycle assessment is a useful tool for assessing the environmental performance of a product or service. In term of accuracy, spatial and temporal scale is important for deriving activity data and for many impact categories in life cycle assessment. It is clear that scale issues are not the focus of labelling, but that technologically it should be possible to forge a closer link between the item labelled and the information on the label. For food products this is particularly important because we know that specific management choices will influence the magnitude of the impacts calculated. Data are increasingly being collected for management, regulation, national statistics and economic reporting, and these will also allow improved calculations for eco-labels if the data are linked to product mass flow. As this is possible for food safety it should be possible for eco-labelling. IoT on farm should in time provide even better information that can be used for eco-labelling.

ABSTRACT

We represented variability and epistemic uncertainty in LCA with different approaches in the same framework. Probability distributions are commonly used to represent variability in populations, while fuzzy intervals are an alternative approach for representing epistemic uncertainty in parameters when information is incomplete or imprecise. We used Dempster-Shafer theory to combine both approaches for representing variability and epistemic uncertainty and propagated them with Monte-Carlo simulation through the LCA model. We applied approaches to a case study of dairy farms to estimate their potential direct environmental impacts. Results indicated that consideration of incomplete information greatly increases overall uncertainty in impacts, as measured by a "relative interval width", which was useful for comparing the influence of input uncertainty among impact categories. Thus, our method provides conservative estimates of impacts by considering incomplete information, which is ignored by the classic probability method commonly used in LCA.

Keywords: life cycle assessment, Dempster-Shafer theory, variability, epistemic uncertainty

1. Introduction

Life Cycle Assessment (LCA) is a useful tool to estimate potential environmental impacts and resource use of farming systems (van der Werf and Petit 2002; Thomassen et al. 2008). The reliability of LCA results, which depends primarily on the quality of data and their pertinence for the system studied, is affected by uncertainty (Weidema and Wesnaes 1996; Finnveden 2000). Including uncertainty analysis in LCA may yield results that provide more useful information for decision making (ISO 2006; Heijungs 1996). Therefore, there is a need to improve uncertainty analysis in LCA to increase the reliability of its results.

Uncertainty analysis includes a variety of methods that are used to express and propagate uncertainty in many fields, such as risk analysis (Vose 2008) and LCA (Benetto 2005; Bjorklund 2002). Most studies define two main types of uncertainty (variability and epistemic uncertainty), which have fundamental differences (Morgan and Henrion 1992). Variability (also called stochastic uncertainty) represents inherent differences among individuals in a population. It cannot be reduced but can be represented more precisely if more population data are available (De Rocquigny et al. 2008; Vose 2008). Probability distributions have been used widely in LCA (Basset-Mens et al. 2009; Henriksson et al. 2011; IPCC 2006b) to represent the variability due to randomness in the distribution of a given sample (e.g., with a mean, variance, and normal distribution). In contrast, epistemic uncertainty is defined as lack of knowledge (imprecise and incomplete information) about the true value of a variable or about the system mechanism. It can be decreased if more precise information or more accurate measurement becomes available. In LCA, epistemic uncertainty in parameters is often represented with probability distributions (Lloyd and Ries 2007; Huijbregts 1998), and both types of uncertainty are propagated by Monte-Carlo simulation (MCS), especially in complex models. MCS is an effective and robust way to estimate the uncertainty in predicted potential impacts (Payraudeau et al. 2007; Sonnemann et al. 2003). Some authors (Tan 2008; Reza et al. 2013; Andre and Lopes 2012; Mauris et al. 2001; Chevalier and Téno 1996), however, emphasize the difference between variability and epistemic uncertainty and argue that fuzzy-set theory (Zadeh 1978), with subjective degrees of plausibility/possibility, better represents uncertainty due to imprecise and incomplete information.

Since variability and epistemic uncertainty represent distinct states of knowledge, many studies have modeled them separately in the same framework. For example, Ferson et al. (2002) constructed "probability boxes" by combining probability theory and set theory. Baudrit et al. (2006) represented random variability and imprecision with probability and possibility distributions, respectively, and then propagated them for risk assessment. And Baraldi and Zio (2008) combined MCS and the possibilistic approach to propagate uncertainty. These three studies introduced the Dempster-Shafer theory (Dempster 1966; Shafer 1976) to incorporate imprecise information into probabilistic models, making a bridge that combines uncertainties from different sources (Yager 1987).

Although variability and epistemic uncertainty have been defined, and sometimes analyzed, separately in some LCA studies (Heijungs and Huijbregts 2004; Basset-Mens et al. 2009), few studies (Clavreul et al. 2013) have modeled them in the same framework. The aim of this study is to demonstrate how to combine two types of uncertainty, via Dempster-Shafer theory, to estimate potential environmental impacts of dairy farms. We then compare this method to classic probability methods.

2. Methods

We used probability distributions and fuzzy intervals to represent variability and epistemic uncertainty, respectively. These two types of uncertainty were propagated into LCA results by MCS and interval analysis using R software (R Development Core Team 2012). For each impact category, distributions of impact were represented by a Dempster-Shafer structure and mean impacts were represented by fuzzy intervals. In addition, two other methods for analyzing uncertainty were applied for comparison purposes.

2.1. Representing variability with probability distributions

In a frequentist approach, a probability distribution assigns a probability of any possible event in a random experiment. It is often used to represent the variability of a variable. A random variable X, which is an element of all real numbers ($\mathcal{R}$), has a probability Pr(x) of having value x. In addition, the probability distribution can be described by its cumulative distribution function (CDF) and explained as the probability that X is less than x:

$$F(x) = Pr(X \leq x), for\ all\ x \in \mathcal{R} \qquad \text{Eq. 1}$$

In general, determining a distribution requires empirical data to identify its shape and basic parameters (e.g., mean and variance). If the amount of empirical data is sufficiently large, it can be considered to represent the entire population. However, since data acquisition is often limited by time and cost in LCA studies, probability distributions are generally determined subjectively based on the literature or expert judgment (Heijungs and Frischknecht 2005).

MCS is the most common method for propagating variability to estimate uncertainty in LCA studies. It consists of sampling input variables from their distributions and then calculating potential impacts through the model. By repeating the MCS many times, a CDF can be constructed to predict a probability range that represents overall uncertainty in impacts due to uncertainty in input variables.

2.2. Representing epistemic uncertainty with fuzzy intervals

Fuzzy-set theory is an alternative approach to express epistemic uncertainty. In this approach, an uncertain variable is modeled by a set of “fuzzy” intervals, each with a level of possibility (α) that ranges from 0 (least possible) to 1 (most possible). Denoting each fuzzy interval as $\pi(\alpha_i)$, there is:

$$\pi(\alpha = 1) \subseteq \pi(\alpha_i \in [0,1]) \subseteq \pi(\alpha = 0) \qquad \text{Eq. 2}$$

An uncertain variable can be mapped by a membership function defined by these “fuzzy” intervals and their corresponding levels of possibility. Commonly-used membership functions are shaped as triangles or trapezoids having minimum, maximum and mode values (mode intervals for the latter) (Fig. 1). For example, the minimum-maximum range of variable x, called the “support” (α=0), indicates all possible values of x. The mode (or mode interval), called the “core”, indicates the most likely value(s) (α=1). At any given α level, there is a corresponding interval (called the “α-cut interval”). To propagate uncertainty, the fuzzy intervals of input variables are decomposed at each α level, and interval arithmetic is applied to generate a set of fuzzy intervals of the final result.

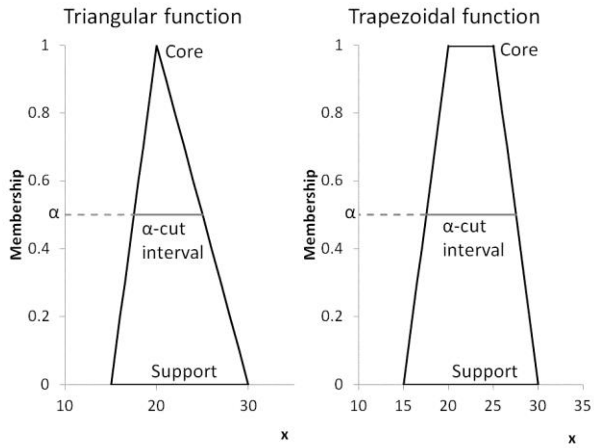

Figure 1. Triangular (left) and trapezoidal (right) fuzzy-interval membership functions for an uncertain variable x defined by core, support and α-cut intervals.

2.3. Dempster-Shafer theory

Dempster-Shafer theory (DST) is a “mathematical theory of evidence” introduced by Dempster (1966) and further developed by Shafer (1976). It is a generalization of discrete probability theory in which probabilities are assigned to sets of values rather than a single value. One important feature of DST is that imprecise information can be used to represent the state of knowledge quantitatively. It includes three basic functions: the basic probability assignment (bpa) function (or “mass function”), the belief function (Bel) and the plausibility function (Pl).

The bpa for a given set *A* (denoted *m(A)*) indicates the proportion of all available evidence that supports the supposition that a particular element of *x* belongs to set *A*. It has axioms such as:

$$m: 2^{\Omega} \rightarrow [0, 1] \qquad \text{Eq. 3}$$

$$m(\emptyset) = 0 \qquad \text{Eq. 4}$$

$$\sum_{A \in 2^{\Omega}} m(A) = 1 \qquad \text{Eq. 5}$$

where 2^{Ω} is the power set that comprises all possible subsets, including the empty set $\emptyset$. *A* is any subset (called a “focal element”) of power set. The belief and plausibility functions are defined from the bpa. The belief function of *A* is the sum of the bpa of all of the subsets (*B*) of *A* ($B \subseteq A$):

$$Bel(A) = \sum_{B \subseteq A} m(B)\,, B \text{ is all of the subsets of } A, \text{and } B \neq \emptyset \qquad \text{Eq. 6}$$

The plausibility function of *A* is the sum of the bpa of any subset (*C*) of power set with the condition that the intersection of *C* and *A is a non-empty set* ($C \cap A \neq \emptyset$):

$$Pl(A) = \sum_{C \cap A \neq \emptyset} m(C), C \in 2^{\Omega}, \text{and } C \neq \emptyset \qquad \text{Eq. 7}$$

The three concepts can also be used in continuous probability distributions where any element of the uncertain parameter *x* is expressed as an interval ($[a_i, b_i]$) with bpa$_i$ (where $a_i \leq b_i$ for all *i*). Thus, the power set *A* is the collection of these intervals with their corresponding bpa$_i$, and the sum of bpa$_i$ equals 1. So, Eq. 6 and 7 can be transformed as:

$$Bel(x \in]-\infty, x]) = \sum_{b_i \leq x} m([a_i, b_i]) \qquad \text{Eq. 8}$$

$$Pl(x \in]-\infty, x]) = \sum_{a_i \leq x} m([a_i, b_i]) \qquad \text{Eq. 9}$$

The belief and plausibility functions can be considered the lower and upper probabilities of a given value of x (Ferson et al. 2002), respectively, and the true probability distribution of x ($Pr(x)$) lies inside them, interpreted as:

$$Bel(x) \leq Pr(x) \leq Pl(x) \qquad \text{Eq. 10}$$

with an interval of the mean of x

$$\sum m_i a_i \leq E(x) \leq \sum m_i b_i \qquad \text{Eq. 11}$$

If uncertain parameter x is determined by a single set of values ($a_i = b_i$ for all i) instead of intervals, the belief and plausibility functions converge on the same distribution, as in a classic CDF.

We considered fuzzy intervals of uncertain parameters as focal elements, used DST to combine variability and epistemic uncertainty in input-parameter values, and propagated them with MCS. Thus, assuming that impact category (y) is calculated by the model ($f(x_1, x_2 \ldots x_k, x_{k+1}, x_{k+2} \ldots x_n)$), we:

1. Randomly generate a matrix (B rows (10,000) × k columns) of the first k variables using each one's probability distribution while preserving correlations between them: $M_b(x_1, x_2 \ldots x_k)$.
2. Select a possibility level α_i (e.g., assign values from 0 to 1 with step 0.1) and its corresponding fuzzy interval ($\pi^{k+1}, \pi^{k+2} \ldots \pi^n$) for the last n-k uncertain parameters ($x_{k+1}, x_{k+2} \ldots x_n$).
3. Using the variables in each row of $M_b(x_1, x_2 \ldots x_k)$, calculate minimum and maximum values of y with all possible combinations of the last n-k variables ($= 2^{(n-k)}$) in α_i, with a lower bound of $L(y) = \max [f(x_1, x_2 \ldots x_n)]$ and an upper bound of $U(y) = \min [f(x_1, x_2 \ldots x_n)]$. For a model with only monotone functions, the optimization algorithm can be simplified by interval analysis.
4. Repeat steps 2 and 3 for all α_i to generate the fuzzy intervals of y_b ($[U(y), L(y)]_b$) and find the support of y_b (denoted $\pi (y_b)_{\alpha=0}$). Then attribute a mass ($m_b = 1/B$) to the support.
5. Repeat steps 2-4 B times to obtain a set of supports ($\pi_1, \pi_2, \ldots, \pi_B$) as focal elements, which is used to construct lower (belief function) and upper (plausibility function) bounds of y using Eq. 8 and 9.
6. Calculate the mean of the lower and upper bounds of y using Eq. 11 for each α to generate fuzzy intervals of the mean of y.

For example, assume that indicator Y is modeled by a function with two uncertain parameters (X_1 and X_2), $Y = X_1 \times X_2$, where X_1 is normally distributed ($X_1 \sim N_{prob}(100,20)$) and X_2 is modeled by a triangular membership function ($X_2 \sim T_{fuzzy}(2, 6, 3)$). Thus, we construct the lower and upper bounds of Y and fuzzy intervals of the mean of Y at each α (Fig. 2) by following the above steps. Consequently, this procedure generates a set of intervals (11, in this study) with their corresponding α, and the mean of Y is represented as a membership function of this fuzzy set that is determined by its support, core and other α-cut intervals.

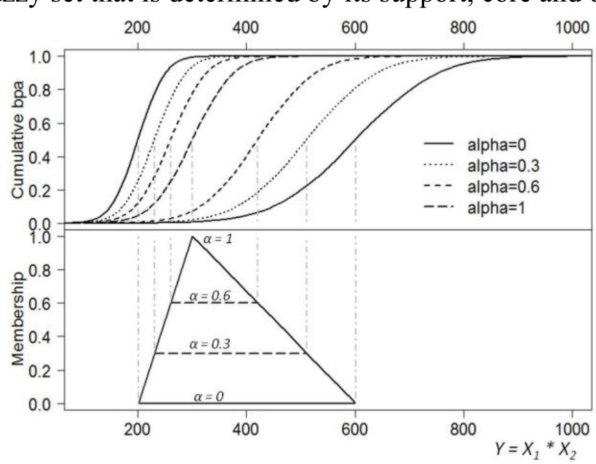

Figure 2. (Top) Lower (belief) and upper (plausibility) bounds of indicator Y at different possibility levels (α) and (bottom) fuzzy intervals of the mean of Y with support (α=0), core (α=1) and two α-cut intervals (at α=0.3 and 0.6).

2.4. Case study

We constructed an LCA model to estimate environmental impacts (climate change, acidification and eutrophication) of on-farm emissions of dairy farms. The functional unit was 1 metric ton of fat-and-protein corrected milk (FPCM). This model was based on the EDEN-E (Evaluation de la Durabilité des ExploitatioNs) tool, developed previously to estimate LCA-based environmental impacts of individual dairy farms (van der Werf et al. 2009). In this study, we focused only on direct impacts of the milk-production subsystem, because they were affected directly by uncertainty in emission factors. We used data from 41 conventional dairy farms from EDEN-E datasets. We obtained input variables such as animal production (e.g., meat, milk), number of animals by age and sex, and usable agricultural area. Other variables such as quantities of nitrogen (N) in farm inputs and outputs (e.g., fertilizers, feed, waste, animals), energy agents (e.g., diesel, gasoline, electricity), lubricants and plastics were also taken from EDEN-E. In addition, emission factors were used to estimate gaseous emissions; their default values and ranges of uncertainty were taken from the literature (IPCC 2006a; EMEP-CORINAIR 2001). These variables were used in the model to estimate direct impacts of conventional dairy farms. We considered two types of uncertainty in input variables: variability in structural characteristics of sampled farms and epistemic uncertainty in emission factors. Impact categories were calculated by multiplying emissions with the characterization factors of the CML-IA database (Guinée et al. 2002).

To compare results with those of the classic probability method, we made three scenarios to analyze uncertainty in the LCA model. For all scenarios, we used truncated normal or uniform distributions to represent variability in each farm characteristic because they provided only non-negative values. Means and standard deviations for each characteristic were determined from the empirical EDEN-E sample. Correlations between these variables were preserved using Spearman rank-order correlation (Helton and Davis, 2003). In the first scenario (S1), uncertainty in emission factors was ignored (default constants used). In the second scenario (S2), we considered uncertainty in emission factors with triangular probability distributions. In S2, default values and ranges of uncertainty were used as the mode and minimum/maximum values in the distribution, respectively. In the third scenario (S3), we used fuzzy intervals with triangular membership functions to represent uncertainty in emission factors. The same default values and ranges of uncertainty were used as the core and support in the membership function, respectively. Indeed, S1 can be considered a special case of S3 that considers only the core interval (α=1). Each emission factor was assumed to be independent. Scenarios S1 and S2 used MCS to propagate uncertainties, while S3 combined MCS and interval arithmetic to generate an interval distribution. Simulations were repeated 10,000 times. In S3, finding minimum and maximum impact values for each of the 10,000 replicates theoretically required calculating all possible combinations of emission factors (2^m combinations, m = number of emission factors), but doing so would have increased calculation time considerably. Therefore, since the LCA model was monotonic (emission factors used only addition and multiplication), calculations were optimized by using the minimum and maximum of each α-cut interval of emission factors.

Statistics (mean, 5th and 95th percentiles) of impact indicators were calculated as single values in S1 and S2 and as intervals in S3. To compare uncertainty in mean impact between categories, we calculated a "relative interval width" (RIW), equal to the maximum of a statistic's interval minus its minimum, divided by its mode. Thus, the RIW of mean impact in S3 was the width of the indicator's mean interval (i.e. its support) divided by its core (i.e. the most likely mean value). Because uncertainty in emission factors was assumed to be zero in S1 and a known distribution in S2, they were considered to have intervals of zero width.

3. Results

Statistics of the three impact categories differed by scenario (Table 1). For all three impact categories, the difference between the 5th and 95th percentiles ($I_{percentile}$) in S1 and S2 was narrower than the difference between the minimum of the 5th-percentile interval and the maximum of the 95th-percentile interval in S3, indicating higher overall uncertainty in S3. The increase in overall uncertainty was due to inclusion and representation of epistemic uncertainty in emission factors. The percentage increase in $I_{percentile}$ from S1 to S2 was 25% for climate change, 80% for acidification, and 0% for eutrophication, while that from S1 to S3 was 212% for climate change, 372% for acidification and 29% for eutrophication. Thus, overall uncertainty in impacts increased greatly when uncertainty in emission factors was considered as imprecise information.

Table 1. Statistics of potential climate change, acidification and eutrophication impacts per t of fat-and-protein-corrected milk (FPCM) in three scenarios that represented uncertainty in emission factors (EFs) differently: S1 - no uncertainty in EFs, S2 - probability distributions for EFs, S3 - fuzzy sets for EFs.

	Climate change (kg CO_2 eq./t FPCM)			**Acidification (kg SO_2 eq./t FPCM)**			**Eutrophication (kg PO_4 eq./t FPCM)**		
Statistics	**S1**	**S2**	**S3**	**S1**	**S2**	**S3**	**S1**	**S2**	**S3**
Lower limit (5th percentile)	775	852	[511, 1383]	8.1	9.5	[3.6, 18.2]	4.3	3.9	[2.7, 5.0]
Mean (support of the mean)	1065	1208	[718, 1874]	10.8	14.3	[4.8, 24.3]	8.6	8.2	[6.6, 9.4]
Upper limit (95th percentile)	1400	1632	[947, 2459]	14.2	20.5	[6.3, 32.4]	13.7	13.3	[11.4, 14.8]
Relative interval width of the mean	0%	0%	89%	0%	0%	134%	0%	0%	35%

When visualized as CDFs (Fig. 3), S1 and S2 were represented by a single CDF each, while S3 was represented by two CDFs (plausibility and belief functions) defining upper and lower bounds of impact in each category (Fig. 3). These bounds were more widely separated for acidification and climate change impact than eutrophication.

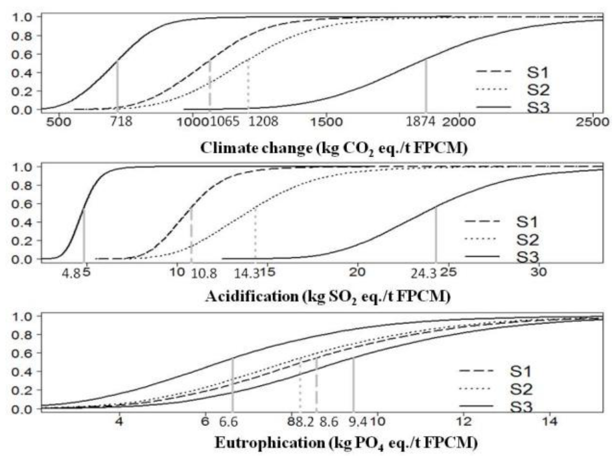

Figure 3. Cumulative density functions of direct (on-farm) climate change, acidification, and eutrophication impacts per t of fat-and-protein corrected milk (FPCM) in three scenarios that represented uncertainty in emission factors (EFs) differently: S1 - no uncertainty in EFs, S2 - probability distributions for EFs, S3 - fuzzy sets for EFs (solid curves bound 90% of possible values). Vertical gray lines indicate the mean impact (support of mean impact in S3) of each scenario.

Membership functions of mean impacts in S3 were nearly triangular, with minor skewness (Fig. 4). For example, the support of climate change ranged from 718-1874 kg CO_2 eq./t FPCM, with a core of 1065 kg CO_2 eq./t FPCM. Note that the core of mean impact in S3 equaled the mean impact in S1, for which default values (considered as the true values) were used for emission factors. RIWs of mean impacts in S3 indicate that uncertainty in mean acidification impact (134%) was larger than that in mean climate change (89%) or eutrophication (35%) impacts (Table 1). However, S1 and S2 each had a single mean (e.g., 1208 and 1065 kg CO_2 eq./t FPCM, respectively) and RIWs of mean impact of 0%.

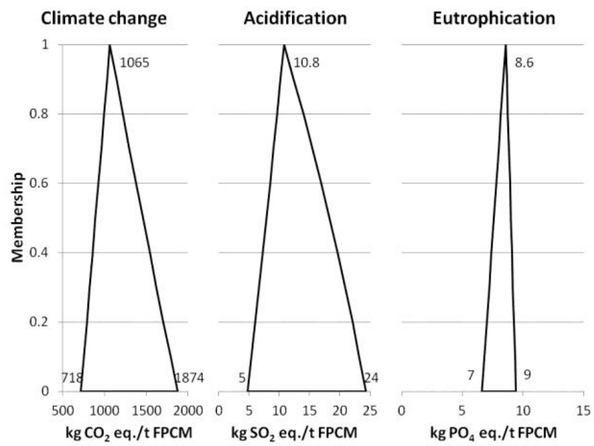

Figure 4. Fuzzy-interval distributions of means of climate change, acidification, and eutrophication impacts per t of fat-and-protein-corrected milk (FPCM) in scenario 3 (based on Dempster-Shafer theory).

4. Discussion

We focused on two sources of uncertainty in this case study: variability (in farm characteristics) and epistemic uncertainty (in emission factors). The classic probabilistic approach expresses both epistemic uncertainty and variability with probability distributions; however, subjectively defining probability distributions may underestimate overall uncertainty. Therefore, unknown distributions should be considered as another source of uncertainty due to incomplete information and modeled with fuzzy intervals. If both probability distributions and fuzzy intervals exist in the same analysis, our DST-based method can combine them to estimate overall uncertainty in impact (S3). It provides a more conservative range of uncertainty (i.e. the interval between the minimum of the 5^{th} percentile and maximum of the 95^{th} percentile) than the classic probabilistic approach. Since S1 considered only variability in farm characteristics, the increase in overall uncertainty in impacts in S2 and S3 compared to S1 reflects the contribution of epistemic uncertainty in emission factors alone. Considering emission factors as fuzzy intervals (S3) increased overall uncertainty more than considering them as random values (S2). Unlike variability, epistemic uncertainty in emission factors can be reduced when more precise information becomes available. For example, any distribution inside the bounds of plausibility and belief yields a mean value and a smaller range of uncertainty, because the true values (S1) or distributions (S2) of input variables are known or assumed to be known.

In parallel, the imprecision in emission factors was propagated into mean impacts, which were constructed from membership functions of their fuzzy sets. Those who used a similar propagation procedure in LCA (Clavreul et al. 2013) or risk assessment (Baudrit et al. 2006) studies considered all fuzzy intervals of impact as a set of random intervals with equal probability and then calculated a weighted-mean interval from upper and lower bounds of distributions. In contrast, we separated this process into two steps: (1) estimate the overall range of all possible impact values using the supports of emission factors and (2) model mean impacts with fuzzy intervals. Indeed, showing the membership function of mean impact instead of a weighted-mean interval provides more information to decision makers, such as the levels of possibility corresponding to the most likely mean impact and mean impacts of best- and worse-case scenarios based on the degree of possibility. This information allows a more precautionary approach than a simple interval of mean impact for evaluating the magnitude of and uncertainty in predicted impacts. For fuzzy intervals, the RIW of mean impact is a comparative indicator that reflects the influence of explicitly representing the knowledge of information as incomplete (an unknown distribution), unlike the classic probability method, which ignores this source of uncertainty. It enables the influence of epistemic uncertainty on different impacts to be compared when calculating a coefficient of variation is difficult or complex (e.g., in S3, which comprised multiple probability distributions). Comparing RIWs among impact categories illustrates the relative influence of epistemic uncertainty on overall uncertainty in the impacts of each. If overall uncertainty is hindering decision making, this information could lead decision makers to focus on reducing the sources of epistemic uncertainty that contribute the most to uncertainty in impacts. For example, since epistemic uncertainty in emission factors had a larger influence on acidification than eutrophication impacts in this study, more precise measurement of acidification-related emissions would have a relatively larger influence in reducing overall uncertainty in an impact.

For the sake of simplicity, we illustrated a simple LCA example based on a previous work. It had far fewer variables and parameters than a full LCA study; in addition, the model was monotonic, which simplified the optimization algorithm in the simulation. Increasing the number of uncertain variables (especially imprecise variables) may increase the complexity of computation and even greatly overestimate uncertainty. Therefore, performing an initial sensitivity analysis of the LCA model is recommended (Heijungs 1996; Henriksson et al. 2013) to focus on the input variables that influence potential impacts the most. This decrease in the number of uncertain input variables may accelerate the optimization algorithm, especially in more complex and non-monotonic models.

Correlations between random variables (i.e., inter-farm variability) were preserved in this study, while independence was assumed between random variables and imprecise parameters (emission factors). This assumption allowed a conservative confidence interval of impacts to be generated for all three scenarios, because all possible combinations of input variables were included in the stochastic simulation. However, representing dependence between random variables and imprecise parameters (if known) could improve the precision of predicted impacts. More research is needed on this issue to improve the validity of LCA results.

The DST-based method constructs two boundary distributions using belief and plausibility functions. This structure has been interpreted as "imprecise probability" (Ferson et al. 2002), which covers all possible probability distributions. Although it reflects the true state of knowledge (e.g., incomplete information about emission factors), an extremely wide range of potential impact is likely to be less useful for decision makers. Thus, simplifying interpretation of results by decision makers remains an open question. To address this problem in LCA, Clavreul et al. (2013) calculated a "confidence index" (Dubois and Guyonnet 2011) to generate a weighted probability distribution. Decision makers can choose this confidence index subjectively, depending on whether their decision policies are more optimistic (close to the upper bound) or pessimistic (close to the lower bound). We concur that this kind of confidence index is useful for decision making in LCA studies when uncertainty is modeled with imprecise and incomplete information.

5. Conclusion

The classic probability method is rigorous in that it requires precise information to express an uncertain variable, but subjective assumption about its distribution may underestimate uncertainty in the predicted result. In addition, it cannot separate epistemic uncertainty from variability, meaning that decision makers will have no information about the relative influence of each on overall uncertainty. Our proposed method overcomes this limit by integrating fuzzy intervals to represent imprecise data (e.g., emission factors) in probability models. As a consequence, a distribution with two bounds and fuzzy intervals of mean impact was generated. Combining the effects of variability and epistemic uncertainty yields a wider range of potential impacts, which may influence decision making. Fuzzy intervals of mean impact model the uncertainty in mean values. The RIW of mean impact, as a comparative indicator, reveals the influence of epistemic uncertainty on uncertainty in impacts, which may help decision makers adopt appropriate strategies if they want to improve the reliability of LCA results.

The paper demonstrated the application of DST in uncertainty analysis in a simple LCA study. Representing the lack of knowledge as fuzzy intervals differs from treating it as randomness. Thus, it provides a conservative but robust way to represent the state of knowledge in LCA studies when information is scarce. Its application in LCA is currently limited, however, due to its greater model complexity and, if epistemic uncertainty is large, greater difficulty in distinguishing potential differences among scenarios. Considering dependence among input variables is also important, since it gives more precise results, but techniques for doing so with fuzzy-interval variables are difficult or complex. Therefore, more research is needed to focus on these issues to improve the feasibility of this method in LCA.

ABSTRACT

The aim of this paper was to perform a sensitivity analysis of different calculation procedures and emission factors to estimate methane (CH_4) and nitrous oxide (N_2O) emissions applied to a case study of slurry management of swine production in southern Brazil. The manure management system (MMS) defined was the slurry tank without a natural crust cover. The calculation procedures used were: (i) GES'TIM; (ii) Static mass flow model from Hutchings et al. (2013); (iii) Calculation procedure described by Hamelin et al. (2011); and three variations of the IPCC guideline (IPCC 2006): (iv) IPCC with European default parameters, IPCC (DF-EU); (v) IPCC with Latin American default parameters, IPCC (DF-LA); (vi) IPCC with parameters adjustment to represent Brazilian reality, IPCC (BR). Finally, it was proposed a model guide for future estimations of MMS emissions in Brazil for slurry tanks (Baseline). Results showed significant differences between the upper and lower CH_4 and N_2O estimative.

Keywords: Emissions, calculation procedure, emission factor, CH_4, N_2O.

1. Introduction

Life cycle assessment (LCA) is a methodology widely used to predict the environmental profile of livestock and other agricultural products. Studies from literature (Basset-Mens; van der Werf 2005; Flysjö et al. 2011; Reckmann et al. 2013; Prudêncio da Silva et al. 2010; Prudêncio da Silva et al. 2014; Williams et al. 2006) have shown that the environmental impacts of these activities are mainly due to ammonia (NH_3), nitrous oxide (N_2O), carbon dioxide (CO_2), nitrate (NO_3) and methane (CH_4) emissions from crops cultivation by fertilizer usage, enteric fermentation from animal rearing, and manure management systems (MMS).

Regarding to swine production, manure handling is an important stage to mitigate the environmental impacts of this activity. According to Chadwick et al. (2011), the MMS selected by the farmers has a direct influence on the magnitude of gaseous losses and consequently the potential to reduce those emissions. For climate change, MMS represents 18-26% of total CO_2 eq. emissions (Kool et al 2009; Nguyen et al. 2011) which highlights the importance of having reliable data for CH_4 and N_2O emissions.

However, these emissions are difficult to be measured on field because of economic costs and the long period to measure it (Javon 2012). Therefore, many LCA studies uses mathematical models and emission factors (EF) to estimate CH_4, N_2O, NO_3 and NH_3 (Basset-Mens et al. 2007; Dalgaard et al. 2008; Flysjö et al. 2011; Nguyen et al. 2010; Prudêncio da Silva et al. 2014; Ruviaro et al. 2014; ten Hoeve et al. 2014; Wesnæs et al. 2009). There are a few calculations procedures and EFs in literature to estimate these emissions (Deltour et al. 2009; Gac et al. 2007; Hamelin et al. 2011; Hutchings et al. 2013; IPCC 2006; Rigolot et al. 2010), which may generate different results. Thus, it is not easy to choose the procedure and EF that better applies in the product system under analysis since these emissions have a high variability due to differences in system production, temperature, management, soil type, manure composition, windspeed and rainfall (Mkhabela et al. 2009, Sommer et al. 2009).

The aim of this paper was to perform a sensitivity analyzes of different calculation procedures and EFs to estimate CH_4 and N_2O emissions applied to a case study of slurry management of swine production in southern Brazil. In addition, we also proposed a calculation procedure for the Brazilian swine production based on the mathematical models and EFs reviewed.

2. Methods

The manure management system (MMS) defined was the slurry tank without a natural crust cover with a minimum storage period of 120 days with the land application of the stabilized manure (Fatma 2009). This system represents the most common MMS used in Brazil (Brazilian agroindustry; Higarashi et al. 2013; Kunz et al. 2005). The functional unit (FU) was the manure management generated to produce 1 ton of swine live weight, with the system boundaries set from the manure ex-house until its application on field. Only the emissions of CH_4 and N_2O produced from manure were considered. The characterization factors were according to IPCC (2007).

The calculation procedures used were: (i) GES'TIM (Deltour et al. 2009); (ii) Static mass flow model from Hutchings et al. (2013); (iii) Calculation procedure described by Hamelin et al. (2011); and three variations of the IPCC guideline (IPCC 2006): (iv) IPCC with European default parameters, IPCC (DF-EU); (v) IPCC with Latin American default parameters, IPCC (DF-LA); (vi) IPCC with parameters adjustment to represent Brazilian reality, IPCC (BR). Finally, it was proposed a model guide for future estimations of MMS emissions in Brazil for slurry tanks (Baseline). The input parameters for the mathematical models are shown in Table 1. We assumed a slurry tank without a natural crust cover, therefore we did not consider the direct N_2O emissions in storage (IPCC 2006).

Table 1. Input parameters for the mathematical models.

[a] Not applied.
[b] VS = volatile solids; Nex = nitrogen excreted.

The methodological guide GES'TIM was elaborated to be reference for the quantification of gas emissions of livestock, soil, energy consumptions, inputs and compensation by carbon storage. The guide provides a homogenized methodological frame, with EFs that are representative of the French agricultural production sectors (Deltour et al. 2009). This method estimate CH_4 and N_2O emissions from manure storage and application in field. Detailed information on GES'TIM model can be found in Deltour et al. (2009), while input parameters considered in this paper are summarized in Table 2. Constant parameters and those that we assume as the same as it was described in the original calculation procedures were not added in this paper. For more details, see Deltour et al. (2009); Hutchings et al. (2013); Hamelin et al. (2011) and IPCC (2006).

In respect to GES'TIM model, we considered the same EFs for CH_4 and N_2O of Deltour et al. (2009) which implicitly assumes that the emissions from swine production in Brazil have the same EFs from swine production in France. These assumptions were also made by Prudêncio da Silva et al. (2014) for broiler chicken production. Therefore, to interpret our results, it should be in mind that there are some differences in the swine production in Brazil and France, such as: in France the manure is stored for some period in housing while in Brazil the manure goes directly to the slurry tanks which decreases the CH_4 emissions in housing (not considered in this paper) but could result in more emissions in storage since more volatile solids (VS) are available for decomposition. Another difference is the period of manure storage, i.e., in Brazil this period is 120 days while in France this period can be somewhat higher (Deltour et al. 2009).

The calculation procedure developed by Hutchings et al. (2013) describes the static mass flow of the manure nutrients, i.e. nitrogen and phosphorus (not considered in this paper) and the emissions of NH_3, N_2O, N_2, and NO_3. Therefore, to estimate CH_4 emissions we used the same model and parameters used in the IPCC (BR). In Hutchings model, the indirect N_2O emissions from NH_3-N and NO_x-N volatilization are not considered.

The calculation procedure from Hamelin et al. (2011) is based on IPCC (2006), however the authors included the estimative of N_2-N and NO_x-N and consider a different equation to estimate the NH_3-N loss in storage and manure application in field.

The scenarios following the IPCC guide differs from each other by the input parameters considered in the equation used to estimate the excreted N (Nex), and the VS content in manure and methane producing capacity (B_0) used to estimate CH_4 emissions. For IPCC (BR) different EFs for the N_2O emission in field and the N loss due to NH_3-N volatilization were also applied (Table 2).

3. Results

The results showed that IPCC (DF-LA) has the highest CO_2 eq. emissions while lower emissions were estimated through the calculation procedure described by Hutchings et al. (2013), see Table 3 and Figure 1.

Table 3. Results per FU (percentage of the contribution per column are given in parentheses).

Emissions per source/Models	GES'TIM	Hutchings et al. (2013)	Hamelin et al. (2011)	IPCC (DF-EU)	IPCC (DF-LA)	IPCC (BR)	Baseline

[a] Not considered.

CH_4 emissions in storage contributed with 41.5-82.7% of total CO_2 eq. Indirect N_2O emissions in storage had a contribution of 0.8-23.0% of total CO_2 eq. Only in GES'TIM model the CH_4 emissions due to manure application in field were estimated, however this emission had minor contributions (0.005%). Direct N_2O emissions in manure application represented 9.7-24.9% while the indirect N_2O emissions (i.e. from volatilization of NH_3-N+NO_X-N and NO_3 leaching) participated with 1.9-8.2% of total emissions.

4. Discussion

Higher climate change potential was observed in IPCC (DF-LA), as displayed in Figure 1, greater CO_2 eq. emissions for this calculation procedure was mainly due to direct and indirect N_2O emissions. This occurred because in this model the default values for N excretion rate used in Equation 10.30 from IPCC (2006) are very high, which results in higher values for the excreted N (Nex in Table 1) when compared to the other models. Comparing to the default values for Western European the N rate for Latin American countries are 3 and 1.3 times (values not showed) higher for the market and breeding swine, respectively. The greater amount of Nex in IPCC (DF-LA) were also the main responsible for higher indirect N_2O emissions due to NO_3 leaching in this model. Another issue that resulted in greater indirect N_2O emissions in IPCC (DF-LA) and IPCC (DF-EU) was the default values for N loss due to volatilization of NH_3-N and NO_x-N considered in IPCC (2006). Ammonia and the nitrogen oxides emissions have greater influence in the results due to the nutrient balance and the indirect N_2O emissions

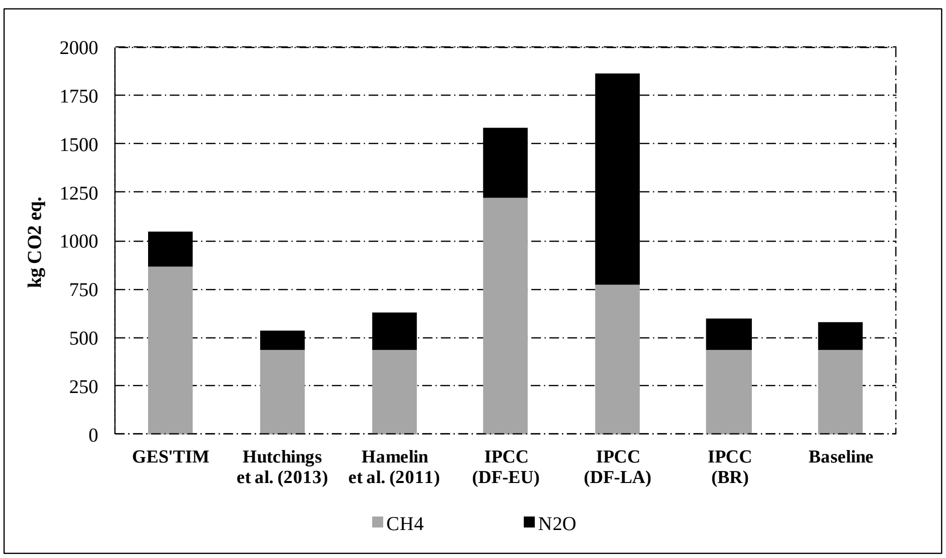

Figure 1. Comparison of mathematical models for CH_4 and N_2O emissions in manure management.

The higher CH_4 emissions in storage stage for IPCC (DF-EU) (Figure 1), compared to the other models, were mainly due to the methane producing capacity (B_0 in Table 1). Most probably, this is also the reason for greater amounts of CH_4 emitted in GES'TIM model. The B_0 for Latin American countries is lower than for Western European (IPCC 2006). Although we assume the same B_0 (i.e. 0.29 m^3 CH_4 (kg VS excreted)$^{-1}$) in IPCC (DF-LA), Hutchings et al. (2013), Hamelin et al. (2011), IPCC (BR) and Baseline models, IPCC (DF-LA) had higher CH_4 emissions due to the VS content used as input parameter.

Regarding the proposed model to estimate CH_4 and N_2O emissions from the MMS in Brazil, it can be noticed a need for a more site-specific data for the EF used for direct N_2O emissions in storage stage and for the constant input parameters used to estimate the proportion of organic N mineralized in slurry tanks and the coefficient factor used for NO_3 leaching emissions.

5. Conclusion

The results showed great differences for both emissions per FU according to the calculation procedure used. The model with lower CO_2 eq. emissions was from Hutchings et al. (2013), it showed a reduction of 71.4% when compared to the IPCC (DF-LA). CH_4 emissions in Baseline, IPCC (BR), Hutchings et al. (2013), and Hamelin et al. (2011) were 64.3% lower than in IPCC (DF-EU). While for N_2O emissions, the calculation procedure described by Hutchings et al. (2013) represented a 91.1% of reduction when compared to IPCC (DF-LA). The range in terms of CO_2 eq. emissions for CH_4 was 436.5-1223.6 kg while for N_2O was 97.7-1091.8 kg.

For CH_4 emissions, the differences were due to the methane producing capacity (B_0) and VS content. For N_2O the amount of excreted N considered and the N loss due to volatilization of NH_3-N and NO_x-N were the main reasons that significantly increased these emissions in IPCC (DF-EU) and IPCC (DF-LA).

Analyzing the models and based on our judgment, the calculation procedure used in Hutchings et al. (2013) seemed to be the preferable because it considers the effect of the mineralized organic N in the emissions, allowing future comparisons with other MMS, such as composting and biodigester. We suggest that future LCA studies also consider different options to estimate the CH_4 and N_2O emissions. Regarding to the Brazilian model proposed in this study, there is a need to develop site-specific data.

ABSTRACT

We created three model healthy alternative diets (HADs) for the US based on USDA recommendations and compared them to the standard American diet (SAD). We estimated the relative risk (RR) for changes in consumption of the foods for three non-communicable diseases based on published meta-analyses. We then calculated the changes in health care costs resulting from reduced RR with the change from SAD to HADs, and the changes in downstream greenhouse gas emissions (GHGE) attributable to these costs. We found significant reductions in disease, health care costs and GHGE. Because we were conservative in the degree of diet change, and in selecting only the highest quality data on disease risk for foods, these results likely underestimate the total potential of diet change to mitigate GHGE. Significantly greater GHGE mitigation is anticipated from larger changes in diet and inclusion of more food-disease risk reductions. In addition, upstream mitigation of GHGE from HADs from changes in the agrifood system will be larger than those presented here for downstream effects—these estimates are included in the larger project on the potential contribution of diet change to mitigating climate change, for which this paper develops a key methodological component.

Keywords: Climate, diet, health care costs, non-communicable diseases, nutrition

1. Introduction

The composition of the diet has a substantial impact on our health and the climate. During recent decades the composition of the standard American diet (SAD) in the US has become markedly less healthy, and these changes, in combination with an increasingly sedentary lifestyle, have resulted in an epidemic of non-communicable diseases (NCDs)(Grotto and Zied 2010). In the US, 35% of the adult population suffers from cardiovascular disease (Go et al. 2014), 9.3% has diabetes(CDC 2014), and 40% is estimated to be diagnosed with cancer during their lifetime (SEER NCI 2014). The epidemic of non-communicable diseases is an important contributor to increasing U.S. health care costs to almost $3 trillion per year, representing 18% of the total US GDP in 2014, and 20% by 2022 (CMS 2013:Table 1). The toll of these diseases can be greatly reduced by adopting a healthy lifestyle, including healthy diets (WCRF/AICR 2007, WHO/FAO 2003).

Our overall goal in this paper is to develop a methodology for assessing downstream mitigation potential, and to use it to estimate the effect on greenhouse gas emissions (GHGE) from the health benefits associated with the adoption of a moderately healthier counterfactual diets by the US population based on USDA recommendations. Our results significantly underestimate potential diet change emissions mitigation potential, because they are based on a limited number of diet change and food-disease links, and do not included upstream GHGE. The research reported here will be expanded in scope to include these aspects, as part of a larger project.

2. Methods

The boundaries of our study were the US, although data for diseased risk were from various countries. The reference year was 2013, and we adjusted data to 2013 based on trends or indices. The system boundaries were the stages of the health care sector associated with the studied diet related diseases.

We estimated the effect of dietary change on GHGE, NCDs, and health care costs in four steps. In step 1, we defined the reference diets, the SAD loss-adjusted food availability at the consumer level in the US (USDA ERS 2014), and healthy alternative diets (HADs). In step 2, we estimated the changes in disease prevalence from dietary change, based on RR (relative risk) estimates found in the literature. In step 3, we estimated changes in health care expenditures from dietary change, based on changes in disease risk from step 3, using the most recent reliable expenditure data. In step 4, we calculated changes in GHGE from changes in health care costs from step

3, using data in the Economic Input-Output Life Cycle Assessment (IO-LCA) based at Carnegie Mellon University (GDI 2014).

2.1. Step 1. Developing dietary scenarios

To analyze the effect of dietary change on health and GHGE in the US, we used as a reference the SAD and compared it with three counterfactual healthy alternative diets (HAD-1, -2, and -3) (Table 1). Dietary intake levels in SAD were based on per capita loss-adjusted food availability data by weight for 2012 (USDA ERS 2014). These data estimate the average actual food intake in the US in cooked weights, based on amounts available at farm gate, adjusted for losses from farm gate through post consumer stages (Muth et al. 2011). In order to distinguish between unprocessed and processed meat, and between whole grains and refined grains which are aggregated in the data provided by the USDA, we assumed that consumption of processed meat accounted for 22% of total meat intake (Daniel et al. 2011), and consisted of 90% red meat, and that consumption of whole grains and refined grains accounted for 90% and 10% of total grain consumption, respectively (Lin and Yen 2007, USDA 2010).

Table 1. Per capita intake[1] of reference (SAD) & model (HAD) diets (g day^{-1}).

Food	SAD	HAD-1	HAD-2	HAD-3
Red & processed meat	92	51	25	0
Fruits & vegetables	328	657	657	657
Beans and peas	7	15	50	84
Total grains	167	131	131	131
Whole grains	17	79	79	79
Refined grains	150	52	52	52

[1]Intake levels in cooked weights. Basis for RR calculations.

To create the HADs, we adjusted SAD only for foods for which (i) USDA dietary recommendations were consistent with international nutrition and health authorities (USDA 2010, WCRF/AICR 2007), (ii) there were documented GHGE synergies, and (iii) there were high quality data on contribution to disease (section 2.2). The dietary recommendations for which there are documented GHGE synergies were: (i) eat no more calories than needed to maintain a healthy body weight, (ii) increase the proportion of calories coming from plant-based food, iii) reduce the consumption of meat (especially coming from red and processed meat), and iv) reduce the consumption of foods with low nutritional value (Garnett 2011). Creation of the HAD diets thus involved only a portion of the total SAD diet; we did not change any other food groups (e.g. unprocessed white meat, fish, dairy, eggs).

In HAD-1 we increased the intake of fruits, vegetables and whole grains, and reduced the intake of red and processed meat and refined grains from the levels in the SAD to the USDA recommended levels (USDA 2010). Processed meat was limited to 10 g of cooked meat per day based on the recommendation by the WCRF that processed meat should be avoided or limited as much as possible (WCRF/AICR 2007). We assumed that whole grains and refined grains contributed to 60% and 40% of total grain intake, respectively, based on the USDA recommendation that at least half of the grain consumption should come from whole grains (USDA 2010). We limited fruit juice to 20% of total fruit consumption based on the USDA recommendation that the majority of fruit intake should come from whole fruits (USDA 2010). By using whole food-based recommendations (e.g. vegetables), as opposed to nutrient-based recommendations (e.g. fiber), we reduced the risk of double counting health effects from nutrients found in various food groups.

We converted recommended food consumption levels provided by the USDA (USDA 2010) into grams day^{-1} using serving size weights given in (USDA ERS 2014). According to these data, one ounce equivalent of meat and grains equals 28.3 g (cooked weight) and 22 g, respectively (USDA 2011); one cup of vegetables, beans and peas, and fruits including juices is equivalent to 123 g, 73 g (cooked weight) and 187 g, respectively).

Intake levels in HAD-2 and HAD-3 are the same as in HAD-1, except that consumption of red and processed meat was further reduced and replaced by an increased intake of beans and peas. For validation, the nutritional content of all dietary scenarios studied was estimated, and found to provide 3500-3900 kJ day^{-1}, i.e. about one third of the average recommended daily energy intake for adults (NCM 2004).

2.2. Step 2. Changes in disease prevalence with changes in diet

We based the selection of diseases to be included in this study on a literature review of epidemiological meta-analyses of research on the relationships between specific foods and diseases. The literature review was performed in the NCBI Pub Med database in March 2014 using as keywords the selected foods groups (e.g. "vegetables") and different NCDs (e.g. "coronary heart disease"). The diseases included in the review were coronary heat disease (CHD), hypertension, adult onset diabetes myelitis (AODM) and a range of cancers. We selected peer reviewed meta-analyses of prospective cohort and randomized controlled trial (RCT) studies, published between 2005 and 2014, that provided RR with 95% confidence intervals (CI). We judged the evidence for the diet-disease relationship as insufficient, probable, or convincing, depending on the RR estimates found and number of studies supporting the relationship: *convincing* if minimum two meta-analysis supported the relationship and if all meta-analysis located showed significant reductions in disease risk from the studied changes in diet; *probable* if a minimum of one meta-analysis located supported the relationship and if the most recently published meta-analyses with significant results showed a reduced risk from the studied changes in diet; and *insufficient* if the criteria for convincing and/or probable were not met. We chose estimates for reduced risk of disease conservatively by only including RR estimates where the evidence was convincing or probable, which limited the diseases studied to CHD, AODM and colorectal cancer (CRC).

The health effects of changing the diet from SAD to HAD were estimated by calculating a revised RR (RR_{re}) for each food-disease RR, assuming a log-linear dose response relationship between food intake and health outcome, as reported in the meta-analyses (Eq. 1):

$$RR_{re} = RR^{((x-y)/u)} \qquad \text{Eq. 1}$$

where RR is the original RR obtained from meta-analyses for diet food f (e.g., processed meat) and disease d (e.g., CHD), x is the level of f in the HAD, y is the level of f in the SAD, and u is the unit increase reported in the meta-analysis identified for disease d. The reductions in RR for a unit change in food consumption were assumed to follow a uniform dose-response relationship across the range of intake levels in the SAD and HAD. When there was more than one meta-analysis RR for a food-disease combination, we used an arithmetic average of the *RR*s. For the relationship between whole grains and CHD, no dose-response RR estimates were located; therefore, a RR value based on the comparison of a high vs. low consumption was used to estimate this health effect. This was considered valid due to the large difference in intake levels of whole grains between the SAD and HADs.

We then calculated the combined effect of the changes in all of the foods contributing to the RR for each disease (RR_{cd}) by multiplying them, based on the assumption that the effect of each food was independent (Eq. 2) (Ezzati et al. 2006):

$$RR_{cd} = RR_{re1} * RR_{re2} * RR_{re3} * \ldots RR_{ref} \qquad \text{Eq. 2}$$

where RR_{re1}, RR_{re2}, RR_{re3}, and RR_{ref} are the recalculated RR values for each of the individual food changes in the diet. Finally, to construct the 95% confidence intervals around the relative risk estimates for the HAD we conducted a Monte Carlo simulation (Rubinstein 2007) with 5000 iterations in which the individual RR estimates were allowed to vary randomly according to a lognormal distribution.

2.3. Step 3. Changes in health care costs from changes in disease prevalence

The Medical Expenditure Panel Survey (MEPS 2011) is a standard source for health care cost data, but has widely recognized methodological limitations, so we used the most recent data for expenditures for the three diseases from alternative sources. Expenditures for CHD and CRC were from (Heidenreich et al. 2011, Mariotto et al. 2011), with spending category percentages assigned by percentages for all heart conditions by MEPS (AHRQ 2014). For AODM, which accounts for 90% of all forms of diabetes mellitus, we used (ADA 2013) for costs and spending category assignments, assuming that category expenditure distribution would remain constant.

Expenditures for each disease were then adjusted for inflation to 2013$. Because health care spending in the United States increases at a rate different than the standard rate of inflation, we used the Bureau of Labor Statistics consumer price index for medical care (BLS 2014) to adjust for inflation of medical expenditures.

2.4. Step 4. Change in GHGE due to changes in health care costs (ΔGHGE-H)

In order to estimate GHGE for health care expenses for each disease, we identified subcategories of expenses, since the types of services vary substantially (e.g., diabetes requires more prescription medications than heart disease). Subcategories were assigned in alignment with the relevant Carnegie-Mellon IO-LCA (GDI 2014) categories of medical expenditures: hospitals, pharmaceutical manufacturing, physician's offices, and home health services. CRC was assumed to have the same proportion of economic activity in those categories as all forms of cancers, CHD was assumed to have the same proportion of economic activity in categories assigned to all heart conditions, both taken from MEPS category spending assignments. The same method was used for AODM in the broader category of diabetes mellitus.

We then used the IO-LCA to determine an initial GHGE for each disease. However, because the IO-LCA uses CO_2e, or global warming potential (GWP), values from older IPCC assessments of various GHGs, we adjusted the GWP for CH_4 from 21 to the most recent IPCC GWP of 34 for a 100-year time frame, and 86 for a 20-year time frame (IPCC 2013:714, Table 8.7). We did this only for CH_4 because the N_2O GWP changed only a few percent.

Since the Carnegie-Mellon assessments were based on 2002 emissions levels, we adjusted for measured decrease in carbon intensity in the US economy from 2002-2011 (EIA 2013), and projected this to 2013. We assumed that the decrease in carbon intensity experienced by the US economy was the same as that in the health care sector.

Finally, we assumed that the RRre associated with HADs would result in a proportional decrease in expenditure.

3. Results

Changing from the SAD to HAD-1 reduced the RR of CHD, AODM and CRC by 20-40%, and HAD-2 and HAD-3 further reduced RR by 5-9%, respectively (Table 2, Fig. 1). The reduced RR of disease also resulted in an a 25-33% reduction in total health care costs for these diseases, and a total reduction in the US of 20-33 million MT CO_2e yr^{-1}, and 65-106 kg CO_2e $person^{-1}$ yr^{-1}.

Table 2. Reduction with change to HADs in disease, health care costs, and GHGE.

Diet change from SAD to	Reduction in									
	Relative risk of disease						Health care costs ($B yr^{-1}) (of $219.5 total for diseases)	Downstream GHGE (kg CO_2e $person^{-1}$ yr^{-1})		
	CHD		AODM		CRC			CH_4 GWP =21	CH_4 GWP =34	CH_4 GWP =86
	Combined effect	95% CI	Combined effect	95% CI	Combined effect	95% CI				
HAD-1	40%	29-51	35%	28-44	20%	13-26	54	64.5	69.0	87.0
HAD-2	45%	31-67	41%	32-50	25%	17-32	65	74.5	79.7	100.5
HAD-3	45%	32-58	43%	34-53	29%	20-37	72	78.5	84.0	105.8

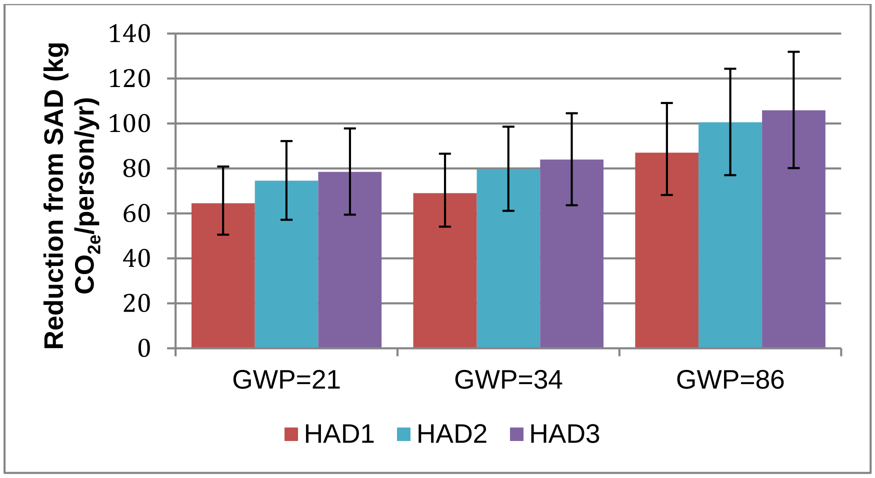

Fig. 1. Downstream reduction in CO_2e person^{-1} yr^{-1} for a CH_4 GWP of 21, 34, and 86.

4. Discussion

4.1. Results in relation to previous studies

Research on the combined effects of diet on the environment and nutrition is new but expanding. In recent years nutritional aspects have increasingly been incorporated into environmental and LCA assessments of food and diets, however, so far this has only included epidemiology to a limited extent. A small number of studies have examined the effect of healthier counterfactual diets on reduced morbidity and mortality, and on GHGE upstream (Aston et al. 2012, Scarborough et al. 2012), and on the effects of diet on GHGE via improved health, for example, by linking increased body weight to increased GHGE from higher fuels energy use (Edwards and Roberts 2009). However, the link between diet, health and GHGE from associated health care costs which we estimated in this paper has to our knowledge not previously been attempted. This study also fills a geographical gap, as most research on GHGE from dietary scenarios is limited to European settings (Hallström 2013)

4.2. Limitations of the research

The results of this study are largely dependent on the assumptions underlying the data we used for food consumption, RR, health care expenses, and GHGE. Of special concern when combining RR estimates as in this study, is the risk of double counting. We designed the study to minimize the risk of double counting by only using RR-estimates coming from meta-analyses that adjusted for influencing confounders, such as other types of food intake, physical activity level and history of disease. Despite these efforts, the risk of double counting remains, meaning that the health effects from the studied dietary change may be overestimated.. The overall uncertainty in results was also estimated with Monte Carlo Analysis. However, other assumptions we made would have resulted in under estimation of GHGE reduction from our counterfactual diets (see below).

4.3. Policy implications

The downstream GHGE reduction for HADs is equivalent to removing 4.3-7.0 million automobiles from the US roadways; it is also significant compared with other mitigation measures, for example, 1.9-2.4% of the Obama Administration's goal of a 17% reduction below 2005 US emissions levels by 2020. When upstream GHGE reductions from the HADs are added these numbers will increase significantly.

Although our results showed substantial potential benefits from dietary change, the total potential of diet change to simultaneously improve health and reduce GHGE is likely underestimated because it only included only a small subset of the possible foods and food-related NCDs. The total assigned expenditures for the diseases studied amounted to only \$220 billion, less than 8% of the projected total health care spending for the US in 2013 od \$2.9 trillion (CMS 2013:Table 1). Therefore, the savings we found from switching to HADS of \$B 76-94 yr^{-1} are likely a small portion of the potential savings, given that many more diseases and conditions are associated with diet. These savings (assuming consumer rebound is not significant), could be used for programs to support diet change and to retrain workers whose jobs would disappear as a result of the macroeconomic benefits of diet change.

But how realistic are the behavior changes required for the HADs? For HAD-1, the intake of unprocessed red meat and processed meat is reduced by 17 grams and 24 grams, respectively. The required change in meat consumption corresponds to eating one quarter pounder less per week and 1.5 sausages per week instead of 5.5. In order to reach the intake levels of fruits and vegetables and whole grains in HAD-1, the consumption in the SAD would have to increase by 2 and more than 4 times, respectively. Regardless of actual behavioral changes that could result over the coming decades, the attribution of GHGE to current behaviors remains a significant policy challenge.

In HAD-2 and -3 we decreased and eliminated red and processed meat. Lower intake levels of meat are also not a concern from a health perspective as long as reductions in meat consumption are compensated for by increased intake of other foods. Guidelines for healthy lacto-ovo-vegetarian and vegan diets are, for example, provided by the USDA (USDA 2010). In fact, there is increasing evidence that animal foods are a significant risk factor for many diseases (e.g. Farvid et al. 2014, Jakobsen et al. 2009, Kim et al. 2013), and also contribute disproportionately to the GHGE of the food system (Garnett 2009).

5. Conclusion

There is growing awareness of the importance of diet in determining GHGE and health care costs. We have reported here a methodology for quantifying this relationship. Our results show that it is possible to estimate the effects of changing to healthier diets with a high level of probability for the small proportion of foods and related diseases for which adequate data exist. The effects are significant in terms of improved health, reduced costs, and GHGE reductions. The methodology developed here is a key component of our larger project to estimate the net GHGE mitigation potential (from agrifood system change to health care) of diet change for a range of diets as alternatives to the SAD. Given the urgency of mitigating emissions over the short term in order to avoid catastrophic climate change, the mitigation potential of diet change should be investigated more thoroughly for incorporation into national, state and local climate policies.

ABSTRACT

LCA tools to certify products and guide farm management have proliferated but a detailed comparison is needed to show whether different tools are consistent. In this work, three widely used tools for cradle-to-gate emissions of greenhouse gases (GHGs) have been investigated - one general tool (Cool Farm Tool) and two crop-specific tools (Bonsucro for cane sugar and PalmGHG for palm oil). Large discrepancies are found even when the same input data are used; they result from detailed model differences so that no individual tool can be identified as "best" or "preferred". The results raise questions over the extent to which comparability can be expected between tools, particularly when they differ in their specificity to particular geographical areas and crops, and whether farm-level calculations can "add up" to provide estimates for GHG emissions at landscape or national level. Furthermore, generic tools may not be sufficiently representative to guide farm management for specific crops. Agreement is needed on how to reconcile results between different tools and levels.

Keywords: Greenhouse gas calculators, carbon in supply chains, farm management, standardization, comparability

1. Introduction

LCA is a scientifically-based analysis, but differs from conventional scientific models in not being amenable to empirical testing. In this respect, LCA has much in common with economic models. The inherent uncertainty in LCA models has led some to assert that even consequential LCA "cannot produce definitive quantitative estimates of actual environmental outcomes" (Plevin et al. 2014) and is therefore of limited value for policy support, even though similarly uncertain economic models are widely used for these purposes. Where LCA is used for certification or comparative claims, standardisation of approaches is therefore essential, even for the kind of attributional analysis which is used for product labelling (Clift et al. 2009).

Greenhouse gas (GHG) emissions from agriculture and forestry are responsible for nearly 30% of global anthropogenic emissions (IPCC 2007). Therefore emissions from agricultural production have attracted political, media, academic, and public attention at both 'macro' (i.e. global and national) level and 'micro' level (i.e. focusing on the individual farm), where the terms 'macro' and 'micro' are used here in their conventional economic senses. Variability and resultant uncertainty are problems for both LCA and economic models of agricultural systems, particularly in comparison to industrial processes whose performance is more uniform and predictable. In recent years there has been a proliferation of both consumer-facing agri-food certification schemes intended to encourage GHG management and measurement of crop production (Keller et al. 2013) and, at the 'micro' scale, of GHG calculators intended to report performance and aid management at the level of specific crops and individual farms (Colomb et al. 2013). However, there has been little attempt to compare and standardise calculators, which can yield different results even given the same input values for the same agricultural system (Colomb et al. 2013; Whittaker et al. 2013). This variability hinders creation of benchmark GHG figures or target ranges to guide producers and may limit their value in guiding on-farm management.

This paper compares three GHG calculators in detail: one general farm-focused calculator, the Cool Farm Tool (CFT) developed by the University of Aberdeen, Unilever and the Sustainable Food Lab (Hillier et al. 2011), and two crop-specific tools used by commodity roundtables, namely Bonsucro's GHG calculator for cane sugar developed at Louisiana State University (Macedo et al. 2008; Wang et al. 2008) and PalmGHG for palm oil developed by the Roundtable on Sustainable Palm Oil (RSPO) (Bessou et al. 2012 & 2014) (Chase et al. 2012). Both crop-specific tools have become central to the certification process (RSPO 2013; Bonsucro 2013). All three tools combine IPCC tier 1 national inventory data (IPCC 2006) with more regionalised tier 2 data, together with farm-specific activity data. Results are reported and compared here on a per land area basis (i.e. as kg CO2e per ha cultivated) to avoid including the additional variability due to the dependence of yield on very local conditions; for a specific farm, the impact per unit of crop is calculated using the actual site-specific yield. The results do not include the effects of specific management practices such as rotational cropping or tillage, nor the impacts of land use change. More detailed results and comparisons, including the effects of land use change, are given by Keller

(2014).

2. Methods

The three calculators have been applied to assess GHG emissions up to the farm gate, including agricultural production and associated inputs (e.g. fertilizer and pesticide production). Processing of the raw products is not included, nor are emissions embedded in infrastructure or equipment. The systems considered are sugar cane production in Brazil (Bonsucro and CFT) and palm oil cultivation in Indonesia (PalmGHG and CFT). Input data were provided by the relevant commodity round-tables (see Keller 2014) specifically for the purpose of comparing calculators; they are representative of common practice at the micro-level in the two cases but must not be interpreted as representing the sectors at the macro- or meso- levels (see Section 4). The tools differ in their data requirements and formats; e.g. only Cool Farm Tool requires information on soil properties. Minor adaptations to the calculators were made to enable them to use input data which were as near identical as possible but without modifying the underlying data or algorithms. Thus the results show the comparison between the tools in their generally available forms but with a few "bugs", identified in the course of this work, rectified in collaboration with the tool producers.

3. Results

The nature and extent of discrepancies between the general calculator and the relevant crop-specific tool are shown for sugar cane in Figure 1 and for palm oil in Figure 2. These Figures also reveal the GHG "hot spots" in the two systems: agrochemical inputs (including all soil or crop enhancers) and energy use (mainly diesel fuel for farm equipment and transport). Land use change is, of course, also highly significant but is not included in the comparisons presented here.

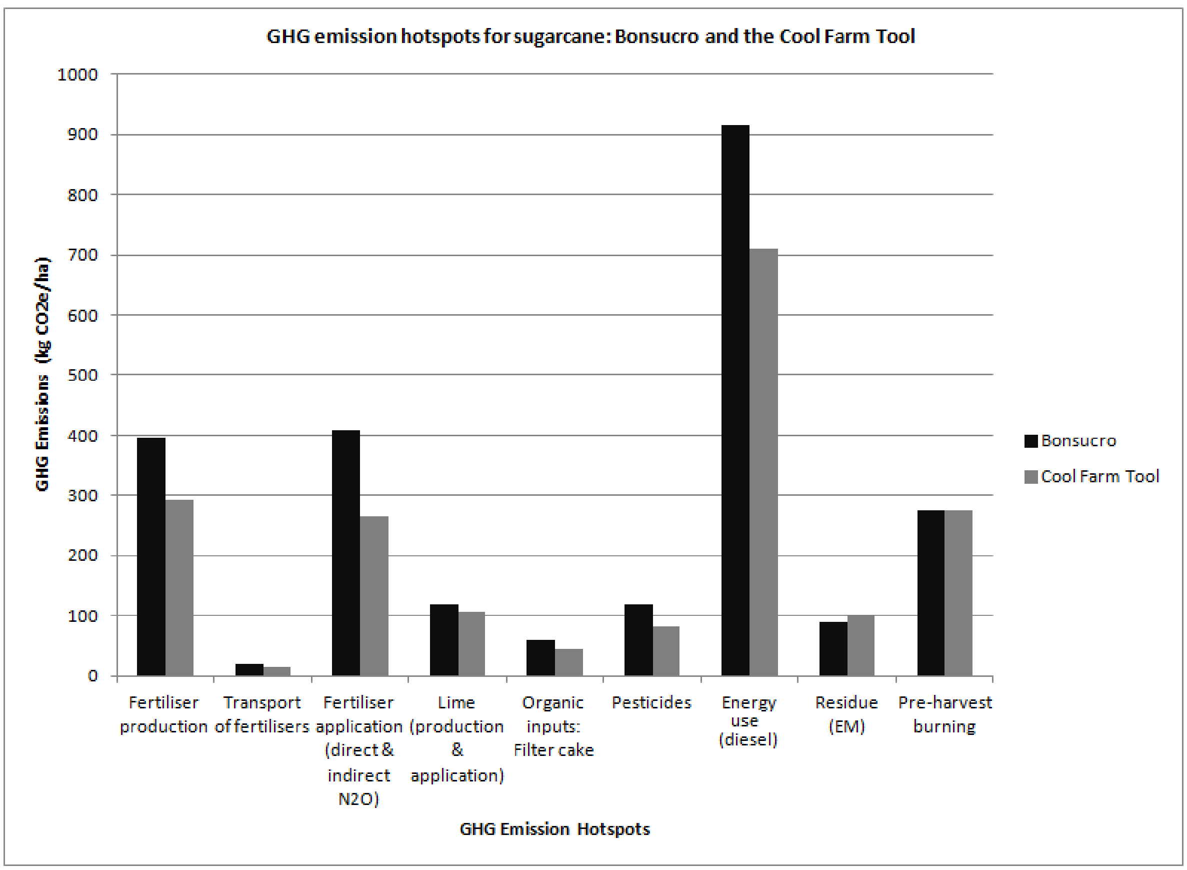

Figure 1. GHG emissions from sugarcane cultivation: Bonsucro and the Cool Farm Tool.

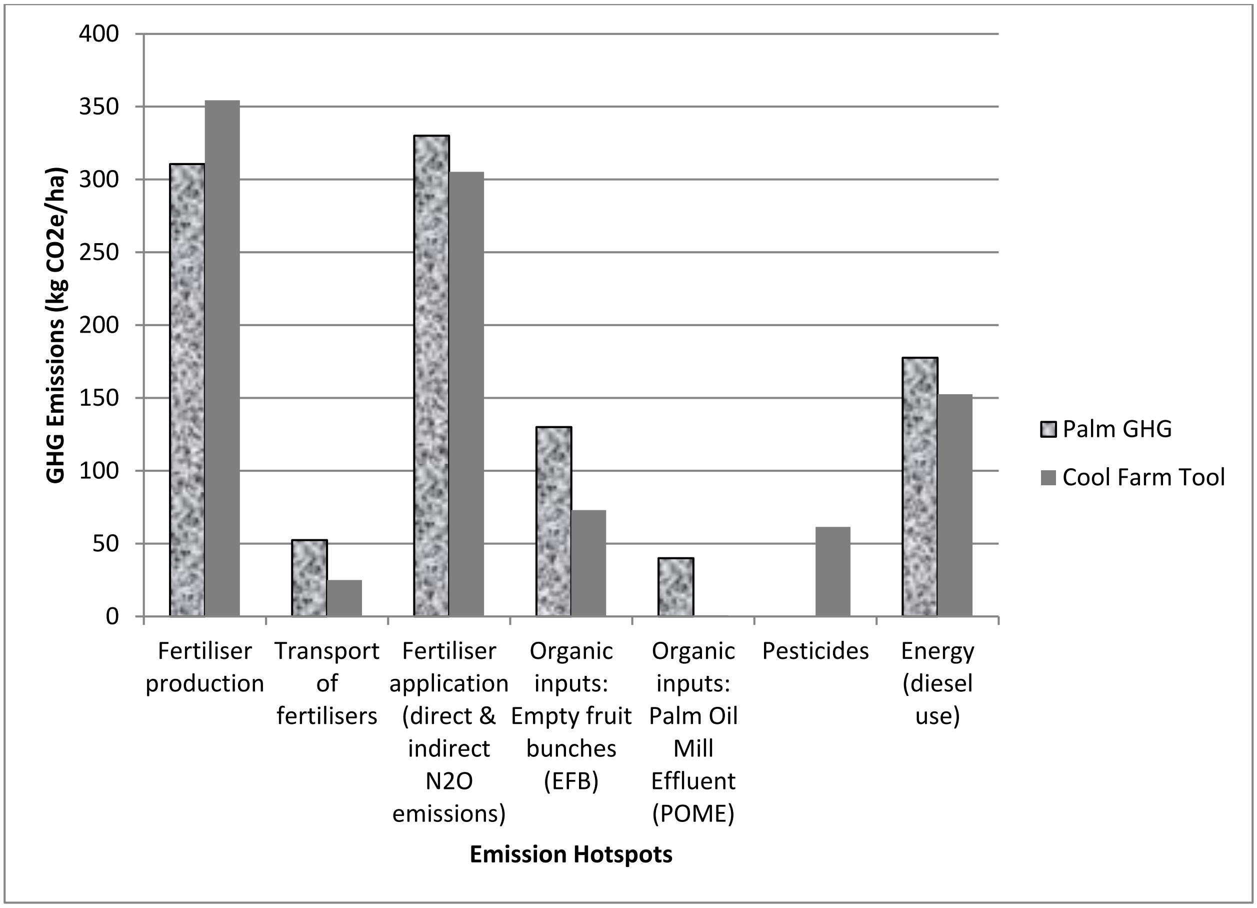

Figure 2. GHG emissions from palm oil production: Palm GHG and the Cool Farm Tool.

For almost all activities, CFT Gives lower estimates than the crop-specific tools. For energy use, the differences result from the emission factors assumed. The differences between the figures from fertilizer use are particularly marked for sugar - as high as 42% for emissions associated with mineral fertilizer. This also results from differences in the background estimates, in this case for emissions from production of nitrogen fertilizer: Bonsucro is based on data from the GREET model (Macedo et al. 2008; Wang et al. 2008) whereas CFT uses data for European fertilizer production that is generally more efficient. These differences illustrate a general problem in comparing calculators: even when they use the same input data and methodology, differences can arise from different background data and models; these aspects are explored by Keller (2014). Moreover, while Bonsucro and PalmGHG enable modeling of different inputs specified by the user, CFT as a multi-crop tool has more in-built flexibility and can model different practices such as reduced tilling and cover cropping. Thus CFT can be used to investigate improvements in management practices, a capability which is missing from Bonsucro and PalmGHG. Figure 3b compares results from Bonsucro with a range of different modes of fertilizer application calculated using CFT. Although the CFT results span a significant range, the range still lies consistently below the value calculated from Bonsucro. However, CFT estimates for different soil types (Figure 3a) span a wider range and do encompass the single estimate from the Bonsucro calculator. GHG emissions from fertilizer production for palm oil is the one component where CFT gives a higher estimate than the crop-specific tool but the range over different soil types is as wide as in Figure 3a so that the difference between PalmGHG and the baseline CFT estimates depends strongly on the soil type adopted as the default in CFT.

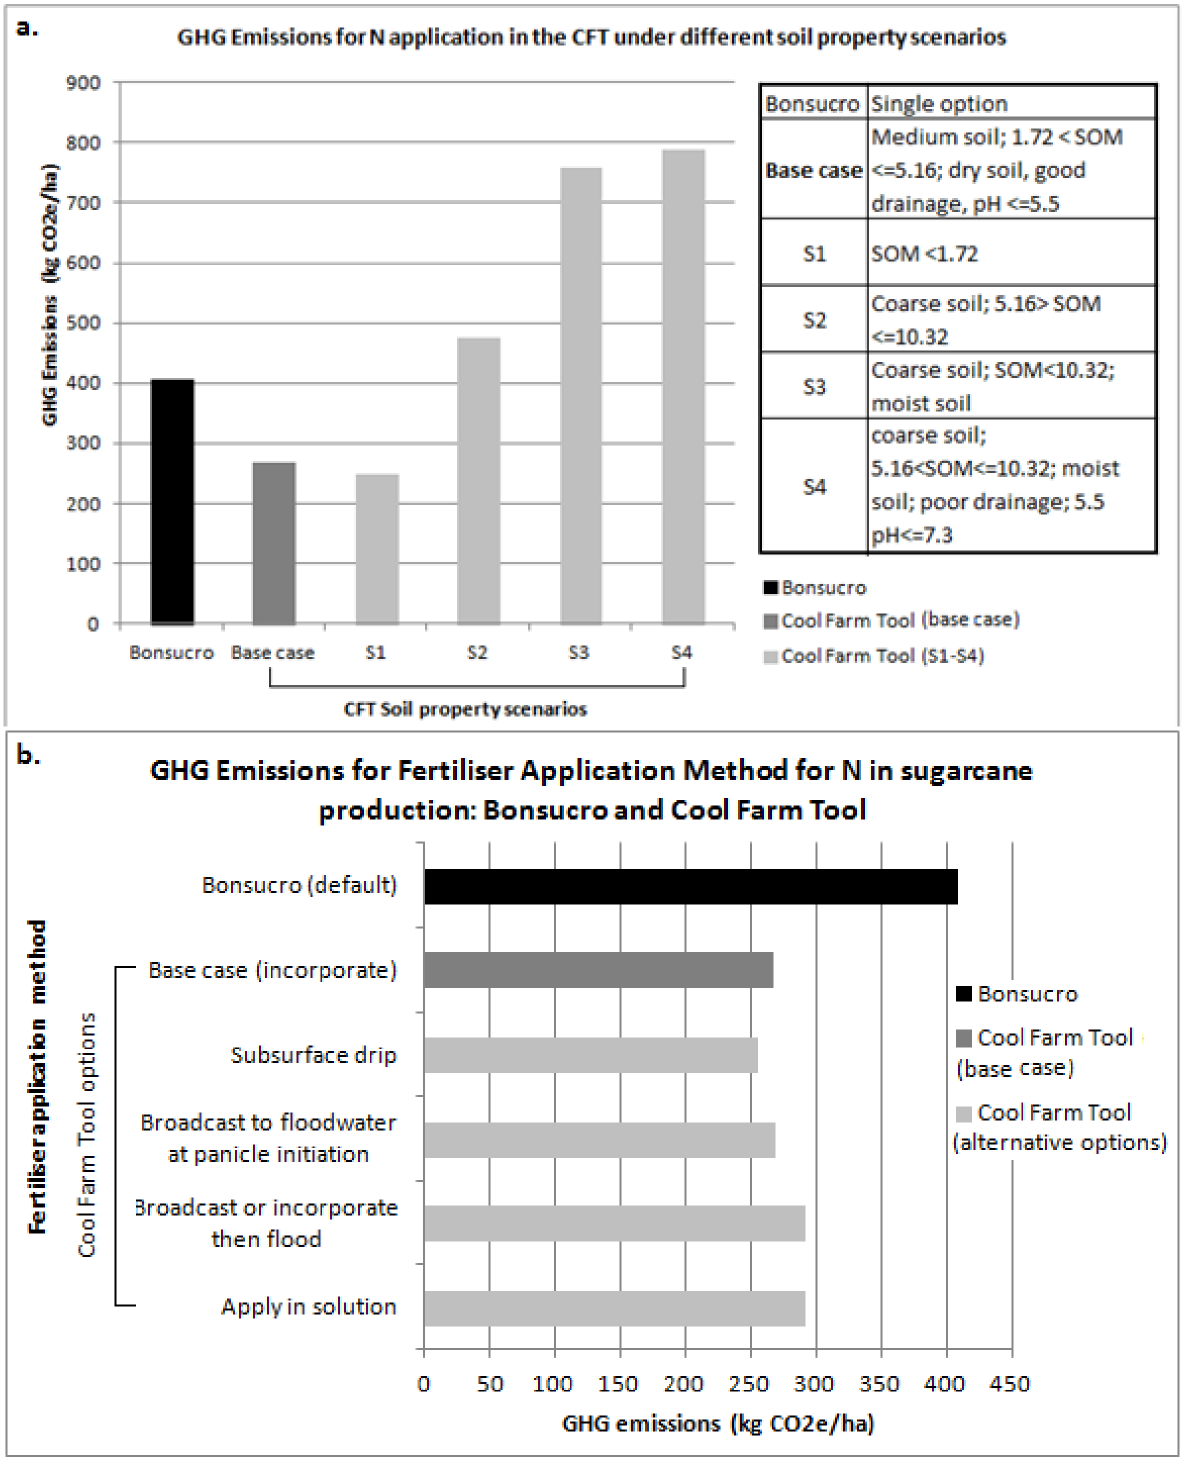

Figure 3. GHG emissions from fertilizer use in sugarcane cultivation: Bonsucro compared with a range of Cool Farm Tool scenarios for soil type and mode of application of fertilizer.
a. effect of soil properties
b. effect of fertilizer application method

4. Discussion

The results above show that, while these tools are in broad agreement, they give results which can differ by considerable margins. Short of detailed forensic examination of the underlying model data and algorithms, it is unrealistic to expect closer agreement. More critically, provided the tools are formulated correctly, there is no basis for prescribing any individual tool as the standard beyond ensuring that the most relevant background data are used. The differences between the results from different calculators are of comparable magnitude to the differences between individual producers; therefore comparative assessments must be based on results from a single calculator. This is particularly relevant to certification schemes (e.g. RSPO 2013) which require quantification of GHG emissions but permit the use of a specific tool (PalmGHG in this case) or an "equivalent" calculator but without guidance on what might be considered equivalent. However, we have not identified any respects in which the tools are contradictory in the sense of giving contradictory indications on ways to improve environmental performance at the farm level.

The discrepancies between these specific calculators raise the question of whether it will ever be possible to devise a single calculator for GHG emissions applicable to all crops and all purposes. In addition to the problems of describing different crops, production systems and farm or plantation management, there is an overarching question of the purpose for which the results are needed (Keller 2014). Going beyond the micro-/macro- distinction, it is useful to distinguish three different scales and applications:

Micro: products from a specific farm;

Meso: crops from similar agricultural systems;

Macro: global or national: relevant to a large area of land or landscape, with a number of different land uses and products.

Even within each level, there is a need for discussion aimed at agreement on appropriate methodology and data. GHG calculations at the micro-level are needed to guide farm management, and sometimes as the basis for certification or payments for responsible farm management; therefore they should be based as much as possible on primary farm-specific data with tier 2 or 3 data used for the background. Meso-level figures may be used, for example, to compare alternative food sources or the sustainability of different diets or as components of personal carbon calculators. Even within a single food supply or retail company, calculations at the two levels are used for different purposes: given the variability between different producers, micro-level calculations may be used to select individual suppliers and to help suppliers to improve their own performance, whereas meso-level calculations can guide what general products to promote and to select the regions from which they should be sourced. Macro-level figures are necessary for national GHG reporting, to support policy development and to support programs such as UN-REDD and REDD+. Tier 1 data are sufficient for this purpose and it could be appropriate to use environmentally-extended input/output calculations.

As usual with process-based LCA, calculations at the micro- and meso-levels do not necessarily add up to give the macro-level figures, for much the same reasons as LCA results for all a company's products may not add up to describe the whole of the company's impacts: the larger scale calculations include shared or background activities which need not be included if the purpose is to improve the environmental performance of a single farm, product or supply chain. Non-additivity should not be a concern provided that the three levels of calculator do not give perverse or contradictory results.

Some certification schemes are beginning to show attention to the landscape level, rather than focusing on individual crops. Rainforest Alliance, Fairtrade, UTZ along with other institutions and certification bodies have recently become members of the Committee On Sustainable Agriculture (COSA) seeking to analyze the impacts of agriculture at a larger scale, particularly associated with the implementation of sustainability initiatives (COSA, 2013). Bringing together and integrating performance information from certification schemes and other supply chain initiatives that may involve GHG calculators with domestic policies and larger programs including REDD could and should enable impacts to be assessed at the landscape scale (Nepstad et al. 2013) and ultimately scaled up to understand the global impact.

5. Conclusion

Even superficially similar "carbon calculator" tools can give considerably different results for identical cases and input data. At least for the tools compared here – Cool Farm Tool (CFT) vs. Bonsucro for sugar and vs. PalmGHG for palm oil – the differences are not attributable to the fact that CFT is a general tool whereas the others are crop-specific; rather, they derive from differences in the underlying models and, most importantly, in the background data which can only be revealed by very detailed forensic examination. It must therefore be anticipated that discrepancies between different calculators will persist. To achieve consistent and comparable results requires the application of consistent and comparable methods. Thus for comparative assessments for a single crop or level, it is essential to use one tool; comparative assessments or claims should be ignored unless they compare results obtained with the same tool.

Micro-, meso- and macro-scale assessments require different approaches. There is a need for discussion aimed at agreement on appropriate methodology and data for the different scales, although this will not remove the differences between different tools. Comparison across different sectors and scales is likely to remain problematic, dependent on understanding in depth of what lies beneath each calculator.

ABSTRACT

AGRIBALYSE is a French research program dedicated to producing Life Cycle Inventories (LCI) of agricultural products, based on a strong partnership of 14 research and technical institutes. It provides a homogenous and consensual LCI database to support environmental labelling policies and to help the agricultural sector to improve its practices. The public LCI database of more than 100 products and its detailed methodology report were published in 2014. The database mainly contains LCIs for average French products, the functional unit is the product mass (kg) and the perimeter cradle-to–farm-gate. The datasets go along with a detailed methodology report (Koch and Salou 2014) and a project report (Colomb et al. 2014). Several key objectives for a follow-up project have already been identified: better estimate of uncertainties, accounting for soil carbon dynamics, impacts on biodiversity and impacts of water consumption. Enlargement of the database with additional products and products from innovative systems is also demanded, as well as stronger connections with international programs. These issues should be addressed in a future AGRIBALYSE 2 program.

Keywords: LCI database, French agricultural products, ecolabelling, ecodesign

1. Introduction

AGRIBALYSE is a French research program (2010-2013) dedicated to producing public Life Cycle Inventories (LCI) of agricultural products. A database of more than 100 products and its detailed methodological report have been published in 2014 (Koch and Salou 2014).

AGRIBALYSE started in 2010, in response to the “Grenelle de l'Environnement” roundtables which decided on the use of Life Cycle Assessment (LCA) to support environmental labelling. The LCA approach was also seen as a tool to support farmers and their organisations to better identify the environmental impacts of their products and to support eco-design strategies to improve their production systems. At the same time, a lack of LCA results and especially homogenous ones was identified concerning French agricultural productions (Ecointesys 2008). Thus, AGRIBALYSE was launched by the French Environment and Energy Management Agency (ADEME). A strong partnership of 14 research and technical institutes (INRA, Agroscope, CIRAD, ACTA and 10 agricultural technical institutes) worked together to build a homogenous and consensual LCI database for French as well as a few imported agricultural products.

This article describes the main methodological choices and the general content of the database, whereas other contributions to the LCA Food 2014 conference describe more specific choices and results for each product sector (animal products/crops/fruits). The potential use and limits of the database will be discussed in the last paragraphs.

2. Methods: modelling framework and main methodological choices

For complete and detailed information on methodological choices, please refer to the AGRIBALYSE methodological report (Koch and Salou 2014).

2.1. General modelling framework and tools

In AGRIBALYSE, data describing agricultural practices have been provided by the technical institutes in an Excel file (called data collection tool), developed for the occasion. The data collection tool was then connected to models to calculate direct (on farm) emissions and resource use via another Excel file (called calculation chain). Indirect fluxes were then added in SimaPro, to obtain LCI and LCIA data. The characterization methods used were chosen based on the recommendation by the ILCD Handbook, the Envifood program and the ADEME-AFNOR platform (AFNOR 2011; JRC and IES 2011; ENVIFOOD 2012; GT1 2012).

2.2. System boundaries (space and time)

The perimeter considered in AGRIBALYSE LCIs is from cradle-to field-gate for crops and from cradle-to-farm-gate for animal productions. It implies that for crop production all the up-stream processes (production of inputs, field operations etc.) are included, but none of post-harvest operations, although they might happen on the farm (storage of potatoes, drying of cereals). All operations required for the animal production phase are included (feed production, transport and storage, fattening of animals, milking, construction and maintenance of buildings and machines).

For managing manure, the distinction between animal and plant production was defined according to Gac et al. (2010). Emissions from storage of manure and any forms of treatment (nitrogen reduction, composting or anaerobic digestion) were allocated to the livestock production system and the emissions associated with loading, transport and spreading were allocated to the plant production system which used the manure.

To be consistent, system boundaries have been described following 9 schemes (3 for plants, 6 for animals) (Figure 1), to cover all agricultural productions.

The reference period for LCIs was 2005 to 2009, except for perennial crops for which it was 2000-2010 to account for the production phases (seedlings, early production, full production etc.) and alternating yield phenomenon.

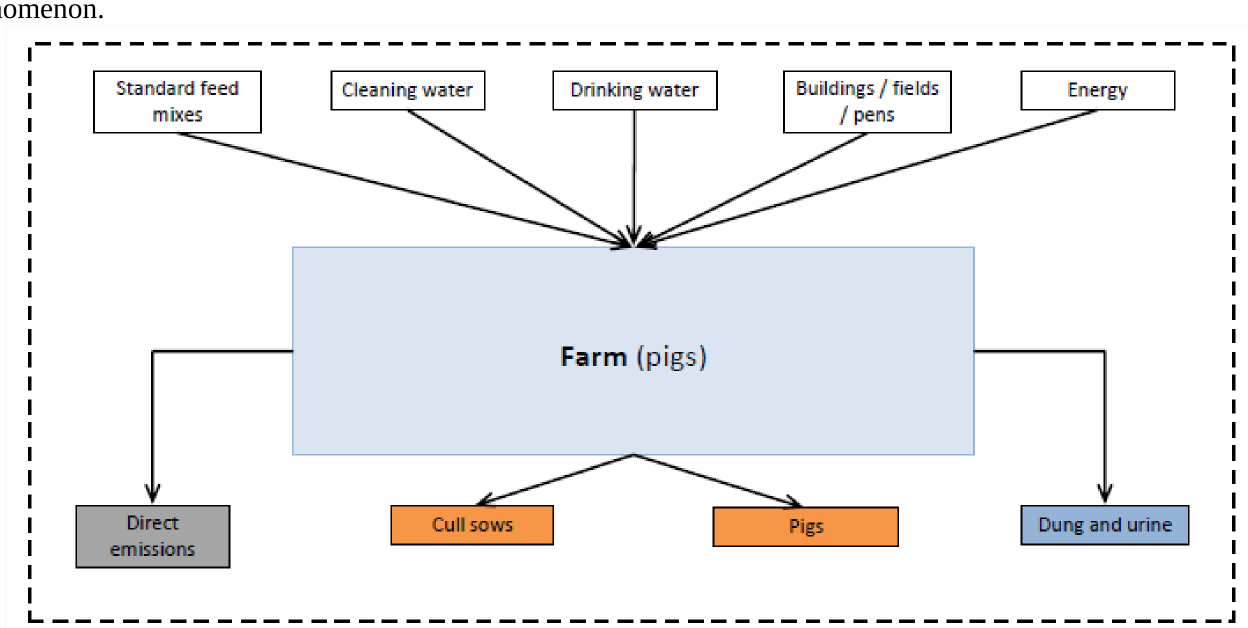

Figure 1. Example of system boundaries for pig production.

2.3. System description, data sources and representativeness

Initially, AGRIBALYSE aimed to provide a representative LCI for every major French agricultural product. The description of production systems by the technical institutes was based on (in order of preference): statistical sources, typical cases (documented in as much detail as possible), expert opinion or individual case / estimate as the last option. The quality of the description of the production systems was a key step for the quality of the database. For many products it was not realistic to identify a single production system to represent the French average. Therefore, several production systems for the same product (variations) were often described. E.g. for potatoes, the following LCIs were calculated: industrial use, fresh market firm flesh, fresh market other varieties, starch potato and a national average. The national average is a weighted average based on the share of each system in the national production. For production systems that count a large number of variations, the weighted average may not be representative of the national production (e.g the five dairy systems LCIs represent 21.1% of the national production of milk). For some products an average product was not meaningful (e.g. grapes) because each product is specific of a production system or an area of production (Beaujolais, Maconnais, etc.) and no national average could be provided. It is very important to be aware of the representativeness of each LCI when using the database.

2.4. Allocation

Allocation rules follow the international recommendations (ISO 2006a, 2006b). The allocation method must always be meaningful for all co-products implicated. For crop production, most of the co-products are generated in the processing step, which is not included in the AGRIBALYSE program. No allocation between different product qualities was applied at field-gate (e.g. export quality versus local market quality for imported fruits). For crops, an important work has been implemented to allocate organic N fertilizer and P and K mineral fertilizers between cropping sequences (Koch and Salou 2014, Annexe D). For animal production, a so-called bio-physical allocation method was implemented, based on Dollé and Gac (2012) for milk. At first, allocation was avoided by decomposing the system in animal classes based on their production phase. Then, for the animal classes where allocation was required (ex: dairy cow in production phase), allocation was based on the metabolic energy required to produce each co-product (calf, milk). The impacts of the animal classes producing a single product were fully allocated to this product. For data imported from pre-existing databases (eg. ecoinvent v2, INRA Rennes internal database), such as for animal feed components, the allocation choice made in the pre-existing database (mostly economic allocation) was not modified.

2.5. Models for the calculation of the direct emissions

AGRIBALYSE identified the most appropriate calculation methods for all direct emissions and resource consumptions, while pre-existing datasets (mainly ecoinvent v2) were used for calculating indirect emissions (up-stream ex: inputs production, material etc.).

Finding appropriate models to estimate direct emissions for each pollutant substance was one of the main challenges. According to the AGRIBALYSE set of rules, such models should not require input data that are too difficult to collect, should have been published, should have been validated for France (or tropical conditions for the tropical crops) and should be recognized internationally. The priority was given to inter-product consistency, with the idea of having specific models for each emission mechanism used across the entire database rather than having specific models for each product or type of product. The list of models used is available in the methodological report (Koch and Salou 2014).

2.6. Quality control

The quality control was performed in two steps: control of agricultural system data and control of LCI data (Figure 2). Quality control of agricultural system descriptions was performed by independent experts. LCI results were controlled by experts of the technical institutes involved in the program, both at the level of the calculation tools and regarding the plausibility of the results. More than 160 system description sets were checked with unqualified acceptance in 30% of cases, minor revisions in 50% of cases and major revisions in 20% of cases. More than 500 suggestions for improvement or comments on technical data and sources were taken into account to meet the recommendations of the experts. The quality control of the LCI results allowed the correction of calculation errors, the detection of anomalies, it ensured coherence and improved the credibility of the results. Performing a quality control on both the system description data and the LCI data sets significantly contributed to the quality of the AGRIBALYSE database.

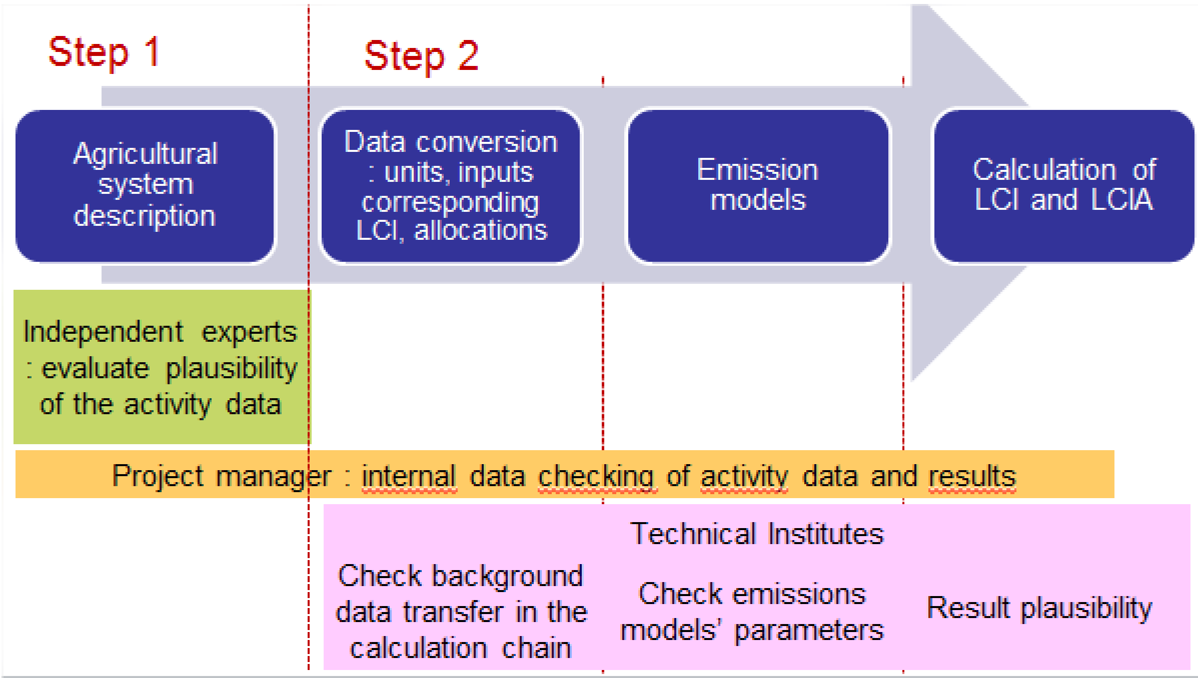

Figure 2: Quality control scheme

3. Results

The outcomes of AGRIBALYSE are a public LCI database, a methodological report (Koch and Salou 2014) and a final report describing the project organization and main lessons learnt (Colomb et al. 2014). The database is available in several formats with various levels of detail depending on the user's requirements:

o Factsheets: a simplified version in PDF format presenting most common and most robust impact indicators. The factsheets are freely available and do not require an LCA software.

o The AGRIBALYSE_vIMPACTS database (system processes, ILCD and Ecospold_V1 formats): containing aggregated LCI data sets considered by the AGRIBALYSE consortium to be sufficiently reliable to be used for a product environmental labelling approach (robustness, representativeness). These LCI data sets are available for incorporation into the ADEME IMPACTS® database, the official French environmental labelling database. An LCA software is required to analyse these data.

o The AGRIBALYSE_vcomplete database (unit processes, Ecospold_V1 format). These data are intended primarily for ecodesign projects and provides the results in a transparent format. An LCA software is required to analyse these data.

ILCD and ecospold formats are suitable for LCA specialists as the data can be used in current LCA software.

The reports and summary factsheets are available on line (www.ademe.fr/agribalyse-en), while the full database is available on demand to ADEME. Finally, a short document "Advices for proper use of AGRIBALYSE results" (AGRIBALYSE 2014) highlights the critical points when using and interpreting the data. The publication of data and the efforts made to ensure transparency, with several formats to respond to different needs has been an important time investment, but should contribute to a large and appropriate use of the datasets.

The products included in the database are 28 crop and 18 animal products (Table 1). For several products a number of variations exist.

Table 1 : list of AGRIBALYSE product groups and number of variants per product group.

Sector	**Type** (the product groups are given in brackets)	Number of product groups	Number of product variants
Arable / horticultural	**Annual crops** *(durum wheat, soft wheat, sugar beet, carrots, rapeseed, faba beans, grain maize, barley, peas, potatoes, sunflowers, triticale)*	12	28
	Grassland/forage *(grass, alfalfa, silage maize)*	3	16
	Fruit *(peaches/nectarines, apples, cider apples, wine grapes)*	4	13
	Special crops grown in France *(roses, tomatoes, ornamental shrubs[a])*	3	6
	Special tropical crops *(coffee, clementine, jasmine rice, cocoa, mango, oil palm fruit)*	6	6
Total	**Arable / horticultural**	**28**	**69**
Livestock	**Cattle** *(cow's milk, beef cattle, veal)*	3	14
	Sheep *(sheep's milk, lambs)*	2	2
	Goats *(goat's milk)*	1	1
	Poultry *(eggs, broilers, turkeys, ducks for roasting, ducks for foie gras)*	5	15
	Rabbits *(rabbits)*	1	1
	Aquaculture *(trout, sea bass / sea bream)*	3	3
	Pigs *(conventional, Label Rouge, organic)*	3	8
Total	**Livestock**	**18**	**44**

4. Discussion and perspectives

4.1. Improvement needs and perspectives

AGRIBALYSE proposes a comprehensive database and a detailed and coherent methodological framework. For further work several methodological improvements have been identified. The main issues to be resolved are the modelling of changes in soil and biomass carbon stocks (due to farmer practices and land use change), of impacts on biodiversity, and of impacts of water consumption.

The methods and models for calculating emissions (nitrate, phosphorus, trace metals, etc) may also be modified to take better account of the specific characteristics of crops, agricultural and animal production practices and soil-climate characteristics. For France, IPCC tiers 2 models for GHG emissions should be ready soon and could significantly modify the results. It will be therefore important to update the database and use the best models available.

The LCI database could also be enlarged, by including new products (ex: fishery products, other vegetables, more imported products, etc.) and new product variations (regional products, Protected Geographical Indication products, quality label products, etc.) could be included to strengthen the representativeness of the database. For a proper comparison of products, it would be necessary to better quantify the uncertainty of the LCI data. The quality of the data was assessed using the ecoinvent pedigree matrix and ILCD criteria. Data for tropical products and for less studied production systems (with less data available, like organic systems) hold the largest uncertainty.

The future AGRIBALYSE database will probably allow the inclusion of LCI data proposed by third parties. This would mean that a procedure should be established to examine whether the proposed LCI data have been produced in accordance with the AGRIBALYSE methodology and quality assurance standards. This will be a complex task that will have to be tackled. Finally, the database being based on ecoinvent v2 datasets, the relevance of updating to ecoinvent v3 should be assessed.

4.2. Contribution to Environmental labelling and Eco-conception

The LCI data needed for the implementation of environmental labelling will depend on the labelling scheme. The companies will need reliable background data (such as AGRIBALYSE) and tools to implement ecolabelling schemes.

By the end of 2013, a French parliamentary report on environmental footprinting highlighted the interest of consumers for environmental labelling of food products; it also identified several specific methodological issues for the food sector (Errante and Saddier, 2013). It advocates that, in France, environmental labelling should become a voluntary but regulated process in the future. The volunteer companies should apply a common methodology and communication framework, which would be defined by public institutes and would limit the risk of green-washing or incomplete analysis. No clear time frame for this development was given, but the will to implement global environmental labelling was reaffirmed. The European Union is also currently carrying out an experimentation on the Product Environmental Footprint (PEF) to determine the appropriateness and feasibility of implementing environmental labelling at the European scale. AGRIBALYSE data could be used for this experiment.

Thus the AGRIBALYSE LCI database is a key element for the environmental labelling of food products. It is however not sufficient as it does not include processing, marketing and end of life stages. The processing steps for food products are currently analysed in ACYVIA, another French LCI database program, that should provide results by the end of 2016. Both data from AGRIBALYSE and ACYVIA will feed ADEME "IMPACTS" LCI database, which should be the official multi-sectorial database supporting the French ecolabelling schemes.

AGRIBALYSE helps to guide the farming sector towards more ecoefficient agricultural systems. By providing a comprehensive method for future LCA studies of agricultural products, it will allow more comparable results and clearer conclusions. In April 2014, the database had been downloaded by more than 65 institutions (130 individual licences provided), research and technical institutes, agro-food companies, consultancies working on ecodesign. The data are also integrated in some LCA computer tools. The database is used for instance in French Ecoalim research project which tries to identify animal feeding strategies with lower environmental impact. Data have also been used for policy studies, for instance in a study for the Swiss government comparing the impacts of Swiss and imported products, in order to define an appropriate agricultural and environmental strategy. Last but not least, the LCI data can be used to explore the impacts of human diets.

4.3 AGRIBALYSE II

ADEME has decided to launch a follow up program for AGRIBALYSE. The general goals, providing data for environmental labelling and supporting ecodesign are still considered to be very relevant and will be conserved. The main goals for this program will be to (a) help users to produce LCI data following the AGRIBALYSE methodology, (b) update and maintain the data, (c) augment the database with LCIs of new key products, (d) promote and include methodological improvements from the LCA field.

Thus, AGRIBALYSE II should be a platform coordinating several thematic projects on dataset production and methodology improvements that would feed the database. The platform should be strongly connected to other European and international database projects.

5. Conclusion

The AGRIBALYSE partnership produced a consensual and homogenous LCI database for French farm products. By its ambition and innovativeness it also consisted in a major learning process for the partners involved. Nevertheless it must be stressed that the amount of work and skills required for such program has been considerable.

The database is now used by many French and international organisations: research and technical institutes, agro-food companies, consultancies etc.. These data are publicly available and can be used in many projects dealing with sustainable production system, eco-labelling, diet studies, agricultural policy strategies etc. For the future, several methodological issues remain to be implemented in the AGRIBALYSE methodology (dynamics of soil carbon stocks, water consumption, impacts on biodiversity) and the characterisation of uncertainty should be improved. Really understanding LCIA results requires understanding of the impact assessment methods including complex scientific models, thus efforts on communication means should be continued.

To conclude, we can say that AGRIBALYSE has been an excellent pilot program that now needs to be connected and enriched with other initiatives.

Impact of transportation on the environmental performance of Brazilian banana production

Leda Coltro*, Thiago Urtado Karaski

Institute of Food Technology – ITAL, Packaging Technology Center – CETEA, Campinas, SP, Brazil
* Corresponding author. E-mail: *ledacolt@ital.sp.gov.br*

ABSTRACT

The increase of consumer's ecological awareness has forced decision-makers and producers to search for scientific information about environmental performance of agricultural production systems. LCA studies on tropical perennial agricultural products are still scarce; furthermore, the great diversity of these products contrasts with the reduced available environmental data in Brazil. As fifth largest banana producer in de world, Brazilian production is almost entirely directed towards the domestic market through small-scale banana producers widely distributed throughout the country. The objective of this study is to evaluate the environmental performance of banana transportation stage through environmental indicators, considering Brazilian largest production regions. In the domestic market most bananas are consumed near its production centers, except for Northern Minas Gerais and Bom Jesus da Lapa - BA regions which distances from the consumers are approx. 1,000 km. The banana consumed in São Paulo has the lowest environmental impact in relation to the transport stage: 23.20 kg CO_2 eq/t, 50.10 MJ/t and 8.41 kg of non-renewable resources/t in the empty return scenario. Exports impact was larger for MERCOSUR than Europe due to the use of different transportation modes.

Keywords: banana, Brazil, transport, environmental impact, GHG emissions

1. Introduction

The Brazilian banana crop in 2013 was 6,931,137 tons, occupied a harvested area of 523,315 hectares and had an average yield of 13.2 tons per hectare (IBGE, 2014a). In 2012, the value of the Brazilian banana production was estimated at 4,396 billion reais (IBGE, 2014b). Brazil features as the fifth largest producer of bananas in the world (FAO, 2012). However, Brazil is not even among the top ten exporters of the product, exporting 110,054 tons in 2011 (FAO, 2014), since its production is almost entirely directed to the domestic market. With the exception of the states of São Paulo, Paraná and Santa Catarina, where crops of Cavendish bananas prevail, most of the national production of bananas is from the subgroup *Prata*, preferred by most Brazilian consumers and more resistant to postharvest injuries and illness, but not well accepted in the export markets (Lichtemberg, Lichtemberg, 2011).

The ten municipalities that stand out in the national banana production account for less than 20% of the Brazilian production. This indicates the wide geographic distribution of small-scale banana producers throughout the country, with only a few poles that stand out as major producers, namely: North of Santa Catarina, the Vale do Ribeira in São Paulo´s Southern coast, North of Minas Gerais, Bom Jesus da Lapa in Bahia, Vale do Submédio do São Francisco, Vale do Açu in Rio Grande do Norte and Vale do Jaguaribe in Ceará. While states in the South and Southeast region export to MERCOSUR countries, especially for Argentina and Uruguay, the northeastern states, notably Rio Grande do Norte and Ceará, have had a growing market share in Europe (Germany, UK, Netherlands, Poland, Spain and Italy) (Vieira , 2009).

The increase of consumer's ecological awareness has forced decision-makers and producers to search for scientific information about environmental performance of agricultural production systems through Life Cycle Assessment (LCA) studies on food products. Nevertheless, additional work is required, as well as the development of a methodology to continue improving LCA studies on tropical perennial agricultural products, which great diversity contrasts with the reduced data, either because these data do not exist or because they have not been published.

A number of studies have reinforced the belief that the stage with the most significant impact for the banana industry is transportation, mainly because of the overseas transport. Craig et al. (2012) estimated the carbon footprint of bananas produced by Chiquita Brands International in Central and South America, and sold to the USA, at approximately 1 kg of CO_2eq/kg of bananas sold. The transportation stage represented the largest part (36%) of emissions by the supply chain, primarily due to overseas transport, followed by the stages of production (22%) and retail (22%).

Ecuador is the largest exporter of bananas in the world (FAO, 2014). Iriarte et al. (2014) analyzed the carbon footprint of Ecuador's Premium bananas for export (Musa AAA – *Cavendish*) using a considerable amount of field data (harvests of 2009, 2010 and 2011). The system boundaries considered from agricultural production to delivery in a European destination port, simulating two scenarios: the best-case scenario, where the refrigerated containers of the ships did not return empty from their trip to Europe and the worst-case scenario, where they returned empty. Accordingly, the carbon footprint of Ecuador's bananas for export ranged between 0.45 kg (best-case) and 1.04 kg CO_2-eq/kg of bananas (worst-case), as shown in Table 1. The study demonstrated the importance of using efficient transportation, i.e. the simple use of containers during the return stage makes possible to reduce the carbon footprint by 57%. The study concludes that the overseas transport stage has the highest contribution to the carbon footprint (27% to 67%) followed by agricultural production (23% to 53%).

Table 1. Contribution of life cycle stages to the carbon footprint of Ecuadorian export bananas (Iriarte et al., 2014).

Life Cycle Stage	**2009**	**2010**	**2011**
	(kg of CO_2eq/kg)	(kg of CO_2eq/kg)	(kg of CO_2eq/kg)
On farm	0.21	0.24	0.26
Post-harvest fruit handling	0.001	0.001	0.005
Packaging	0.08	0.09	0.09
National transport	0.008	0.008	0.008
Overseas transport[a]	0.12/0.71	0.12/0.70	0.12/0.70
Total carbon footprint[a]	0.42/1.01	0.46/1.04	0.48/1.06

[a] The first value shown represents the Best-case scenario for overseas transport while the second value shows the worst-case scenario.

Therefore, the aim of this study is to evaluate the environmental performance of banana transportation stage through environmental indicators, namely climate change, energy use and non-renewable resources, considering Brazilian largest production regions. Both domestic consumption and exports are taken into account in this study.

2. Methods

The LCA methodology employed was based on standards ISO 14040 and 14044 (2006). The modeling of transport data was carried out using Brazilian data on fuel consumption by the fleet and IPCC emission factors for GHG emissions (Ministério, 2011; IPCC, 2006). Partial life-cycle inventories related to fuel production and pre-combustion developed by CETEA - Packaging Technology Center (Coltro et al., 2003; Garcia et al., 1999) were incorporated into the transport inventory for bananas.

The goal and scope of this study was to evaluate the environmental impact of banana transportation inside and outside the country. The environmental indicators may be incorporated in LCA of bananas produced in Brazil, which could boost ecolabeling of this product and larger volumes of trade.

A broad survey on recent banana production data in Brazil characterizing it geographically, both domestic consumption and exports, was performed in trusted databases and literature. The information considered in this study (distances, fuel consumption, capacity of the transport modals, packaging etc.) were obtained via the collection of data from reliable sources. Extrapolations were justified based on data published in the literature.

The functional unity adopted was 1,000 kg of bananas delivered to retail in the domestic market or at port in case of export.

The system boundaries considered the fuel production and the transportation in the domestic market and exports to MERCOSUR and EUROPE, simulating three scenarios, as follow: 1) the ships and trucks returned empty from their trip, 2) they returned full, and 3) they returned full but with 33% loss due to injuries during the transportation.

Transport distances were estimated using Google Maps inserting the main producing cities in the region considered and the main consumption centers of its production. Exports to Europe considered Germany and the cities of Buenos Aires and Montevideo, when exported to Argentina and Uruguay respectively.

The considered impact categories are: climate change (CO_2 eq), energy use (MJ) and non-renewable resources (kg). GHG emission factors for transport and energy production were obtained from GHG Protocol Brasil (2012). The inventory quantities primary energy demand (PED) and non-renewable resources were analyzed. GWP (100 years) were estimated according to the CML method (GUINÉE, 2002).

3. Results

In Brazil, banana production is almost entirely directed towards the domestic market due to its large population and high per capita consumption, 29.1 kg of bananas per inhabitant per year (FAO, 2009). Accordingly, the country has not developed good postharvest handling and conservation practices for transportation to overseas markets, as have the more traditional banana exporting countries: Ecuador, Philippines, Colombia, Costa Rica, Guatemala etc. (Lichtemberg, Lichtemberg 2011). Small producers scattered over national territory are mostly responsible for Brazilian production.

In 2011, the domestic market consumed 98.5% of the banana production and a mere 1.5% was exported, primarily to Europe and MERCOSUR countries as seen in Figure 1 (IBGE, 2014b). In 2010, exports had been a little higher, reaching 2%. The main destinations for Brazil's exports in 2011 were Germany (31% of total value and 25% of the exported volume), Uruguay (25% of the total value exported), UK (16% of total value) and Argentina (14.5% of total value). In 2011, approx. 52% of the volume of banana exports was destined for MERCOSUR (SECEX, 2014).

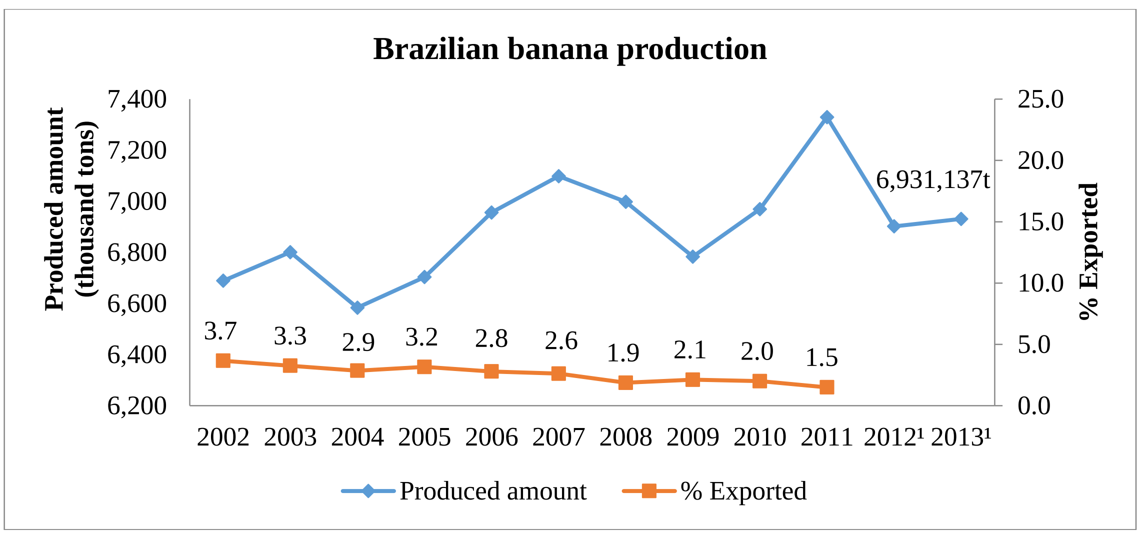

Figure.1. Brazilian banana production historical series (IBGE, 2014a, 2014b) and exports (SECEX, 2014).

Another reason for the low level of postharvest care in Brazil is that the largest part of domestic production comprises bananas of the *Prata* subgroup, which are more resistant to inadequate handling in the postharvest period (Lichtemberg, Lichtemberg, 2011). According to Reinhard et al. (2013), only 2% to 5% of Brazilian banana production is exported, domestic consumption amounts between 65% and 70% of production and postharvest losses are approx. 30%. Banana productivity in Brazil, between 13 and 14.5 t/ha (FAO, 2014), is still low when compared to the global average of approx. 20 t/ha. Europe has a rate of 36 t/ha and Asia 28 t/ha (EMBRAPA, 2009).

The main banana producing regions in Brazil are the Northeast (34.1%) and Southeast (33.5%), as shown in Figure 2. The value of production for these two regions, in 2012, was 3,162,691 thousand Brazilian reais (IBGE, 2014b).

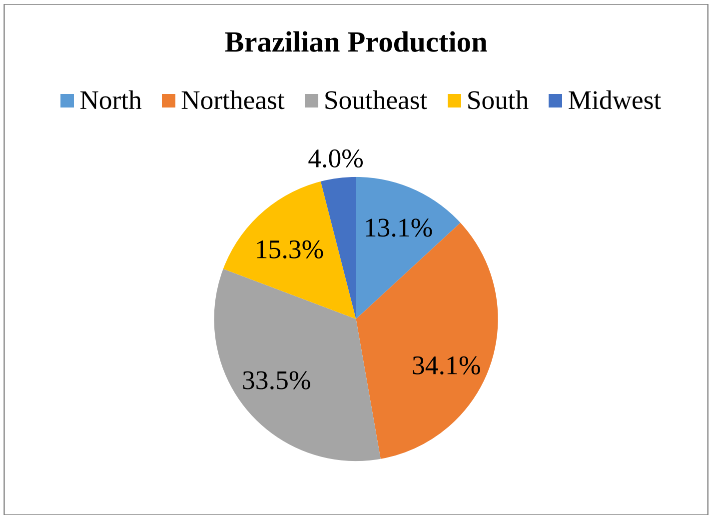

Figure 2. Regional production share for the 2013 banana crop (IBGE, 2014a).

The main banana producing states in Brazil are: São Paulo, Bahia, Santa Catarina, Minas Gerais and Pará, together accounting for 61% of domestic banana production and over 63% of the value of the 2012 crop, as shown in Table 2 (IBGE, 2014b).

Table 2. States with the highest share of domestic banana production in 2012 (IBGE, 2014b).

State	Yield (t)	Share of Domestic Production (%)	Value of Production (000´s Brazilian Reais)	Share of the value of Domestic Production (%)	Productivity (t/ha)
São Paulo (SP)	1,215,435	17.6	851,210	19.36	22.5
Bahia (BA)	1,083,346	15.7	734,725	16.71	15.0
Santa Catarina (SC)	689,815	10.0	275,528	6.27	23.3
Minas Gerais (MG)	687,293	10.0	639,030	14.54	16.4
Pará (PA)	547,098	7.9	275,409	6.26	13.1
Ceará (CE)	415,763	6.0	217,275	4.94	8.8
Pernambuco (PE)	407,574	5.9	168,451	3.83	9.7
Paraná (PR)	276,890	4.0	127,579	2.90	24.0
Espírito Santo (ES)	241,997	3.5	151,224	3.44	11.3
Goiás (GO)	197,990	2.9	155,626	3.54	15.8
Brazil (Total)	6,902,184	100.0	4,396,349	100.00	14.1

In 2012, the municipalities where the main banana producers were located are the following: Corupá/SC (2.4% of domestic production), Miracatu/SP (2.3%), Cajati/SP (2.1%), Bom Jesus da Lapa/BA (1.8%) and Luiz Alves/SC (1.8%). In terms of the value of production, the following are worthy of mention: Cajati/SP, Sete Barras/SP, Eldorado/SP, Wenceslau Guimarães/BA and Jaíba/MG. As can be seen in Table 3, the top ten municipalities for domestic banana production account for less than 20% of the share of domestic production as well as value of production. This demonstrates the wide geographical distribution of banana producers throughout the country (present in the 27 states of Brazil as well as the federal district of Brasilia), with only a few centers that stand out as the largest producers, as shown in Figure 3. In 2012, the vast majority of producing municipalities had a turnover of as much as 3 million Brazilian reais. Only Cajati/SP and Sete Barras/SP earned more than 90 million Brazilian reais from banana production. The strategic banana producing regions are the follow: the Southern coastal region of the state of São Paulo, the North of Minas Gerais, the Southern coastal region of the state of Bahia, the Southwest of Pará and the Northern Santa Catarina.

Table 3. Municipalities with highest values of banana production in 2012 (IBGE, 2014b).

Municipalities	Quantity produced (t)	Share of Domestic Production (%)	Municipalities	Value of production (´000 Reais)	Share of value production (%)
Corupá - SC	165,420	2.4	**Cajati - SP**	130,950	3.0
Miracatu - SP	158,400	2.3	**Sete Barras - SP**	100,000	2.3
Cajati - SP	145,500	2.1	**Eldorado - SP**	87,750	2.0
Bom Jesus da Lapa - BA	127,179	1.8	**Wenceslau Guimarães - BA**	83,680	1.9
Luiz Alves - SC	127,100	1.8	**Jaíba - MG**	82,820	1.9
Wenceslau Guimarães - BA	115,900	1.7	**Jacupiranga - SP**	70,200	1.6
Sete Barras - SP	100,000	1.4	**Registro - SP**	69,750	1.6
Eldorado - SP	97,500	1.4	**Bom Jesus da Lapa - BA**	69,313	1.6
Guaratuba - PR	96,480	1.4	**Luiz Alves - SC**	68,507	1.56
Jaíba - MG	82,000	1.2	**Janaúba - MG**	58,888	1.34
Total	1,215,479	17.6	**Total**	821,858	18.7

This study was concentrated on several centers that stand out as being the largest producers, namely Northern Santa Catarina, Vale do Ribeira, Northern Minas Gerais, Bom Jesus da Lapa - BA, Vale do Submédio do São Francisco, Vale do Açu - RN and Vale do Jaguaribe - CE and the Southern and Central-Southern regions of the state of Bahia. Figure 3 locates these production centers and the arrows indicate the main destination markets. Production in these centers is, for the most part, intended for the large cities in the region, however the states with the highest exports are Rio Grande do Norte, exported 21.8% of its production to Europe in 2011 (31,000 tons, corresponding to 28.3% of exports from Brazil); Santa Catarina, which exported 8.3% of its production (54,300 tons, or 49.3% of Brazilian exports) to MERCOSUR countries (Uruguay and Argentina); and Ceará, which exported 23,000 tons of bananas to Europe (21% of Brazilian exports) (SECEX, 2014, IBGE, 2014b).

The distances considered for the assessment of the environmental impact of bananas transporting in Brazil, as well as the burdens associated with this life cycle stage are shown in Table 4. Figure 4 shows the contribution of the different scenarios to the burdens evaluated.

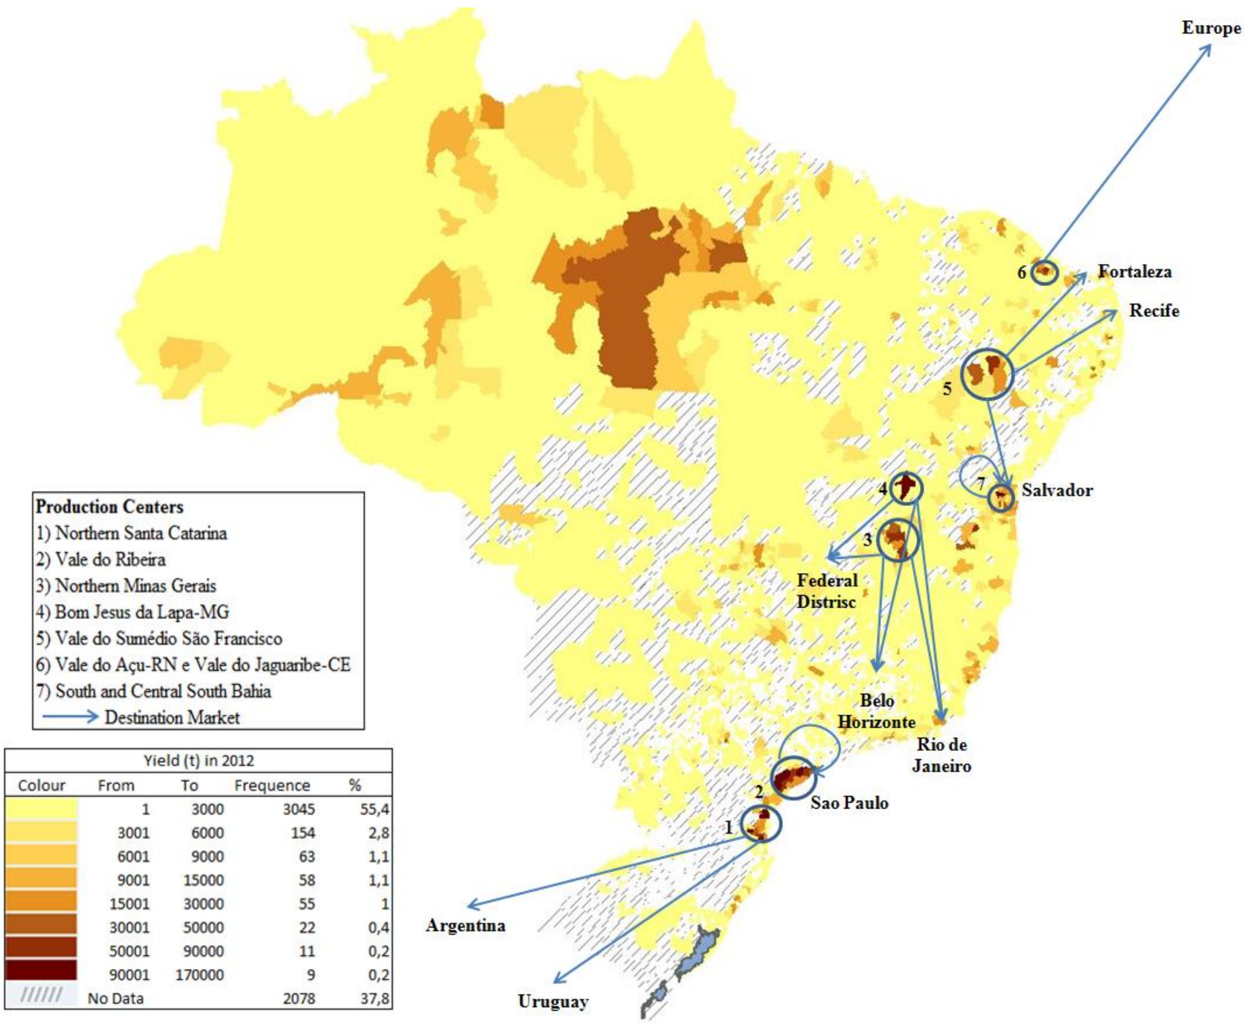

Figure 3. Banana production hotspots in Brazil and main destination market (IBGE, 2014b; Embrapa, 2009).

Table 4. Burdens associated with the transport of bananas in Brazil (Functional unity = 1 ton).[1]

Production center / Distance from domestic markets[2]	Burdens	Scenario 1 Return full	Scenario 2 Return empty	Scenario 3 Return full and 33% losses in T
Northern Santa Catarina State / 378 km	CO_2 eq (kg)	22.72	45.44	33.86
	Energy use (MJ)	49.06	98.13	73.11
	Non renewable resources (kg)	8.24	16.48	12.28
Vale do Ribeira / 193 km	CO_2 eq (kg)	11.60	23.20	17.29
	Energy use (MJ)	25.05	50.10	37.33
	Non renewable resources (kg)	4.21	8.41	6.27

4. Discussion

Brazil has seven banana producer regions distributed along the country. Most of the banana produced in Brazil are consumed near the production centers, except for Northern Minas Gerais and Bom Jesus da Lapa - BA regions which distances from the consumers are approx. 1,000 km.

The banana consumed in São Paulo has the lowest environmental impact related to the transport stage since it was produced in the Vale do Ribeira region that is the region with the shortest distance between production site and consumers (193 km).

On the other hand, the banana consumed in Rio de Janeiro, Brasília and Belo Horizonte has the highest environmental impact related to the transport stage since it is produced in the Bom Jesus da Lapa - BA region which is the region with the highest distance from the consumers (approx. 1200 km).

There have been various studies on the LCA of bananas, the majority having a "cradle-to-gate" scope (from production to retail in Europe), except for Kilian et al. (2012) who took into account the “cradle-to-grave” scope which includes up to consumption stage and the study by Svanes & Aronsson (2013), which took both scopes into consideration. Kilian et al. (2012) stated that this tropical fruit emits 1.09 kg of CO_2-eq per kg of exported bananas, with overseas transport being responsible for 78% of emissions, followed by agricultural production with 15% and distribution with 7%. Lescot (2012) calculated that the carbon footprint of bananas exported to Europe is 0.85 kg of CO_2e per kg of bananas, the stages with the greatest impact being overseas transport (43%), agricultural production (29%) and packing (12%). Luske (2010) estimated the carbon footprint at 1.12 kg of CO_2-eq per kg of exported bananas and also showed overseas transport and agricultural production to be the stages with the greatest impact, whose contributions were 62% and 12%, respectively. Svanes and Aronsson (2013) found the carbon footprint (from farm-to-retail) of 1.37 kg of CO_2-eq/kg and concluded that the banana hot spots in their study were overseas transport, which accounted for around 55% of the carbon footprint, followed by agricultural production, which accounted for 16%.

Differently from the other studies on LCA of banana available in the literature, the export stage of Brazilian banana to Europe is the life cycle stage with the lowest environmental impact due to the optimum relation of the load per trip ratio of the ships which minimizes the consumption of fuel per ton of transported banana.

Surprisingly despite a travelling distance 3 times larger from the northeastern Brazil to Europe than Santa Catarina to MERCOSUR the average overseas transport impacts are 4.2 to 4.5 times smaller (436.13%) than export via truck to Argentina and Uruguay. Besides, the exports of banana to Mercosur is the highest environmental impacting stage since it is based on truck transportation while all the transportation to Europe are made by ship.

Apart from the higher consumption of fuel per ton of banana transported by trucks than ships, the distances of the producer regions from domestic market can reach values over 1,000 km due to the continental dimensions of Brazil which contributes to enhance the environmental impact of this stage of the life cycle.

The data shows that in the domestic market the burdens vary in more than 80%, that is, the banana consumed in São Paulo has an estimated transport emission of 23.2 kg of CO_2 eq, 50.1 MJ of energy use and 8.41 kg of non renewable resources, while the largest environmental impact of the banana that is produced in Bom Jesus da Lapa – BA, serving cities in Rio de Janeiro, Brasília and Belo Horizonte has emissions of 145.21 kg of CO_2 eq., 313.55 MJ of energy use and 52.65 kg of non renewable resources. This variation is smaller when analyzing exports to MERCOSUR and Europe: (29.5%) in CO_2 eq, and 39.5% of energy use and non renewable resources.

Taking into account the different scenarios, the impact of the transport of bananas in scenario 3 (truck returns full and 33% banana losses in transport) is 1.5 times higher than scenario 1 (truck returns full). If the cultivation stage is being accounted, the impact of banana loss is even higher. So, efforts must be made to reduce the product loss through the life cycle.

5. Conclusion

The results have shown that the banana consumed in São Paulo has the lowest environmental impact related to the transport stage since it was produced in the region with the shortest distance between production site and consumers.

On the other hand, the banana consumed in Rio de Janeiro, Brasília and Belo Horizonte has the highest environmental impact related to the transport stage since it was produced in the region with the highest distance from the consumers.

Despite three times higher distance, the exports to Europe has 70% lower environmental impact than exports to MERCOSUR since it is based on ship transportation while transportation to Argentina and Uruguay is made by truck.

This study reinforces the importance of the transport modals and reduction of food loss in reducing the product environmental impacts.

ABSTRACT

Life cycle thinking was applied to the rice production system in order to evaluate the possibilities of environmental impact reduction. Improvements have been applied to several stages of the life cycle as follow: 1) Irrigation, 2) Drying, 3) Core and clean stage, 4) Packaging and 5) Transport. The work was carried out from June 2012 to August 2013. The functional unity adopted was 1,000 kg of packed rice (5 kg packs), available at retail. The system boundary considered the field operation, including transportation after harvest, fertilizer production, packaging and transport until the retail. The results have shown the new rice production system has significant environmental performance improvement, mainly water (approx. 200,000 L/t) and energy consumption (approx.. 200 MJ/t) as well as GHG emission (approx.. 30 kg CO2 eq/t) and yield (1,152 kg/ha), being the new irrigation system responsible for the majority of the benefits.

Keywords: rice, irrigation, environmental performance, design for environment, life cycle thinking

1. Introduction

Rice cropping fields are important contributor to climate change since they are a major methane source. The area of rice cropping fields in the world is gradually increasing and this area is expected to continue expanding as the world population increases. So, mitigating methane emission in these areas is an important issue. This can be accomplished through water management practices. According to study developed in central Japan by Kudo et al (2014), a compound treatment with a combination of flooding, midseason drainage and intermittent drainage may be an effective water management practice for mitigating greenhouse gas emission and maintaining rice yield.

Study developed by Perret et al (2013) on rice production in the North-eastern Thailand in 2010 evaluated 45 diverse rice cropping systems according to three systems, namely wet-season rain-fed, wet-season irrigation, and dry-season irrigation systems. According to the authors, a wide-ranging performances and impacts were observed, despite cropping practices were relatively homogeneous. The differences among the systems were originated mostly from differences in yield, which were largely impacted by water supply. The results showed the low performances and high impacts of dry-season irrigated systems, since they require mostly blue water, while the two other systems rely primarily on green water. Besides, the dry-season irrigated systems require more energy, labor, fertilizers, pesticides, and ultimately yield lower production.

Khoshnevisan et al (2014) applied LCA to evaluate the environmental impact of consolidated rice farms (CF) – farms that have been integrated to increase the mechanization index, and traditional farms (TF) – small farms with lower mechanization index, in Guilan Province, Iran. The results have shown that the energy ratios for CFs and TFs were 1.6 and 0.9, respectively. The two main reasons for the higher energy ratio by the CFs are the total input energy in the CFs was less than that of the TFs and the CFs employed better agricultural management, including the use of higher-yielding varieties of rice that generated higher yields. Then, the results showed that CFs produced fewer environmental burdens per ton of produced rice. The same conclusion was reached for land-based functional unity, which indicates that the differences between the two types of farms were not caused by a difference in their production level, but rather by improved management on the CFs. The study also showed that electricity accounted for the greatest share of the impact for both types of farms, followed by P-based and N-based chemical fertilizers. The LCA results indicated that the use of more mechanical power and an associated increase in the mechanization index will lead to better environmental performance rather than increased environmental burdens from rice cultivation. Besides, the cultivation of higher yielding rice varieties and the use of agricultural inputs according to crop requirements and soil analyses can improve the environmental performance as well.

Rice straw can cause environmental impacts if burned in situ in the field. Then, Silatertruksa and Gheewala (2013) conducted life cycle assessment of four rice straw utilization systems, which are (1) direct combustion for electricity, (2) biochemical conversion to bio-ethanol and biogas, (3) thermo-chemical conversion to bio-DME, and (4) incorporation into the soil as fertilizer, in order to compare their environmental performances. According to the authors, the bio-ethanol pathway resulted in the highest environmental performance in relation to reductions in global warming and resource depletion potentials. Rice straw bio-DME was preferable in relation to reduction in acidification potential. Rice straw electricity and fertilizer brought several environmental benefits. However, removal of agricultural residues must be managed carefully since excessive residue removal can degrade the long-term productive capacity of soil resources.

Rice (160.3 g/day) and beans (182.9 g/day) are the basis of Brazilians food consumption (IBGE, 2011), that is why rice has been chosen as one of the 18 products of the project “End-to-End Sustainability” developed by Walmart Brasil and its main suppliers (Walmart, 2013). In this project, Pilecco Nobre Alimentos Ltda. implemented several improvements in the rice production with the aim of reducing the environmental impact of the product with the assistance of CETEA/ITAL. Life cycle thinking was applied to the rice production system in order to evaluate of possibilities of reducing the environmental impact of the rice production.

2. Methods

This work was conducted in accordance with the International Standard ISO/TR 14062 (ISO/TR 14062, 2002). Taking into account the life cycle thinking, improvements have been applied to several stages of the life cycle of rice production as shown in Table 1. The goal of this work was to reduce the environmental impact of rice production. Traditional rice production system was established as a baseline case against which the impacts of the conditions could be quantified.

Table 1. Life cycle stages and respective improvements applied to the rice production.

Life cycle stage	Traditional production system (baseline)	New production system
Irrigation	Irrigated rice cropping system	Underground drip irrigation rice cropping system
Drying	Firewood furnace and temperature rate system with high grains breakage	Steam radiators and homogeneous temperature system with reduced grains breakage
Core and clean	Without rice recovery	Rice recovery after straw removal
Packaging	Plastic packaging from non-renewable resource	Plastic packaging from renewable resource, sugar cane
Transport	Conventional diesel truck fleet	Diesel S10 and more efficient truck fleet

The work was carried out from June 2012 to August 2013. The new irrigation system was implemented by Pilecco Nobre Alimentos Ltda. in a cultivation area of 64 hectares, in Alegrete, Rio Grande do Sul, Brazil.

The functional unity adopted was 1,000 kg of packed rice (5 kg packs), available at retail. The system boundary considered the field operation, including transportation after harvest, fertilizer production, packaging and transport until the retail (Figure 1). Only the steps that have been improved were taken into account. The emissions from fertilization and methane emission from rice fields were calculated using IPCC models (IPCC, 2006).

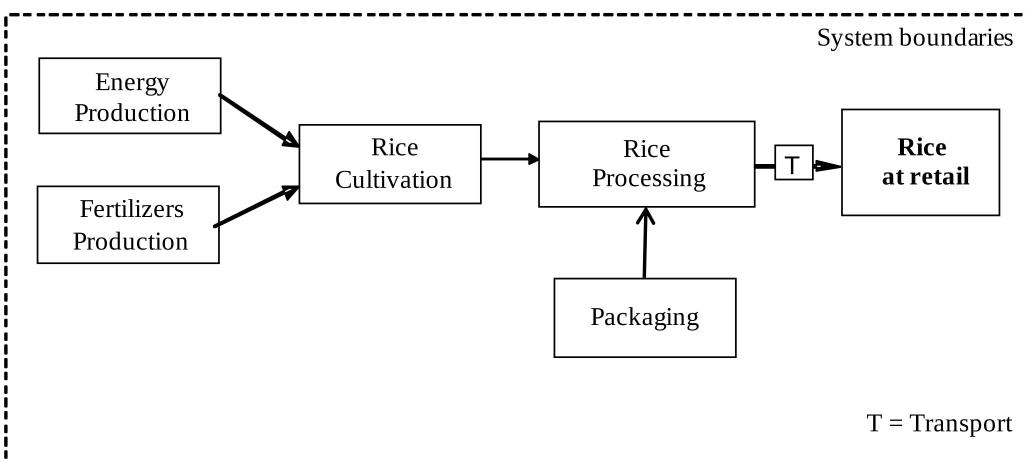

Figure 1. System boundaries adopted in this work.

Farm specific data along with industrial production data have been combined in order to model a rice production system. GHG emission factors for transport and energy production were obtained from GHG Protocol Brasil (2012). The environmental aspects relative to the fertilizers production were taken from recognized database and included in the boundary.

The inventory quantities fossil/renewable primary energy demand (PED), land use and water use were analyzed. GWP (100 years), eutrophication (EU) and acidification (AP) were estimated according to the CML method (GUINÉE, 2002).

3. Results

The improvements applied to rice cultivation, processing and transport are described below as well as the gains of these changes to the environmental impact of the product.

3.1. Irrigation

The rice cropping system used in the traditional production system – baseline case (Figure 2a) employs continuous irrigated field, which needs a pumping system with a high flow demand since this process is based on water drainage from the pumping point to all the crop area. Due to the high extension of the irrigated area, this takes several days to complete irrigation. Besides, in this process occurs a great water loss due to evaporation and shifting in the channels, as well as contamination of the catchment rivers by fertilizers and pesticides.

(a) (b)

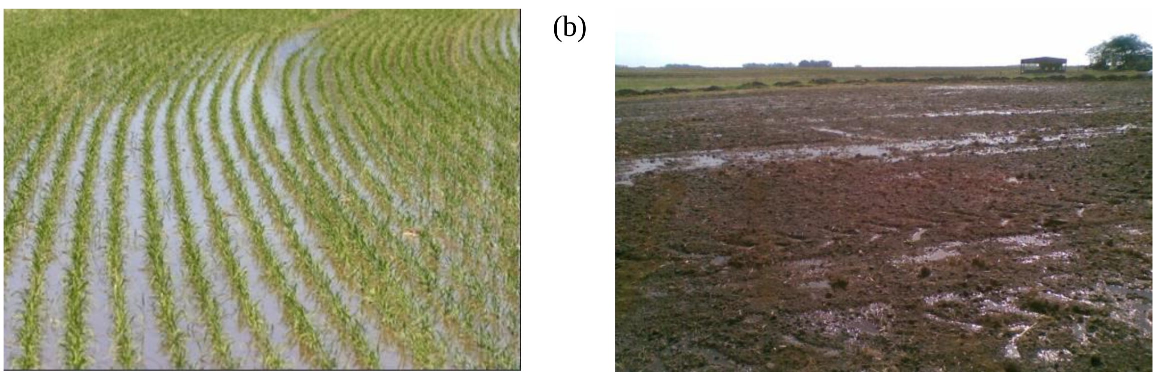

Figure 2. Irrigation of rice cropping system moved from: (a) Irrigated system to (b) Underground drip irrigation system.

The substitution of the irrigated system by the underground cropping system (Figure 2b) allows absorption of the water directly by the radicular system of the plant avoiding water loss by evaporation and shifting since it is based on a system of channels that directs the water flow always to the same place. Besides, the underground cropping system allows all fertilizers and pesticides be applied without loss.

The installed pumping power of the underground drip irrigation system is significantly lower than the irrigated system due to the higher water flow in the canalizations. As a result, the underground drip irrigation system has lower energy and water use than the irrigated system, besides lower aquatic eutrophication and ecotoxicity.

3.2. Drying

The rice drying process consists of reducing the humidity of the rice grain, still with straw, to values of approx. 10% in order to avoid fermentation and pest propagation (worm, moth, caterpillar). The traditional processes use dryers with furnaces feed by rice straw or firewood to generate hot gases, which gradually remove the humidity from the rice grain.

If this process is not well controlled it can degrade the grain by breakage due to formation of temperature gradient. The breakage of the rice grain can also occurs due to the high recirculation the traditional dryers require in order to get high productivity. Broken grains are not used as quality rice.

So, in the second semester of 2012 a drying system that uses vapor from thermal power plant feed by rice straw instead of firewood was installed - GEEA project - Alegrete Electric Energy Producer Ltd.. Besides elimination of the firewood, this new system has a differentiated system of drying rack that allows a more homogeneous distribution of the hot air avoiding the breakage of the grains due to temperature gradient, as shown in Figure 3. Since this drying system is more efficient than the traditional one, it reduces the recirculation of grains inside the equipment, which decreases the breakage by moving.

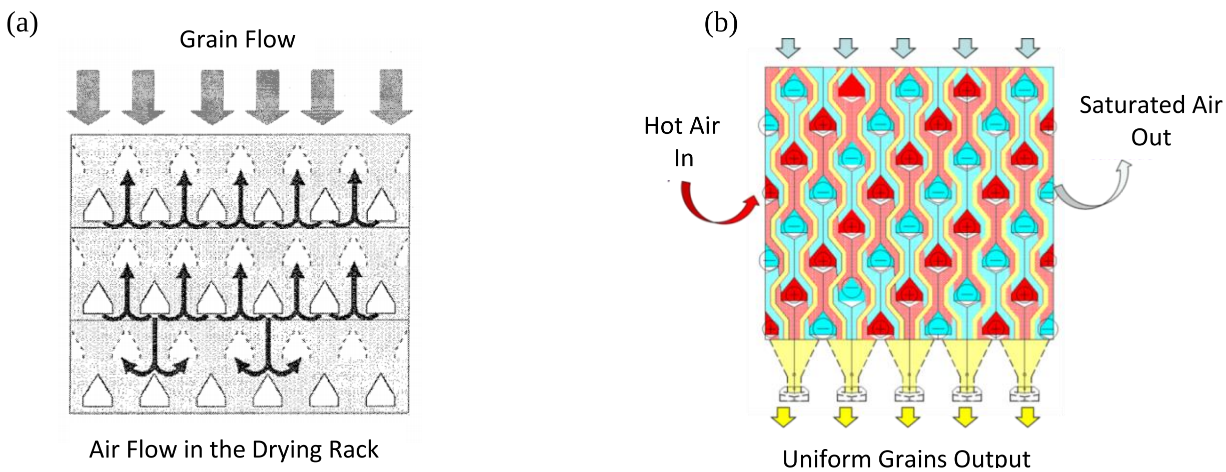

Figure 3. Drying systems: (a) traditional drying rack, (b) new system of drying rack.

The benefits of this improvement are the use of renewable energy from waste as well as a better yield of whole rice grains.

3.3. Core and clean

All rice straw generated by Pilecco Nobre is sent to GEEA - Alegrete Electric Energy Producer Ltd., where it is used as raw material to produce electric energy and silica. However, a fraction of rice without straw as well as rice still with straw is lost during the straw removal process, being forwarded with the straw itself to electric energy generation.

The new rice production system has a rice recovery from straw (Figure 4) which works by weight difference between the straw and the grain. This improvement allowed to recover the rice that used to be burnt with the straw and then increased the yield of the productive system.

Figure 4. Equipment for rice recovery after straw removal.

3.4. Packaging

The packaging of the rice was changed from polyethylene from non-renewable resource to polyethylene from renewable resource (ethanol from sugar cane). The polyethylene from renewable resource has the same properties, performance and versatility of applications as the polyethylene from non-renewable resource, which makes easy its use. For the same reason it is recyclable in the same recycling chain of the traditional polyethylene.

The benefits of this improvement are the use of renewable resources and reduction of non-renewable resources consumption (oil), as well as decrease of GHG emissions.

3.5. Transport

The transport of rice used to be in a truck fleet based on traditional diesel consumption, which emits 500 mg of sulfur per liter of diesel and has an average fuel consumption of 0.33 L of diesel per km. The improvement of this life cycle stage was based on the substitution of seven trucks by new trucks that uses diesel S10 which emits 10 mg of sulfur per liter of diesel, besides an average fuel consumption of 0.29 L of diesel per km.

The benefits of this improvement are reduction of non-renewable resources consumption (oil), as well as lower GHG emissions and acidification potential than the previous fleet.

Table 2 summarizes the relative reduction of the environmental impacts considered in this work, taking into account all the improvements made in the rice production system, while Figure 5 shows the contribution of each improvement.

Table 2. Improvement of the environmental performance of the rice production system evaluated: Traditional vs New production system. (Functional unity = 1,000 kg of packed rice).

Parameter	**Improvement**
Yield (kg/ha)	1,152.36
Primary energy demand (MJ)	-234.85
Electric energy consumption (MJ)	-206.94
Non-renewable energy (MJ)	-26.45
Water consumption (L)	-198,505.31
Non-renewable resources (kg)	-7.61
Firewood consumption (kg)	-71.55
Rice waste (kg)	-1.42
Land use (ha)	-0.03
GWP (100yr) (kg CO_2 eq)	-31.43
Aquatic eutrophication (kg PO_4---eq)	-15.75
Aquatic acidification (kg SO_2 eq)	-46.16

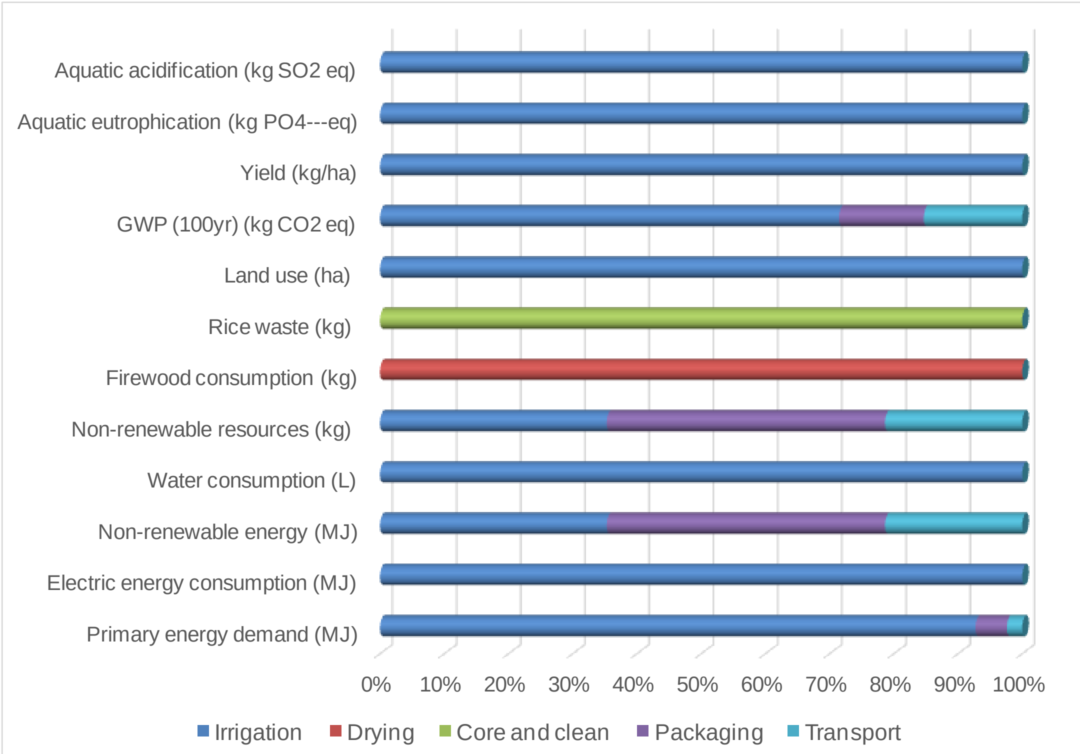

Figure 5. Contribution analysis of the improvements made in the rice production system to the impact categories evaluated.

4. Discussion

The combined modifications clearly produced substantial benefits for the environmental performance of rice production, mainly reduction of water, energy and firewood consumption as well as GWP and aquatic acidification.

The key opportunity in terms of environmental benefit is the reduction of water consumption (approx. 200,000 L/t of rice) which is quite relevant due to the water scarcity we are facing nowadays because of the climate change. According to the last IPCC report (2014), the already observed and the projections of climate change for the South America will compromise the water availability for this region and direct impacts should occur in the domestic and industrial water supply as well as in sectors strongly water dependent as hydroelectricity production and agriculture.

Besides, the yield increased by 15%, which means less land use for cultivation, reduction of inputs (fertilizers, pesticides etc.) and associated emissions, besides feeding more people.

The new irrigation system was responsible for the majority of the environmental impact reductions, i.e. electric energy and water consumption, land use, yield, aquatic eutrophication and acidification. Besides, this improvement contributed also to reduce the non-renewable resources consumption and GHG emissions.

The new drying system contributed to the reduction of firewood consumption, while the improvement made in the core and clean stage reduced the rice waste.

The change in the packaging material contributed to reduce the non-renewable resources and non-renewable energy use as well as GHG emissions.

The modification made in the transport stage contributed to reduce the same burdens than the new packaging, but with lower reduction of the non-renewable resources and non-renewable energy use.

5. Conclusion

This work supplied important results for the better environmental performance of the rice production, making this product a lower environmental impact than the traditionally cultivated rice.

An expressive reduction of water consumption was observed in the rice cultivation due to the substitution of the irrigated rice cropping system by the underground drip irrigation rice cropping system, besides other benefits like reduction of energy use, fertilizer and pesticide loss and GHG emissions.

The 15% increased yield was mainly a result of the new cultivation system.

ABSTRACT

Instead of focusing on GHG emissions, farmers might be more willing to implement improvements in farming systems if the benefits were shown in terms of energy use and energy risks. Reducing energy costs has a direct benefit to farmers, and moving a farm's net energy budget towards a surplus improves the farm's resilience for energy price fluctuations. We developed a tool for strategic energy management analysis of farms. The tool uses life cycle assessment approach for estimating the embodied energy inputs of the farm, and quantifies the energy outputs in form of agricultural products and surplus of renewable energy produced at the farm. We demonstrate the benefits of the tool by using a case study of a dairy farm in the United Kingdom. We compare the energy balance and GHG emissions of the farm with two alternative scenarios. The results show that synergies between energy risk management and GHG mitigation exist.

Keywords: agriculture, embodied energy, greenhouse gas emissions, tools, energy risk

1. Introduction

Many tools for estimating greenhouse gas (GHG) emissions from farming are widely available (Bochu et al. 2013; Hillier et al. 2011). However, the farmers' willingness to use such carbon calculators is often low due to lack of direct benefits gained by using them (Elbersen et al. 2013). Instead of focusing on GHG emissions, farmers might be more willing to implement improvements in their farming systems if the benefits were shown in terms of energy use and energy risks. Reducing energy costs has a direct benefit to farmers, and moving a farm's net energy budget towards a surplus improves the farm's resilience for energy price fluctuations. Our hypothesis is that reduction in embodied energy inputs and increase in on-farm bioenergy production helps to reduce GHG emissions, partly because of synergies between energy, but largely because it motivates farmers to take action.

We developed a tool, called Energy Positive, for strategic energy management analysis of farms. The tool uses life cycle assessment approach for estimating the embodied energy inputs of the farm, and quantifies the energy outputs in form of agricultural products and surplus of renewable energy produced at the farm. The assessment helps to identify the main energy inputs of the farm and to compare alternative farm management scenarios in terms of energy risks. The tool shows how the farm's input costs reflect fluctuations in energy prices.

We demonstrate the benefits of the tool by using a case study of a 350 ha dairy farm located in the United Kingdom. We compare the current energy balance of the farm with two alternative scenarios: a low GHG emission scenario and a high renewable energy production scenario. In order to test our hypothesis, we analyze the GHG emissions of those scenarios by using the Carbon Calculator developed by the European Commission (Bochu et al. 2013).

2. Methods

2.1. General approach

LCA was used for comparing energy balances and GHG balances of a case study dairy farm located in the Southern England, in the United Kingdom. The impacts of various management choices on GHG emissions and energy balance were modelled. The functional unit (FU) was the whole farm.

The system boundaries included the production of farming inputs (e.g. fuels, fertilizers and pesticides), machinery manufacturing and farm operations, including crop cooling and drying. The soil carbon emissions and sequestration were not taken into account, because net sequestration or emission only occurs when the soil management type has been changed until a new equilibrium level is reached. Energy balances were calculated by using the Energy Positive tool, whereas GHG emissions were calculated with European Commission carbon calculator (available from: http://mars.jrc.ec.europa.eu/mars/Projects/LC-Farming). The methodology of the EC's carbon calculator has been explained elsewhere (Bochu et al. 2013). The Energy Positive tool calculates the LCA based primary energy balances of farms based on data from Williams *et al.* (2006). The biogas yields for manure and straw were based on data from Michel et al. (2010)

2.2. Case study farm

The case study farm is a 350 ha dairy farm located in southern England in the United Kingdom. The farm has 200 milking cows (production level 6000kg milk/cow/yr), 50 heifers and 50 calves. All feed is produced at the farm utilizing 253 ha (Table 1). The livestock is grazing 50% of the time in a year.

Table 1. Details of the feed production system.

Area (ha)	**Crop**	**Tillage**	**N fertilizer (kg/ha)**	**Manure (kgN/ha)**	**Pesticides (yes/no)**	**% clover in grassland**	**Yield (t/ha)**
25	Corn silage	full	200	50	Herb, fung		40
25	Wheat	low	150	50	Herb, fung		7
60	Clover-grass	full	30	no	Herb, fung	50	11
10	Barley	full	120	25	Herb, fung		5
133	Permanent pasture	No-till	no	no	no	no	7

2.3. Alternative production scenarios

The impacts of some alternative production scenarios were assessed. To enable smooth comparison, the farm area, number of animals and product output were assumed to be the same in each scenario. The impacts of the following practices were assessed:

1) No-tillage: applied to the whole agricultural area.
2) Reduced use of synthetic nitrogen fertilizer: the use of synthetic N fertilizer was halved for corn silage and wheat. Barley was replaced with a legume crop. The clover content of the clover-grass was increased to 75%.
3) Anaerobic digester: the livestock manure and straw from wheat was assumed to be used for biogas production. It was assumed that 50% of the manure produced by the whole cattle was used for anaerobic digester, resulting in biogas yield of 50,000 m^3 (22.2 MJ/m^3). The biogas yield for straw was assumed to be 7.1 GJ tDM^{-1} (Berglund and Börjesson 2006), and straw yield 3tDM/ha. It was assumed that 12% of the biogas energy was used for the running the biogas reactor (heating, pumping and mixing). The biogas was assumed to be used for electricity generation, yielding 30% electricity and 50% heat. The rest was assumed to be lost.
4) Solar panels: were assumed to be installed on south-facing roof surface area (500 m^2).

2.4. Method for estimating GHG reduction potential of the mitigation actions

The methods for estimating the GHG mitigation potential of the mitigation actions are explained in more detail in (Bochu et al. 2013) and only summarized here:

1) No tillage: the mitigation effect is calculated based on increase in soil carbon, reduction of CO2 emissions from fuel consumption and increased N2O emissions.
2) Reduced use of synthetic nitrogen fertilizer: avoided emissions from manufacturing of synthetic N fertilizers, and the change in emissions due to replacement of barley with a legume crop and increase of

the clover content in clover-grass. The emission factor for synthetic N fertilizer production is based on data from Wood and Cowie (2004), varying between 5.1-7.1 t CO_2-eq/t N depending on the type of N fertilizer used.

3) Anaerobic digester: avoided N_2O and CH_4 emissions from manure storage, and avoided emissions from manufacturing of N fertilizers due to reduced N losses as NH_3 and N_2O.
4) Solar panels: avoided emissions from electricity production (average UK electricity mix used as a reference).

3. Result

Table 2 shows the GHG mitigation actions recommended by the carbon calculator and the mitigation potential per ha for the base scenario. The mitigation potential for no-tillage and biogas production are different between Table 2 and 3 due to the fact that the mitigation potential presented in Table 2 includes increase in carbon storage in the soil whereas that is not included in the results presented in Table 3.

The results in Table 3 show that in the case of milk production, there is not direct correlation between energy input and GHG emissions. The main GHG emissions sources are enteric fermentation, N_2O emissions from soils and manure management, which all are independent of energy use. The main energy inputs are electricity use and production of fertilizers.

The results also show that combined effect of all mitigation actions included in the study resulted in nearly energy positive farm even when not considering the surplus energy produced at the farm. The same actions however, reduced only 23% of the GHG emissions.

Table 2. Results of mitigation action recommendations generated by the carbon calculator for the base scenario.

Rank	**Actions**	**tCO_2e saving/ ha/ year**	**New level of tCO_2e/ ha/ year**	**% saving**
	Current situation		5.34	
1	No-tillage	0.50	4.85	9.3%
2	Biogas production	0.41	4.93	7.8%
3	Reduce methane from enteric fermentation	0.34	5.00	6.5%
4	Agroforestry	0.26	5.08	4.9%

Table 3. Results of the impact of various farming practices on the carbon footprint and embodied energy input of the farm (changes relative to the base level).

	Base		Relative change compared to the base case (as % of the base case)							
			No-till		Reduced N fertilizer		Anaerobic digester		All together	
	GHG (tCO_2-eq)	Energy (GJ)	GHG	Energy	GHG	Energy	GHG	Energy	GHG	Energy
Tractor fuel	26	491	-0.7	-5.4	0.0	-5.7	-0.6	-4.6	-1.3	-15.7
Enteric fermentation	862	0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0
Manure management	134	0	0.0	0.0	0.0	0.0	-7.8	0.0	-7.8	0.0
Direct N_2O emissions from soils	167	0	0.0	0.0	-1.4	0.0	-1.4	0.0	-2.9	0.0
Indirect N_2O emissions from soils	14	0	0.0	0.0	0.0	0.0	-0.1	0.0	-0.1	0.0
Electricity purchased (i.e. on the grid)	68	1089	0.0	0.0	0.0	0.0	-5.0	-45.1	-5.0	-45.1
Mineral and organic fertilizers (processing and transportation)	81	559	0.0	0.0	-2.8	-9.1	-3.4	-11.6	-6.2	-20.7
Other crop inputs (seeds, pesticides)	0	275	0.0	-1.5	0.0	-7.9	0.0	-7.9	0.0	-17.3
Total	**1352**	**2414**	**-0.7**	**-6.9**	**-4.3**	**-22.7**	**-18.3**	**-69.2**	**-23.3**	**-98.8**

4. Discussion

In this paper, a fairly simple case study was presented. Perhaps more significantly, the Energy Positive tool also enables comparison of alternative management scenarios on the farm – allowing farmers to see how structural changes to their farm system would influence their energy budget in the future. All of these outputs can be linked to financial data, and given existing concerns about energy costs, this may motivate farmers to take a fresh look at their farm systems. Energy intensity of farms and their products will be of interest to people further along the food chain, in particular retailers, who are increasingly aware of the need to manage risk in their supply chains.

The critical difference between Energy Plus and existing tools is that it focuses on energy and energy cost risk management, not carbon or GHG emissions. Farmers find this much more compatible with their business needs. Energy Plus is a scenario-based strategic planning tool, not a detailed auditing tool. This allows the user to think beyond simple ‘efficiency adjustments’, compare the implications of structural changes to their land management system, and make strategic-level decisions.

5. Conclusion

The results show that synergies between energy risk management and GHG mitigation exist. Therefore, we conclude that focusing on energy risk instead of climate change may be a more effective way of motivating farmers to implement improvements in their farming systems. However, especially in livestock farms with ruminants extra mitigation actions are needed to reduce the GHG emissions from enteric fermentation.

ABSTRACT

The aim is to contribute to a deeper understanding of the differences between the consequential (cLCA) and attributional (aLCA) modeling approaches and to show how the choice between cLCA and aLCA in some cases can be decisive for the outcome of an LCA. We present cradle-to-gate CO_2-eq. emissions (carbon footprint) of barley, soybean meal and palm oil and discuss the differences between the cLCA and aLCA methodologies and results.

Keywords: Consequential LCA, Attributional LCA, Life Cycle Inventory modeling

1. Introduction

Is consequential (cLCA) or attributional (aLCA) modeling the correct choice for life cycle assessment? This is among the most discussed questions within the LCA community during the last 10-15 years. Although an ISO standard was launched several years ago, massive disagreement between LCA practitioners still exists, as the norm does not distinguish between them. The two most important differences between cLCA and aLCA are the handling of multi-functional processes (allocation versus substitution) and whether or not constrained suppliers are included in the market mixes. According to Weidema and Moreno (2013) a comparison between cLCA and aLCA results in ecoinvent showed that more than 12% of the LCIs deviate with more than a factor 2. In this article we discuss the cradle-to-gate CO_2-eq. emissions (carbon footprint) of several food products, namely barley, soybean meal and palm oil. The aim is to contribute to a deeper understanding of the differences between the two modeling approaches and to show how the choice between cLCA and aLCA in some cases can be decisive for the outcome of an LCA.

2. Methods

LCA data on barley, soybean meal and palm oil from Dalgaard et al. (2014) were used to investigate how the modeling approach affects the carbon footprint results. Four different modeling approaches were used to calculate carbon footprint of milk in the study of Dalgaard et al. (2014) and the data are from 2005. The four approaches consist of consequential modeling and three different versions of attributional modeling. However, in the current study, only data from the consequential modeling and the attributional version named ‘allocation/average modeling’ are presented for simplicity. The by-products are accounted for by substitution (cLCA) and price allocation (aLCA). In cLCA only flexible suppliers are included, whereas in aLCA also constrained suppliers are included. Constrained suppliers are suppliers that do not respond to a change in demand for a certain product. In order to reduce complexity, the effects related to indirect land use changes are excluded. For more details on modeling assumptions, see Schmidt and Dalgaard (2012) and Dalgaard and Schmidt (2012).

3. Results

The differences in carbon footprint depending on the applied modeling approach are presented in Figure 1. Both barley, soybean meal and palm oil are products deriving from multi-functional processes. The by-products are the following: Straw from barley production, soybean oil from soybean meal production and palm kernel meal and empty fresh fruit bunches from palm oil production. The allocation in the attributional modeling is based on product prices from 2005. The differences in carbon footprint of barley are and presented in more detail in Figure 2. The cLCA carbon footprint for soybean meal is negative (-0.40 kg CO_2-eq.) because the by-product soybean oil substitutes palm oil on the market (Dalgaard 2008), and the saved emissions from palm oil production more than counterbalance the emissions from soybean production and processing. The difference between the two carbon footprints of palm oil is small. This is mainly because the by-product allocation factors are small in aLCA, due to the low value of the by-products (e.g. palm kernel meal, fresh fruit bunches), so that the oil is attributed most of the impact. In cLCA the by-products have low avoided emissions.

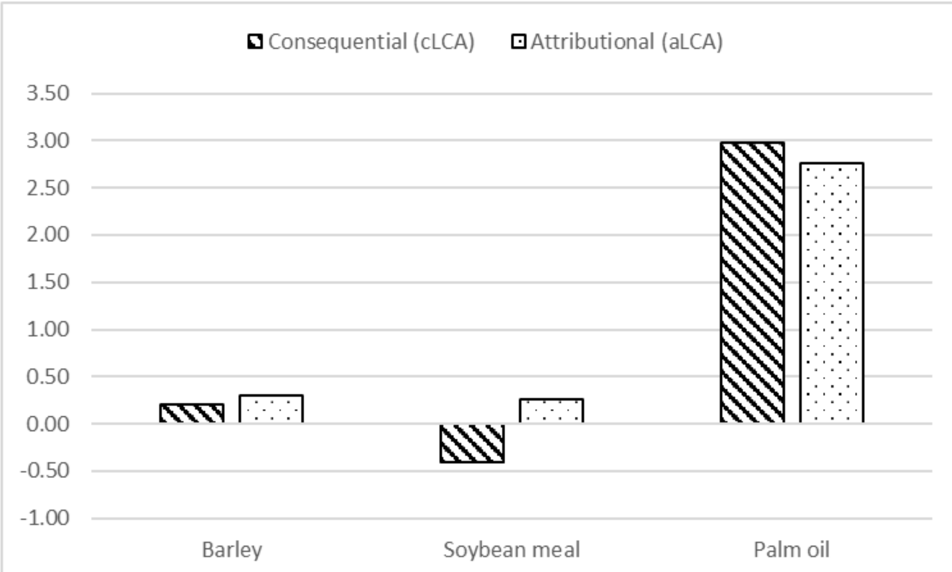

Figure 1. Carbon footprint of barley, soybean meal and palm oil using respectively cLCA and aLCA modeling. Unit: Kg CO_2-eq. per kg.

In this case the production of barley is a multi-functional process from which both barley and straw/energy are produced. According to Statistics Denmark (2012) 75% of the straw was removed from the grain fields in 2005. Barley and straw constitute respectively 75% and 25% of the biological material removed from the field. In cLCA this is handled by substitution. All emissions from the production of barley/straw are ascribed to the main product barley and afterwards the emissions from the saved energy caused by incineration of straw are deducted.

The CFs are 0.21 (cLCA) and 0.30 (aLCA) kg CO_2-eq. per kg barley. The contributions from each part of the product chain are presented in Figure 2. The emissions from the field, fertilizers, diesel and services & capital goods are lower for aLCA mainly because 40% of the GHG-emissions are allocated to straw. However, this is more than counterbalanced by the avoided energy production in cLCA, which is deducted from the barley and reduce the GHG-emission by 0.30 kg CO_2-eq.

However, the emissions related to fertilizer production are 65% lower in the aLCA scenario compared to the cLCA scenario. The main reason for the lower emissions is, as described earlier, that 40% of the emissions from fertilizer production are ascribed to the straw. The remaining 25% of difference between cLCA and aLCA is mainly caused by the differences in fertilizer market mixes used in the cLCA and aLCA. Both manure and mineral fertilizers are applied to the field during the barley cultivation. In cLCA the manure applied to the fields for fertilization is considered as constrained and excluded from the fertilizer mix, whereas in aLCA both manure and mineral fertilizer are included in the mix. The inventory for manure in aLCA is from a multi-functional process from which both manure, beef, milk and energy are produced. Energy is from incineration of fallen cattle. The emissions from the multi-functional process are distributed between the four co-products and only 1% is ascribed to the manure. This results in considerable lower carbon footprint per kg N for manure compared to mineral fertilizer and that contributes significantly to the lower GHG emissions from barley cultivation, when applying the aLCA methodology.

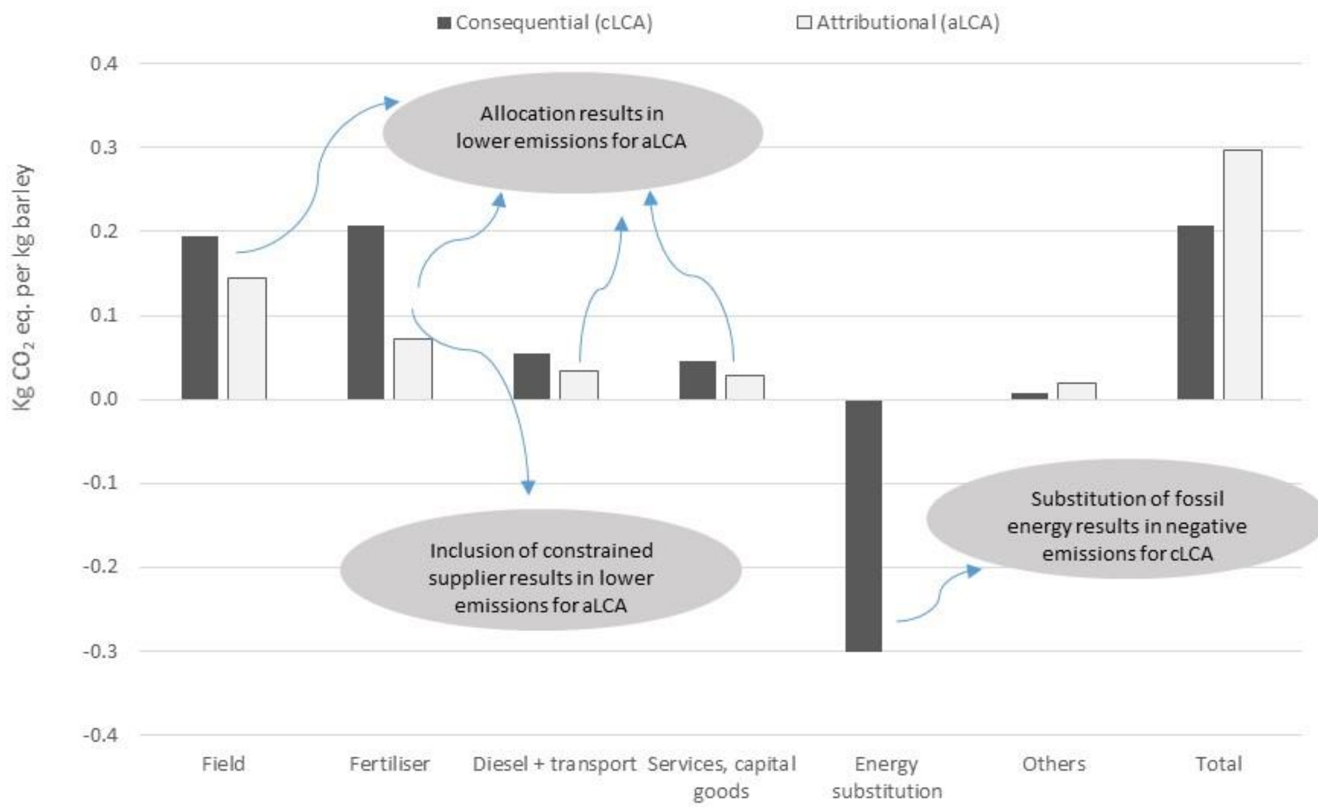

Figure 2. Contribution to GHG emissions from different parts of the barley production chain. Unit: Kg CO_2-eq. per kg barley.

4. Discussion and conclusion

The cLCA and aLCA carbon footprints above show that the main reasons for the differences in results are:

- Substitution (cLCA) versus allocation (aLCA) for handling of multi-functional processes
- Exclusion of constrained suppliers from market mix (cLCA) versus inclusion of constrained suppliers in market mix (aLCA)

Substitution is fundamentally different from allocation. In the barley case it is obvious that the production of barley results in straw production, which again results in saved fossil energy. On the other hand the allocation is a rather artificial way to overcome the multi-functional process issue. In this case, the allocation is based on prices of electricity and heat, but it could as well be straw prices or mass of barley and straw respectively. The definition of allocation method is normative and not based on reality. However, in cLCA the definition of the type of energy substituted can also be challenging for the less experienced cLCA practitioner. If the farmer uses the straw for energy production the carbon footprint of barley will be lower regardless which of the modeling approaches are applied.

Constrained suppliers are excluded in the cLCA modeling, but included in the aLCA modeling. Misleading results might be a consequence of including constrained suppliers in a market mix. In the example with barley the market mix for fertilizer includes manure. If advice to the barley producers was given on the basis of the aLCA, an increased use of manure instead of mineral fertilizer would obviously be a good solution, because the carbon footprint of N in manure is lower than the average N in mineral fertilizer. But in reality, a shift from use of mineral fertilizer to manure will not increase manure production but rather the production of mineral fertilizer. Farmers have cattle because they want to sell milk or beef and not manure, thus an increased demand for manure does not result in more manure production.

ABSTRACT

Land demand is constantly increasing due to increasing population and consumption patterns. When new land is required land use changes are triggered, causing several environmental and social impacts. Particularly debated is the assessment of indirect Land Use Change effects. Several methodological approaches have been proposed for carrying out the assessment. In this paper we reviewed state-of-the-art iLUC models and classified them in two main categories: economic models and deterministic models. Five models have been selected and compared according to fifteen criteria covering modeling framework, impact categories assessed and models' transparency.

The results show that, within a Life Cycle Assessment approach, progresses have been made in Economic General Equilibrium and Deterministic Models and a combination of those can achieve a markedly robust assessment of iLUC. There are still wide margins for improving current models. In particular, there is room for improving precision of data, identification of marginal land and inclusion of a broader range of impact categories.

Keywords: Land Use, indirect Land Use Change, Life Cycle Assessment

1. Introduction

Land demand is increasing due to population growth, demanding food, feed and pasture land. Land use is also caused by demand of fibers, fuel wood and more recently industrial scale biofuels. The result is a constantly rising environmental and social impact. Land use has long been underestimated or ignored in environmental assessment techniques (Lindeijer 2000) but is increasingly being included in impact assessments. Land Use Change (LUC) impacts have recently been introduced in environmental (Banse et al. 2008) and economic analysis (Hertel, Rose, and Tol 2009B). The debate around LUC effects accelerated with the publication of two articles by Fargione et al. (2008) and Searchinger et al. (2008). Until then, the term LUC was mainly referring to direct Land Use Change effect (dLUC), such as greenhouse gas (GHG) emissions, caused by a change in land use, where the change is taking place. Fargione et al. (2008) and Searchinger et al. (2008), instead, investigated the relevance of indirect LUC (iLUC) effects: a change in land use caused indirectly as an upstream consequence of a direct LUC taking place somewhere else in the world. ILUC and dLUC were defined in standards only in 2012 (ISO/TS-14067 2013).

Different approaches and models have been proposed in recent years to solve those controversies but a broad consensus on them still needs to be reached. The controversies include the theoretical framework as well as ways to model the complex global land use dynamics; in particular, difficulties related to: understanding and modeling where land LUC takes place; establishing the relationship between demand of agricultural products and land use changes; accounting for the effect of by-products; the overall level of uncertainties caused by the multiple modeling assumptions (Marelli, Mulligan, and Edwards 2011). The first rather high GHG emissions esteems cause by iLUC rouse a high concern (Fargione et al. 2008, Searchinger et al. 2008); further researches contributed to a progressive downsizing of the estimated effects: in a recent work Dull et al. (2013) show that the estimated LUC GHG emissions from corn ethanol gradually decrease in newer studies. Refined and improved models predict a lower iLUC impact compared to earlier esteems; some authors conclude that iLUC emissions might even be irrelevant (Kim and Dale 2011); other studies still prove how the existence of iLUC effects have neither disappeared nor can be considered as negligible (USA-EPA 2010). Indeed, with the current ethanol and biodiesel production trend, increasing population and pro-capita consumption, it seems difficult to challenge the hypothesis that iLUC is taking place. Tyner et al. estimated that only in the USA a third of corn ethanol production is intended to ethanol (2010). In the meantime, the annual yield growth rates are stationary or decreasing while crop demand is increasing, leading to a constant increase in crop prices (Brandão 2012). Yet, the challenges in estimating the magnitude of LUC and related effects are numerous and models still future a relevant degree of uncertainties, mainly related to data availability and modeling constraints.

The goal of this paper is to underline recent improvement upon models and the aspects that still remain hotspots. Following an extensive review, five models have been chosen to assess their characteristics according to a set of fifteen criteria including: completeness of scope; impact assessment relevance; scientific robustness and certainty; transparency, reproducibility and applicability. For each criterion the models' performances were compared and scored relatively to each other. The data required for reviewing and scoring the models were obtained from scientific literature and models' reports. Since a complete product/process assessment is usually carried out within the framework of Life Cycle Assessment (LCA), this paper reviews iLUC models as part of a more comprehensive LCA framework, in which the modeling results are included, independently of the model used for their assessment.

2. Methods

The review criteria used to assess the performances of the five selected models are reported in Table 1. The criteria were built on the work of Hauschild et al. (2013) modifying the assessment categories and relative criteria to fit the purpose of the current review. The models criteria were grouped in four categories.

Table 1. List of criteria: the criteria are grouped in four categories. Each criterion is meant to answer a specific question reported on the right.

A - Completeness Of Scope	**How in detail does the model covers the environmental mechanisms associated with land use changes?**
i - Dataset	What is the underlying dataset of the study?
ii - Land Classification	Which types of land are classified by the model?
iii - Origin of Marginal Land	How the location of the identified marginal land type is identified?
iv - Co-product	How is the effect of co-product accounted for?
v - Distribution of Emissions	How is the time of GHG emissions associated to the activity?
B - Impact Assessment Relevance	**To what extent are the critical impacts of LUC included and modeled in accordance with the current state of the art?**
vi - Non GHG Emission	Which non-GHG emissions are considered?
vii - Other non-Environmental Impacts	Which non-Environmental Impacts are considered?
C - Scientific Robustness And Certainty	**Does it represent state of the art, can it be validated against monitoring data, and are uncertainties reported?**
viii - Peer-review	Is the model peer-reviewed/presented in peer-reviewed articles?
ix - Uncertainties	Are scenario and model uncertainty taken into account?
x - Updating	How can the model be updated/further developed?
xi - Science-Based	Are the data and assumptions consistent with a science-based approach?
D - Transparency, reproducibility and Applicability	**How accessible are the model, the model documentation and the applied input data? Are the models applicable to different contexts?**
xii - Documentation	Is the model documentation published and easily accessible?
xiii - Input Data	Are the input data publicly available?
xiv - Applicability	Can the model be applied to other contexts/products?
xv - Transparency	How transparent is the reviewed documentation?

According to their main characteristics, existing LUC models have been grouped in three types: Economic Equilibrium Models (EEM), Deterministic Models (DM) and Normative Models (NM); they differ in the extent they address iLUC modeling challenges and the approach used. EEM are divided in Partial Equilibrium models (PE) and Computable General equilibrium models (CGE). Normative Models are simplified approaches, based on rules, established 'norms', not necessary scientifically justified, but based on statistical metadata or normative assumptions. Due to their more simplified nature they have not been considered for comparison with other models. They are however discussed in section 3.

An accurate review following the criteria introduced above was completed for five among EEMs and DMs (Table 2): a modified version of the CGE model GTAP (GTAP 2014, Hertel, Rose, and Tol 2009B) named GTAP-AEZ, the PE model Common Agricultural Policy Regional Impact (CAPRI 2012), the EU Joint Research Center (JRC) hybrid model (Hiederer et al. 2010) and two DM (Bauen et al. 2010, Schmidt et al. 2013). These models were selected after a broad review of the existing literature to cover a wide range of different approaches.

Table 2. Models selected for comparison and description of models' typology

Model	Model type	Selected iLUC Models
Economic Equilibrium model (EEM)	Partial Equilibrium (PE) model	CAPRI
	Computable General Equilibrium (CGE) model	GTAP-AEZ
	Hybrid CGE-PE model	EU-JRC
Deterministic Model (DM)	Participative model	Bauen et al.
	Avoiding type allocation of emissions	Schmidt et al.

GTAP is a global network of researchers coordinated by Purdue University, developing models and databases used also in other CGE models (e.g. IMAGE, LEITAP); CAPRI model is an agricultural sector PE model developed by the European Union (EU) research fund for policy impact assessment in the EU. The EU JRC developed an harmonized spatial dataset integrates data obtained from the CGE model IFPRI-MIRAGE and the PE model AGLINK-COSIMO; the hybrid model expressly assesses GHG changes (including soil) caused by the production of biofuels; Bauen et al. (2010) is a regional DM commissioned by the UK department of transport to assess the GHG emission associated with iLUC caused by biofuel production; through a more transparent and participative approach, it attempts to overcome previous models' limitations by consulting a panel of experts and stakeholders in the development process. The model developed by Schmidt et al. (2013) is a flexible DM, applicable to any land or crop in any location in the world, overcoming a frequently used normative assumption used to distribute emission over time; a similar approach is also proposed by Kløverpris and Mueller (2013).

The performances of the five selected models were scored through a paired comparison analysis: for each criterion, the models were compared against each other and ranked by assigning a comparative value ranging from 1 to 5.

3. Results and discussion

According to the criteria introduced in Table 1, the models were assessed and compared. The results of the comparison are schematically presented in the Table 3.

The final score are expressed as an average and shows considerably homogeneous values, with the exception of the JRC and Bauen et al. models; this is due to the scope of those models, restricted to a regionalized analysis of the biofuel sector. EEMs are generally more robust with regard to the group of criteria 'A': the average score obtained by EEMs for the first four criteria is in fact 2.9 (3.1 excluding the hybrid JRC model), while the average score obtained by the DMs for the first four criteria is 2.5. EEMs show a lower average score when the JRC model is included because the JRC model does not account for the effect of co-products (criterion iv). The calculated average excluded criterion v (Distribution of emissions) from group 'A' because the value for this criterion are rather imbalanced between EEMs and DMs; this is simply due to the fact that EEMs provide an iLUC GHG emission factor but do not suggest a methodology to handle the distribution of the emissions. In the compared EEMs this aspect is left to the results' users. To some extent EEMs consider the issue outside the scope of iLUC modeling and as a general problem to be dealt with anytime emissions' impacts are accounted.

It can be observed that the robustness gained by EEM through the complex methodological framework (group of criteria 'A') tend to be lost in the group of criteria 'D', reflecting a loss of transparency and clarity and traceability of the model. The average score obtained by EEMs in group of criteria 'D' is in fact 2.9 (3.0 excluding the JRC model), while the average score obtained by the DMs is 4. The trend is especially visible in the traceability of the input data (criterion xiii) and overall transparency of the model (criterion xv). The smaller score obtained in criterion xiv (Applicability) by the JRC and Bauen et al. models reflect instead their regional scope and the focus restricted focus to biofuel production. Model uncertainties (criterion ix) are also more difficult to assess in complex EEMs than DMs. On the other hand, because of their complexity, EEMs and the respective databases are generally maintained by large scientific networks or institutions and are more likely to be updated and peer-reviewed.

Group of criterion 'B' shows a very interesting result: at present, the focus of iLUC models (including the compared models) is almost exclusively restricted to GHG emissions impact; among the compared models. CAPRI is the only case in which an attempt is made to assess other environmental impacts than GHG emission, namely, water quality impacts and impacts on biodiversity. There are however other consequences triggered by increasing land use, both environmental (Wicke et al. 2012), social and economic. In life cycle analysis of LUC they are often not included, or only partially (Gawel and Ludwig 2011). The inability to include a full range of impacts caused by iLUCs is a notable limitation of current iLUC models. A more thorough analysis might in fact leads to very different results, suggesting different development patterns than the one indicated by current analysis.

From a LCA perspective, it might be argued that iLUC models concerns data inventory modeling rather than impact assessment and that broadening the range of iLUC impacts is an impact assessment problem rather than an inventory one. Moreover, data collected for quantifying LUC GHG emission (land classes, marginal land, yields etc.) are in some cases the same underling data necessary for a broader impact assessment. If occupation of new land (forest land) and its location are identified for example, it might be relatively easy to assess the consequent loss of biodiversity. Nevertheless, impacts on biodiversity are always pointed out as the most serious when occupation of new land is concerned and comprehensive iLUC models are not consistent if their scope do not included its assessment; yet, to broaden the assessment to further environmental aspects as soil depletion, water use, and non-environmental as social and economic impact, the collection of further data is unavoidable and a the goal and scope of the model needs to be radically reformulated.

Table 3. Results of the paired comparison analysis applied to the five selected models.

A - Completeness Of Scope	**CAPRI**	**GTAP-AEZ**	**JRC**	**Bauen et al.**	**Schmidt et al.**
i - Dataset	3	4	4	2	2
ii - Land Classification	3	5	3	2	5
iii - Origin of Marginal Land	2	2	3	2	4
iv - Co-product	3	3	0	3	0
v - Distribution of Emissions	1	1	1	3	5
B - Impact Assessment Relevance					
vi - Non GHG Emission	2	0	0	0	0
vii - Other non-Environmental Impacts	1	0	0	0	0
C - Scientific Robustness And Certainty

Average score	**2.7**	**2.9**	**2.1**	**2.1**	**3.1**

Regarding group of critera ‘C’, EEMs obtain and average score of 3.5 while the average score of DMs is 2.6. Generally, the assumptions behind the models are motivated through science-based argumentations (criterion xi) with the exception of the allocation of GHG emissions flows associated with LUCs over an arbitrary period of time followed by Bauen et al (criterion v). Distributing GHG emission over time is a widely used normative approach but, as such, non-scientifically justifiable. Acknowledging this limitation, Bauen et al. DM calculates the iLUC GHG emission factor considering different allocation time (30 and 100 years). Schmidt et al. DM instead proposes a science based alternative approach, avoiding a normative assumption (criteria v and xi), further discussed in section 3.2. CAPRI and GTAP models have been peer reviewed in scientific journals articles available on the model webpage. The DM by Schmidt et al. is currently under review. Peer-reviewed version of JRC and Bauen et al. models have not been found but their development involved multiple stakeholders and panels of experts. With the exception of Bauen et al. the models are periodically updated but the JRC model does not directly assess uncertainties; yet, the PE and CGE models upon which is based have been both peer-reviewed and show models’ sensitivity to main assumptions.

A further discussion is presented in the following subsections.

3.1. Economic models

EEMs are distinguished between PE and CGE models: PE models represent only a specific subset of economic sectors for a country or region, with no link to other economic sectors, giving an incomplete but rather detailed picture of it. On the contrary, CGE models account for the entire economic flow among different production sector within an economic system (national or global). However, completeness entails an increasing complexity and a loss of details in the model; the representation of land uses, land use alternatives and emissions cannot be sufficiently detailed for modeling land use change. For this reason CGE models are usually expressly modified to suit the model of iLUC. Complexity also adds to CGE models uncertainties difficult to estimate (Dunn et al. 2013).

3.1.1. CAPRI model

Economic models have usually a national level of data aggregation; in some cases efforts have been made to further regionalize models: CAPRI (Common Agricultural Policy Regional Impact) divides the EU territory in about ca. 250 NUTS2 sub-regions (CAPRI 2012). Data are mainly drawn by FAOSTAT, OECD and the Farm Accounting Data Network (FADN). Land use change data are drawn from EUROSTAT land use and land cover data but no particular plausibility check is carried on this datasets. Land uses are classified according to the LUCAS survey, which means 36 crop land classes and 2 of permanent grass rearranged according to the crops present in CAPRI. Since CAPRI has been built to model agricultural activities, forest land, water and urban areas are all aggregated in category 'Other' (criterion ii). Obviously the difference between an urban area and a forest land is rather big. This is of course a limit when modeling LUC. Other than GHG emissions indicator, CAPRI features indicator accounting for ammonia emissions, NPK leaching, water balances, and nitrate concentration in water and chemical emissions. The model also accounts for by-products of land-requiring product by means of physical replacement ratios. Alternatively, other CGE models accounts for by-products by substitution based on relative prices, as the GTAP model, which includes corn ethanol DDGS as a co-product.

3.1.2. GTAP-AEZ model

The Global Trade Analysis Project (GTAP) develops databases and CGE models which have recently seen improvements (GTAP version 8 database has been released in 2012) aiming at assessing LUC impacts. For this purpose it has further been regionalized, linking it to agro-ecological zones (AEZ) model (Fischer et al. 2012): since land types differs, land substitutability is possible only among zones showing similar characteristics (Hertel et al. 2009A). GTAP-AEZ is a special version of the model suited for estimating land use changes. The biofuel sector is here better represented through disaggregation of corn and sugarcane ethanol, and biodiesel, the three major biofuels. Environmental issues, such as climate change, resource use and technological progress in agriculture, are better pictured by dynamic models; GTAP-Dyn, a dynamic version of GTAP (Ianchovichina and Walmsley 2012) aims at projecting future land use change patterns linked at growth rate in each world's regions to identify the marginal land. Forest dynamics are accounted integrating the Global Timber Model (Sohngen and Mendelsohn 2006) while land heterogeneity is limited by the use of AEZ and land mobility across uses by the Constant Elasticity of Substitution (CET) function, estimating land supply elasticity. The CET function simulates the competition for land in economic models through the parameter 'σ', elasticity of land transformation. GTAP database is built upon the integration of several datasets on crop harvested area, production and yields (FAO 2006, Monfreda, Ramankutty, and Foley 2008). However, accounting at global scale for interaction among different economic sectors and regions poses some problems and for this reasons GTAP database aggregates in eight sector all crop productions.

3.1.3. EU JRC model

The hybrid model based on a CGE, PE and geographical information was developed by the Joint Research Center (JRC) of the EU (Hiederer et al. 2010). To calculate the GHG emissions from LUC the model use the cropland demand data acquired by CGE model IFPRI-MIRAGE and the PE model AGLINK-COSIMO. Moreover, the model spatially allocates agricultural land demand: combining different datasets to estimate existing cropped areas, land availability and land suitability they predict the geographically location where the land use change may occur (the location of the marginal land) and create a land suitability map. The model provides precise results with regards to GHG emissions by iLUC since it also includes soil properties information (such as carbon content) drawn from the Harmonized World Soil Database. However, the land demand spatial allocation module also increases the overall complexity, assumptions and consequently, the model uncertainties; at present, uncertainty analyses of the JRC model have not been undertaken (Hiederer et al. 2010). Due to the considerable number of assumptions (economic trends, market variables) and the complexity of model's framework (CET function, prices elasticity etc.), EEM results are rather complex: the extent to which they depend on the assumptions are not intuitively understandable (Nassar et al. 2011). The use of prices and price elasticity to determine yield change and cropped area variations in EEM does not reflect the role that other factors, such as technological and infrastructure constraints, yearly harvest capacity, trade agreement and other factors may play in determining those changes; even when these factors affect prices, price response is not visible in the short term. Yet, the complexity of the EEMs does not broaden the spectrum of the analysis and aspects as land degradation and biodiversity are generally not included in these models.

3.2. Deterministic Models

Alternative approaches to EEMs are causal-descriptive or Deterministic Models. DMs provide a simpler and more transparent framework than EEM where those data can be applied. They describe the future states of a system based on cause-effect relationships observed through statistical and historical data. They tend to have a more simple approach than EEMs (Nassar et al. 2011). That reduces the computational effort, data requirement and makes them conceptually easier to understand. Nevertheless, DMs do not necessary exclude economic aspects driving the supply/demand patterns: in some cases DM also includes market information such as cross-price elasticity of products, making them hybrid models, able to draw from different approaches. According to current market trends and assumptions on agriculture supply/demand trajectories, they forecast future production and consumption patterns. From this scenario, future land uses and origin are estimated.

3.2.1. Bauen et al. model

On behalf of the UK's Department of Transport Bauen et al. (2010) developed a DM to assess iLUC from five biofuels, taking into account future yield and area changes' trends, products substitutability and the effect of co-products; data were extrapolated from databases through statistical analysis of historical trends. A peculiar characteristic of this study is that future predictions were estimated consulting a panel of expert and stakeholders, to integrate their views in the assessment and guarantee a more democratic approach compared to the economic models' approach. Cederberg et al. (2011) used a deterministic approach to assess the impact of beef production in Brazil. This regional focus and product-oriented model make it unfit for application to different contexts, a limit generally observed in many DMs. As Bauen et al. (2010), also Cederberg et al. only account for iLUC GHG emissions effects. Within the LCA framework DMs are also distinguished between models using averages of historical data and future oriented models; the latters may also use historical data but to predict future trends, which can also diverge from historical patterns. This difference is also reflected in the LCA approach chosen, Attributional (A)LCA or Consequential (C)LCA (Sanchez et al. 2012). The dispute between ALCA-CLCA is beyond the scope of this paper; however, thorough discussions upon details of the two approaches are present in the scientific literature (Weidema 2003, Schmidt 2008, Thomassen et al. 2008, Finnveden et al. 2009, Rehl, Lansche, and Müller 2012).

3.2.2. Schmidt et al. model

A limit of iLUC models, regardless of the approach used, is the time allocation of the emission over an arbitrary period of time, generally 20 years (Fritsche, Hennenberg, and Hünecke 2010, IFPRI 2010) or 30 years (Bauen et al. 2010). Since this choice has no scientific bases, Schmidt et al. proposed an alternative DM approach, avoiding time allocation of emission, similar to the approach proposed also by Kløverpris and Mueller (2013). Kløverpris and Mueller model (2013) is applicable to any phenomenon causing LUC, based on current trends and future predictions of land uses. The starting point is the principle that land uses baseline is dynamic rather than static therefore in a region with expanding agricultural area, further occupation of land is seen as "accelerated expansion" and in a region with decreasing agricultural area as a "delayed reversion" (Kloverpris and Mueller 2013). As Kloverpris and Mueller (2013), Schmidt et al. (2013) avoid time allocation of emission considering an increasing land demand as a dynamic baseline; the result is only a time shift in the emission profile and consequently in the measured Global Warming Potential (GWP) effect. Doing so, the GWP is caused from the accelerated expansion of land and the resulting effect is accounted only in the specific year the activity 'land occupation' is taking place; therefore, the emissions do not need to be allocated over an arbitrary period of time. In accordance with a LCA framework Schmidt et al. see "Land" as an input to a process creating an output (the product), as in LCA is treated any other process's input. Schmidt et al. (2013) model is a more comprehensive model than Kløverpris and Mueller (2013). Based on global statistics (FAOSTAT, FAO) and IPPC guidelines, the model is applicable to all crops and regions in the world. Despite being a DM, it does not refrain from drawing upon different toolboxes: economic tools, such as cross-price elasticity tables, are used to identify product substitute and calculate the related environmental consequences (e.g. GHG emissions impact measured by GWP). The authors draw from bio-physical relations and statistical data to identify the marginal land and the share of land intensification. The model assumes that changes in land uses are a consequence of change in land demand; land is treated as any other LCA input and land productivity (the reference flow) is measures in Net Primary Productivity (NPP) (Haberl et al. 2007). The result is DM tending towards a hybrid approach. The limit of this approach is that its validity is limited by the hypothesis that land demand is constantly increasing worldwide: despite at present this is globally a valid hypothesis, it will inevitability fall at some point due to the fact that land is a constrained resource and, if not contained earlier, land demand will be in the end constrained by land availability.

3.3. Normative Models

The last type of modeling approach is the most simplified Normative Model explained above. Flynn et al. (2012) for example proposed a NM based on IPCC national GHG inventory methodologies to assess LUC impacts from crops. The model is intended to be applied in context where complex process-based spatial models to feed agro-economic models are not available, such as in developing countries, and when information on crop origin and growing conditions is limited. The model allows to convert per ha emissions from LUC to a per-ton of product basis (Flynn et al. 2012) but the analysis is restricted to the top 20 producing countries of the assessed product, and a single yield value is assumed for each county. Generally, NMs are intrinsically based on normative assumptions, regardless of whether those being scientifically justifiable or not. NMs are hence suitable for simple applications, such as for illustrative or didactical purposes but are not suitable to support policy making or decision making processes, where more accurate, scientific-sound analysis are required.
A normative approach is also adopted in calculating the iLUC factor by Fritsche et al.(2010), obtained dividing the share of land for biofuel production in 25% as coming from intensification of "set free" land, with a zero displacement risk, and 75% from "new land" representing the actual iLUC factor. This simplified solution to quantify the GHG emissions associated to iLUC is paid by a least reliable result since the factor is calculated ignoring the complexity of cause-effect relationships triggered by LUC. Normative assumptions can be found also in non-normative models: the distribution of GHG emissions over an arbitrary period of time of 20 or 30 years described above can be found for example both in analysis using DM and EEM. Searchinger et al. (2008) for example, used for their model the FAPRI-CARD PE model but assumed bioenergy as the only source of iLUC, since ethanol is a relatively new product demanding a large amount of land, therefore responsible for increasing the global land demand compared to usual trends. This normative assumption is not completely true as land demand is caused by any conventional agricultural activity (Nassar et al. 2011) as well as increasing demand of conventional agriculture products, urban sprawl, forest fires, logging etc.

4. Conclusion

There are very diverse solutions to model iLUC in literature. Considerable progress has been made to adapt EEMs and DMs to capture the complex dynamic of land use changes. Transparency is usually inversely proportional to complexity but complexity of models is to some extent necessary to compensate for the lack of primary data. New studies aiming at collecting global land use and yield data will in the future help reducing complexity. Currently few hybrid economic models, linked to bio-physical and geographical models, can provide scientific sound and accurate picture of iLUC. They are however complex, and computationally intensive and are therefore recommended for large scale applications, such as policy making. For small scale applications, such as LCA of product or processes for companies or small institutions, DMs provide a more useful picture of the cause-effect relationships and product chain. Time allocation of emissions can however be avoided also by EEM using the approach proposed bt Schmidt et al. (2013). A substantial limitation of current model is the inability to include the full range of impacts caused by iLUC since the focus is generally restricted to GHG emissions impact. More comprehensive analysis might show very different results and suggest completely different development patterns. It is therefore in this direction that future research should be addressed.

ABSTRACT

The European research project SENSE will deliver an affordable and comprehensive environmental evaluation system oriented to small and medium enterprises (SMEs) in the food and drink sector. The system aims at simplifying data collection and information requirements by compiling key environmental performance indicators (KEPIs) throughout the value chain in a web-based tool. Cradle-to-gate life cycle assessments (LCA) were conducted in three selected food sectors, namely meat and dairy, fruit juice and aquaculture salmon, in order to verify, if the KEPIs that had been selected for the tool contributed to the main environmental impacts. Since the impact categories cover a wide range of environmental impacts such as acidification, climate change, eutrophication and toxicity, the KEPIs can be used to deliver a comprehensive environmental evaluation. An overview of the main results of the LCA studies and justification for the selection of KEPIs is presented. Moreover, aspects of regionalization of background database is discussed since this may affect the results and needed to be considered when designing the simplified SENSE tool.

Keywords: LCA, key environmental performance indicators, food and drink supply chains, regionalization

1. Introduction

Life cycle thinking and taking responsibility in environmental issues beyond the operation of the companies is gradually being implemented in large businesses along with the awareness of the concept sustainability. This trend is less pronounced in small- and medium sized enterprises (SMEs), often because of lack of understanding and limited capacities to look beyond their daily operation. Moreover, SMEs may not be familiar with environmental assessment methods. Measures to assess environmental performance need to have a positive economic impact, since data gathering is often regarded a burden and companies therefore are not willing to undertake such an assessment. However, when given opportunities to implement life cycle tools, there appears to be potential incentives in SMEs to use Life Cycle Assessment (LCA) results to create an image for the product and the organization, to use in marketing, and for product development (Witczak, 2014). The SENSE project aims at enhancing environmental awareness in SMEs in the food sector by offering a harmonized data collection system and simplified assessment of environmental impacts.

The main environmental challenges of European food and drink supply chains and their environmental impacts have been assessed in the project based on earlier LCA studies (Aronsson et al., 2014). The approach has been to select a set of harmonized input data, defined as key environmental performance indicators (KEPIs) which are essentially the required information for LCA (i.e.: water, energy, materials consumption). Full scale LCAs for three selected food and drink supply chains were conducted in the project and the result interpreted to justify the validity of the selected KEPIs to reflect the main environmental challenges. Key attributes and suitable scope of essential input data was thus prioritized according to the most important environmental impacts in order to simplify data collection in SMEs. The KEPIs are either common performance indicators such as electricity consumption, water consumption, fertilizers and pesticide use, but also key parameters such as the composition of the feed. The results from the LCA studies presented herein thus confirm the most relevant stages in the life cycle of the respective food products and the suitability of the KEPIs to be applied in the SENSE tool.

2. Methods

Three LCA case studies were performed on current food production and supply systems and investigated from a regional perspective:

- orange juice production in Spain (Doublet et al. 2013a)
- dairy and beef production in Romania (Doublet et al. 2013b)
- salmon aquaculture in Iceland and smokehouse in France (Ingólfsdóttir et al. 2013)

Further information on the definition of goal and scope, the life cycle stages included, definition of the system boundary, input materials/items included and excluded, justifications and assumptions made, detailed life cycle impact results and interpretation are available in the respective reports. The environmental impact assessment methods initially selected by the SENSE project team comply with the ones later recommended by ILCD (JRC, 2011). These are the same methods as later recommended by the European Commission on the Product Environmental Footprint (EC, 2013) and in the ENVIFOOD protocol except for water depletion where a revised approach to water footprinting is recommended in the ENVIFOOD protocol (ENVIFOOD, 2012).

In the LCA case studies the allocation for the aquaculture and the orange juice supply chains followed economic allocation as recommended by the ENVIFOOD protocol (ENVIFOOD, 2012). The allocation for meat and milk at the dairy farm followed the physical allocation approach suggested by the International Dairy Federation (IDF 2010). The allocation for the meat produced at the slaughterhouse followed an economical approach, while the allocation for the dairy products at the dairy plant follows a physico-chemical approach as suggested by IDF (2010).

3. Results

The results of the life cycle impact assessment in the three food supply chains analyzed by LCA show similarities as expected. The cultivation of biomass was the main contributor in the orange juice and beef and dairy food supply chains due to the environmental impacts of use of water, land, pesticides and fertilizers, and fuel for tractors. This is also the case for the aquaculture food supply chain including the feed from marine resources where the fuel use for vessels in fisheries is a significant contributor (Figures 1-3).

3.1. Life Cycle Assessment - Orange juice

The impact assessment of the Not-From-Concentrate orange juice shows that the main contribution of life cycle step depends on the impact categories assessed. About 50 % of the climate change and abiotic resource depletion are due to the bottling process.

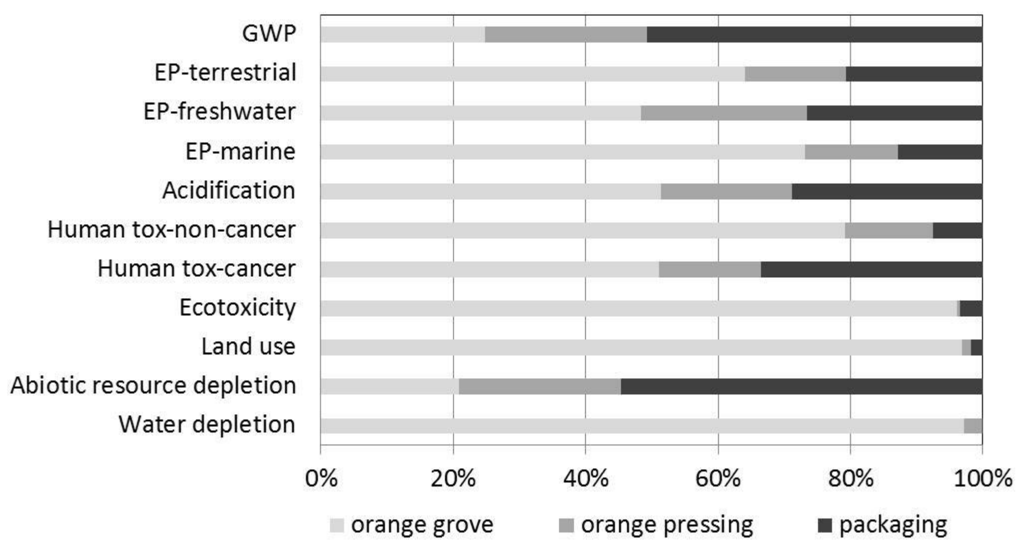

Figure 1. LCA of orange juice in Spain. Impact assessment of one litre NFC orange juice (Doublet et al., 2013a)

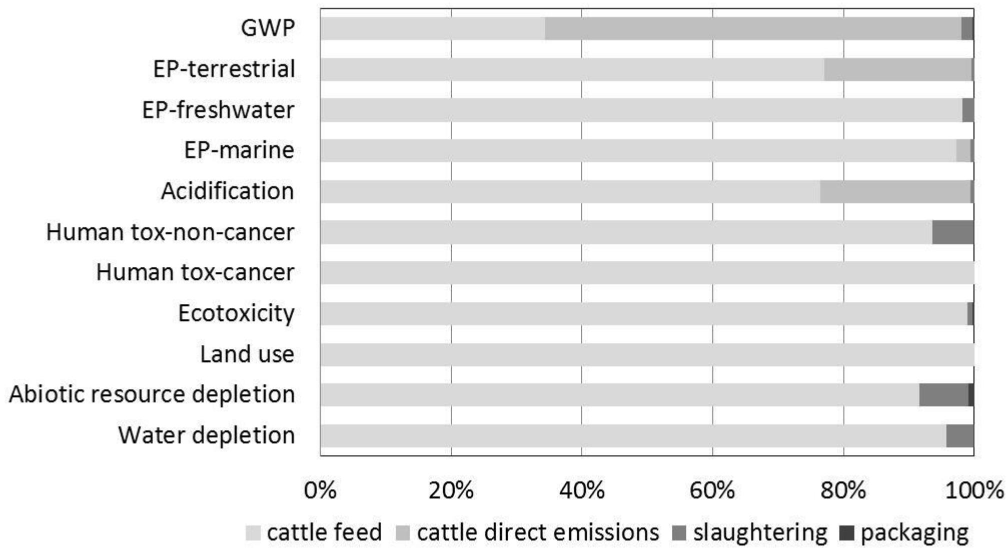
The impact categories land use, water depletion and freshwater ecotoxicity are dominated by the orange cultivation (more than 95 %). The orange cultivation contributes around 50 % to the acidification and freshwater eutrophication. The four main contributors to the orange cultivation are the electricity use for the irrigation, the production and use of fertilizers and the application of pesticides.

The most relevant processes for the juice pressing are the electricity use and thermal energy use. The main contributor to the bottling process is the manufacture of the PET bottle.

3.2. Life Cycle Assessment - Beef and dairy

The impact assessment of the beef shows that the feed cultivation at the dairy farm is the main contributor to the results (Figure 2). The slaughtering process and the packaging are negligible to most of the impact categories.



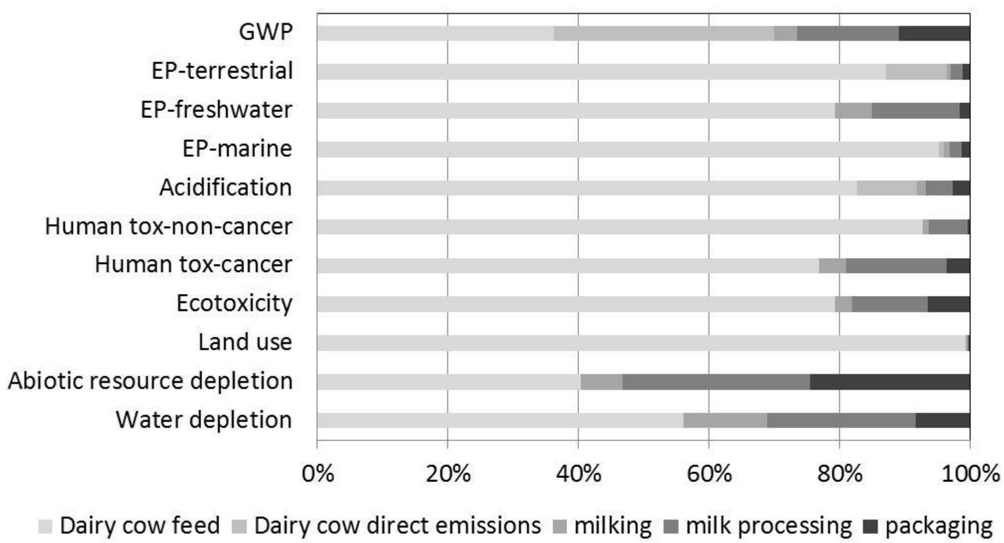


Figure 2. LCA of beef and dairy products in Romania. Impact assessment of 1 kg beef at slaughterhouse (above) and impact assessment of 1 liter milk at dairy plant (below) (Doublet et al., 2013b)

The emissions from the use of fertilizers, manure and diesel for the agricultural machinery influence the results most. The cattle emissions due to the enteric fermentation are the main source for the climate change. The animal waste disposal from slaughtering is also an important step due to its processing into animal flour before its incineration. The impact assessment of the dairy products is similar to the beef because raw milk is produced by the dairy cows. The dairy farm is also the most important step to most of the dairy products. However, the contribution of the processing step to the production of dairy products is higher than the contribution of the slaughtering process to the beef production.

3.3. Life Cycle Assessment of aquaculture

The impact assessment of fresh salmon (head on gutted) transported from Iceland to Europe by sea freight verified that the feed production is by far the dominant life cycle stage in all impact categories. For most of the impact categories (GWP, terrestrial eutrophication, freshwater eutrophication, acidification, human toxicity potential (cancer effects), ecotoxicity, resource deletion and water depletion) this is due to the harvesting and processing of feed ingredients (marine and crop).

For the marine eutrophication impact category it is the release of organic matter to sea (feces, uneaten feed and dead fish) which is the major cause of impact at the farm and for the human toxicity potential (non-cancer effects) the main contribution is the transportation of the feed from feed mill to the farm and long distance distribution of products.

The impact assessment of smoked salmon fillets where fresh salmon (head on gutted) is transported from Iceland to Europe by sea freight and further processed in France showed that for nine impact categories the aquaculture farm life cycle stage is the main contributor of environmental impacts, mainly due to the feed. In two impact categories the human toxicity potential (non-cancer effects) and the water depletion the operation of the smokehouse in France is the main source of impact (Figure 3).

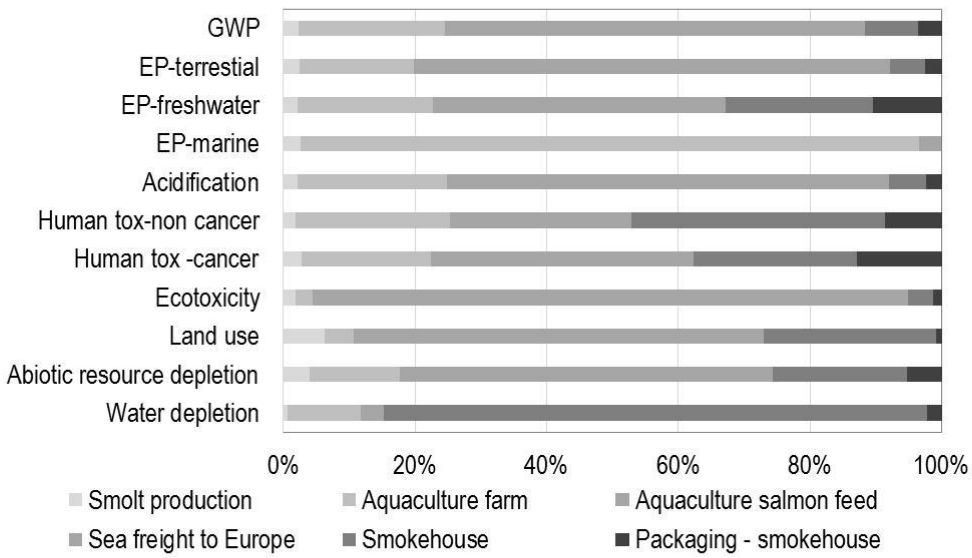

Figure 3. LCA of aquaculture Iceland and smokehouse in France. Impact assessment of 1 kg smoked salmon fillets (Ingólfsdóttir et al., 2013)

3.4. Key Environmental Performance Indicators (KEPIs)

The key environmental performance indicators were proposed as simple-to-measure indicators that could be used as input data in the SENSE tool to calculate the environmental impacts. The criteria for selection of input data for the SENSE tool, was the contribution to the main environmental impacts in the respective life cycle stage. The LCA results thus confirmed the validity of the selected KEPIs to be applied in the SENSE tool based on their relevance for the environmental impact, the data availability and the ease of measurement.

The KEPIs have been grouped according to the different production steps in the supply chain and are presented in a table for each production step. The following production steps were defined:

- Plant production (food and feed)
- Fisheries
- Aquaculture
- Livestock

- Food and feed processing
- Transport

Impact category	Plant production								Fisheries	Aquaculture						Livestock - ruminants					Food and feed processing					Special			Main pollutants / Challenges
																										Dairy	Slaughtering	Juice processing	
Unit	kg N/hectare kg N/kg crop	kg-P2O5/hectare kg-P2O5/kg crop	kg N/hectare kg N/kg crop	kg/hectare kg/kg crop	l/hectare l/kg crop	ha/kg crop	ha/kg crop	m3/hectare m3/kg crop	MJ/kg product	kg feed /kg fish	MJ/kg product	kWh/l product	kg waste/kg product	m3/kg product	kg/kg product	kg raw milk/dairy cow	kg feed/kg live weight	m2/kg product	kWh/kg raw milk	m3/ kg raw milk	MJ/kg product	kWh/l product	m3/ kg product	type/kg product	kg waste/kg product	kg raw milk/kg product	kg live weight/kg meat	kg orange/l orange juice	
Key Environmental Performance Indicator (KEPI)	N-fertiliser use	P2O5-fertiliser use	Manure and slurry application	Pesticide and active substance content	Diesel use incl. machineries	Arable land use	Grazing land use	Water use	Energy use	Feed Efficiency (FCR)[1]	Energy use	Electricity use	Organic waste to sea	Water use	Packaging material	Raw milk production	Feed efficiency	Buildings	Electricity use milking	Water use milking	Energy use	Electricity use	Water use	Packaging material	Waste	Raw milk input	Meat production	Yield	
All impact categories										x						x	x								x	x	x	x	
Climate change	N2O		N2O		CO2				CO2		CO2	CO2			CO2	CH4			CO2		CO2	CO2		CO2					CO2, CH4, N2O
Human toxicity		HM			HM													HM											Heavy metals (HM)
Acidification	NH3		NH3		NOx											NH3													NOx, NH3
Eutrophication,	NOx		NH3		NOx																								NO3, NH3
Eutrophication,		PO4		PPP	PO4	PO4	PO4																						PO4
Eutrophication, marine	NO3		NO3		NOx								x																NO3 (Nitrate), NOx
Ecotoxicity, freshwater		HM		PPP	HM																								Heavy metals (HM)
Land use						x	x																						Land use (m^2 and type)
Abiotic resource	x	x		x	x				x		x	x			x			x	x		x	x		x					Fossil resources
Water depletion					x			x						x						x			x						Water use

[1] FCR = Feed Conversion Rate: Feed used/Fish produced

Figure 4. Selection of Key Environmental Performance Indicators (KEPIs) for each production step for the three investigated supply chains in the SENSE project (Landquist et al., 2013)

The KEPIs selected for the production of all the food supply chains are shown in Figure 4. Each KEPI is given a name and a unit. When the contribution of the KEPI to an impact category is relevant, the cell is shaded and either filled with a cross or with the main pollutant emitted by the KEPI, e.g. carbon dioxide, heavy metals, ammonia, phosphate, etc. The selected KEPIs covered 95%, on average, of the environmental impacts of the respective food supply chains.

Allocation factors were computed on the basis of the shares of the different output products in the turnover, which were given by the plant. Hence, the "shares of products in turnover" is a KEPI.

It should be noted that most of the KEPIs are relevant for many more food products since most food supply chains have common characteristics and similar processing steps. For example the KEPIs for Plant production and for Food and feed processing are the same for many food chains. In all cases KEPIs were adjusted to fit general supply chains although these were not identified as a KEPI in the case studies. There are also some indicators that are specific for some production step, e.g. feed composition and feed conversion ratio (FCR) are specific to the aquaculture chain and the livestock.

3.4.1. Plant production

The plant production corresponds to the crop cultivation including the crop for feed (livestock and aquaculture) and orange cultivation. Plant production requires the use of fertilizer, manure, liquid manure, pesticide, agricultural machinery, land, water and storehouse. It is vital to know the composition of the feed as the impacts differ for the different ingredients.

The KEPIs N-fertilizer use and P_2O_5-fertiliser use refer to the production and use of these fertilizers. It is important to differentiate between the types of fertilizers applied on crops. The N-fertilizer has a higher contribution to the climate change, acidification, terrestrial and marine eutrophication whereas the P_2O_5-fertiliser contributes mainly to the human toxicity, freshwater ecotoxicity and the freshwater eutrophication. Therefore, it is important that the farm informs separately the amounts applied of each type of fertilizers. The production and the emissions to air, soil and water are covered in the background system and not asked to the farm.

The KEPI manure and slurry application refers to the manure and liquid manure (or slurry) applied on crops and are determinant for the climate change, acidification, terrestrial and marine eutrophication. The farm provides the application rate and the emissions to water and to air are included in the model.

The KEPI pesticide and active substance content includes the production of pesticides and the emissions from the active substances contained in the pesticides applied. It is important that the farm provides the pesticide name and the content of active substance. If the latter is not known, it can be found in literature from the pesticide name. The active substances are necessary to estimate the emissions that affect the freshwater ecotoxicity. In a similar way as for the fertilizers, the production of pesticides is included in the background system.

The KEPI diesel use incl. machineries, refers to the diesel consumption including its production and the agricultural machineries used. The diesel production and the emissions resulting from use are included in the background system. The CO_2 emissions due to combustion of fuels can be directly calculated with the amount of fuel burned. The agricultural machinery fleet contributes to the human toxicity and eco-toxicity impacts as well as the freshwater eutrophication. It can be difficult for a farm to estimate its agricultural machinery fleet. It was suggested to have an estimation of the agricultural machinery as a background process linked to the diesel consumption, as it was done also for the case study. Indeed, the diesel use for the agricultural processes is modelled with a dataset that includes the diesel fuel consumption, the corresponding amount of agricultural machinery needed (tractor, trailer, harvester, tillage) and its production and the shed corresponding to the machinery use.

The arable land use and the grazing land use are KEPIs for the land use impact category. The emissions of phosphorus to water due to land use affect the freshwater eutrophication impact category.

The direct water use is also a KEPI related to the water depletion impact category.

The construction of the farm buildings affects mainly the human toxicity due to the impacts of the construction material production. The farm should provide the area of the storehouse, but office buildings can be omitted based on the experience in this case study. It has to be noted that in the current case study on meat production the fodder was produced on the same farm as the animals. If animal feed is bought on the market the relevant KEPIs have to be investigated for the production of all the different type of feed bought by the farm, e.g. soy bean, maize, by-products of food and bioenergy production etc.

3.4.2. Fisheries

The feed used at the hatchery and aquaculture farm consists of marine and crop ingredients. The energy use at the fisheries was identified as KEPI for the aquaculture salmon supply chain since fossil fuels have a high contribution to climate change, acidification, human toxicity, terrestrial eutrophication and abiotic resource depletion.

3.4.3. Livestock

The farm should provide the herd size and the shares of dairy cow, bull, calf, suckler cow. This is covered in the KEPI herd size. It determines the fodder production, the manure and slurry production and the milk and animals sold to the slaughterhouse. By giving the cattle average weight in each category and the raw milk production together with its fat content and protein content, the livestock emissions of methane and ammonia can be estimated. This is the reason why these three parameters are considered as KEPIs. The feed efficiency is also an important parameter to compare different kind of feeding system. This information was however not available for the beef case study.

The KEPI animals sent to slaughtering and raw milk production together with the protein and fat content are needed for the allocation approach. The farm should also give the area of the cattle housing. The construction materials affect mainly the human toxicity and ecotoxicity.

Milking: The KEPIs electricity use and water use were identified for this process. The electricity use covers the electricity production. However, environmental impacts of electricity production vary from country to country. Consequently different impact categories might be affected by the electricity use if case studies are elaborated in another country.

Slaughtering: The KEPIs meat production and meat waste should be provided by the slaughterhouse in order to allocate the slaughtering process to the production of beef and assess the meat yield, i.e. the ratio of meat per livestock animal. The case study on meat includes the slaughtering waste treatment with background data.

3.4.4. Aquaculture

The aquaculture includes both the smolt production and the salmon farming. The KEPIs identified for the smolt production are feed, water use and electricity. The composition and amount of feed used are important in terms of climate change, human toxicity, acidification, eutrophication (terrestrial, freshwater) and ecotoxicity. Information on the total production at hatchery as well as at the aquaculture farm and share of products in turnover are also identified as KEPIs for allocation purposes.

For the aquaculture farm the feed composition and amount, organic waste to sea, electricity use, fossil fuels, water use and packaging materials are identified as KEPIs. The slaughtering and primary processing (gutting) are included in aquaculture. Water use and electricity use are identified as KEPIs even though these indicators are not significant in the net pen aquaculture system analyzed in this study However, these KEPIs can be very important for other aquaculture systems for example land based systems in other regions where renewable energy sources are not available and water is scarce. The other KEPIs affect climate change, human toxicity, acidification, eutrophication as well as abiotic resource depletion. The feed efficiency (FCR, feed conversion ratio), i.e. the weight of feed used (kg) compared to weight of fish produced (kg) is a key factor to assess environmental performance of the aquaculture farm. Furthermore, to assess the performance of aquaculture farms, the amount of marine resources that is consumed in the production of farmed fish, the FIFO ratio (fish in - fish out) is commonly used in the industry.

Feed intake and feed efficiency may change during the lifetime of the farmed fish. In this study the feed conversion ratio was available from the company based on the annual production. However, because the life cycle of salmon is 2-3 years, the annual data may give misleading information about the actual feed conversion ratio. In order to avoid this variation affecting the LCA results it may be more appropriate to use a three year average for the operation of aquaculture farms.

It is important to mention that the aquaculture farm in this study does not use anti fouling agents. Therefore, it is possible that in the case where anti fouling agents are used that they can be of importance. Furthermore, land based aquaculture was not analyzed in this study.

3.4.5. Feed and food processing

Dairy plant: The dairy plant does not only comprise the infrastructure but the whole process of transforming raw milk into dairy products. The raw milk input as well as the electricity use, thermal energy use and water use can be given on a whole of factory basis and allocate to each dairy product thank to the allocation approach applied, e.g. the IDF matrix (Doublet et al., 2013b). Furthermore the produced amount of each single dairy product has to be reported. The infrastructure of the dairy plant could be included in the background data related to the raw milk input processed at the dairy plant. It is also important to know the packaging material and its weight especially for the milk PE bottle and the yoghurt. The production of the packaging should be included in the background system.

Smokehouse: For the smokehouse the following KEPIs are identified: electricity, fossil fuel and water use as well as raw material inputs (salmon HOG), total production and share of products turnovers. The electricity and fuel have impact on climate change, human toxicity, eutrophication (terrestrial) and abiotic resource depletion. Water use has potential influence on water depletion; depending on the region the process takes place in. For land use impacts, the use of wood chips for the smoking process can also be of importance as a KEPI. The head and bones from filleting process as well as cut offs and trimmings from finished products are discarded and do therefore not carry any environmental burden in this study. This may however be of interest if sold as added value by-products.

Orange Juice processing: The juice processing plant must provide the input mass (kg) of oranges needed to produce 1 l of orange juice. The electricity use, the thermal energy use and the water use are the three main KEPIs. Both electricity and thermal energy contribute to the abiotic resource depletion and the climate change.

The water use determines the amount of wastewater that will be treated. The phosphate emissions resulting from the wastewater treatment affect the freshwater eutrophication.

There are by-products from the orange juice processing, e.g. peels, pulp, and essential oils. An allocation approach is necessary to allocate the energy and material flows to the orange juice. In our case study, the allocation factors were computed on the basis of the shares of the different output products in the turnover, which were given by the plant. Hence, the "shares of products in turnover" is a KEPI.

Bottling process: In most cases, the bottling plant does not only bottle orange juice. Therefore, the share of orange juice in the total amount of juice processed is a KEPI necessary to allocate the energy and material flows to the orange juice. The KEPIs electricity use and the thermal energy use cover the energy consumption of the bottles dryers and blowers, compressors, labelling machines, palletizers etc.

The environmental impacts of the KEPI "type of container" depend on the packaging investigated. In our case study, the packaging investigated is a PET bottle. The KEPI includes the PET material production, the PET granulates injection molding into PET preforms and the production of other materials that are included in the PET bottle e.g. secondary packaging, intermediate layer etc. It is relevant for the abiotic resource depletion, the human toxicity, the climate change, the acidification and the freshwater eutrophication. All these processes are included in the background system but the weight of the PET bottle and the other materials must be provided by the bottling plant.

3.4.6. Transportation

In the case study on meat the transportation distances between farm and further processing were quite small. There are also not major transports of fodder products to the farm. Therefore impacts due to transportation were not found to be a major issue and are not considered in the definition of KEPIs for the meat and dairy chain. This conclusion is however not valid for cases with higher transportation distances involved between processing stages as is the case in the aquaculture chain. For transportation the KEPI identified is transportation mode and distance travelled. The fuel is important factor in terms of climate change, acidification, human toxicity, eutrophication (terrestrial) and abiotic depletion.

4. Discussion

4.1. Regional characteristics and background database system

An important question of the project is the adjustment of the SENSE model to regional characteristics. The regional variation affects some of the identified KEPIs and the environmental impacts.

In the SENSE web-based tool the background information is based on the ecoinvent database and is not under the direct influence of the SME. Regionalization of background data is important when designing the simplified SENSE tool, since this may affect the results.

In many cases LCI background data are just available for a global or a European production mix. But, in practice the markets in different regions might be supplied with a different mix of products. Thus, also LCI data can be adapted to the market situation in a specific region. One example of regionalization of background LCI data is the application of a country-specific electricity mix. Publicly available country-specific electricity mix datasets have been implemented in the SENSE tool as background data.

Other important regionalized impact assessment methods were included in the SENSE tool such as water depletion, acidification and terrestrial eutrophication. For acidification regional characterization factors for many countries in Europe are available (Posch et al., 2008). Acidification characterization factors for sulfur dioxide, nitrogen oxides and ammonia are available for France and differ somewhat from the weighted average factors used in this case study.

In the context of the current LCA study on smoked salmon in France, terrestrial eutrophication, regionalized characterization factors are available for France which are higher than the weighted average applied in this study. Furthermore, for marine eutrophication it is important that datasets for emissions of organic matter to sea are available in the SENSE tool. Background LCI datasets need to be available on the nitrogen content in different aquaculture fish species to be able to assess the marine eutrophication potential from dead fish. Additionally, datasets should be available in the tool for N content from feces and feed deposition for sea based aquaculture in different regions. For other background data it was not expected that including regionalized data for diesel, natural gas, fuel oil would make major differences in the environmental impacts results.

Availability of water differs greatly between countries and regions. Regional characterization factors are available for water scarcity (Frischknecht et al., 2009). In this case study regionalization factors for water depletion were used. The smokehouse in France has considerably higher impact on water depletion than the hatchery and aquaculture farm in Iceland, although they use significantly higher amount of water. This is because water is defined as abundant in Iceland.

The feed for aquaculture is composed of both crop products (e.g. soya, rape, wheat) and marine ingredients. The use of diesel for fisheries is the main contributor to CO_2 emissions contributed by the use of fish ingredients in the feed and this varies depending on the type of fishery. Often the information on the feed ingredient composition is not publicly available. It was recommended that Life Cycle Inventory (LCI) background data for different types of aquaculture feed and feed ingredients would be generated and implemented in the tool.

The regionalization of emissions models was only implemented for the livestock methane emissions factors by using IPCC guidelines. Easy-to-apply models for European regions are so far not available in order to regionalize other emission models.

The regionalization of the impact assessment method (LCIA) means that different characterization factors are used for each country or for a specific region. The characterization factors of ammonia and nitrogen oxides for terrestrial eutrophication in Romania are higher than the weighted average implemented in SimaPro (Posch et al. 2008). In this assessment a regionalized approach for water depletion was applied (Flury et al. 2012). Furthermore it would be relevant to better differentiate the impacts of different types of land occupation which is not possible with the LCIA method used so far.

Several calculations for direct emissions due to the application of fertilizers and the animal rearing are based on scientific emission models and not on real measurements. One issue of the regionalization is to assess the possibility of having emission models that can be directly fed with data provided by the SME and thus better considering the local circumstances. Some of the models used in this case study are based on regional experiences e.g. in Switzerland. In principle the outcome of these calculations can be influenced by regional circumstances such as rainfall, soil quality, slope of fields, average temperatures, irradiation, etc. Therefore, it would be necessary to better adapt the models to the specific regional situation. But, such easy-to-apply models for the whole of European regions are so far not available. Therefore, only a case specific model for the methane emissions of the animals on the farm was applied according to the tier 2 approach of the IPCC. This emission model is now specific to the Romanian dairy farm (milk yield, animal mature weight, feeding situation etc.). A quite relevant question for a regionalized model would be the calculation of phosphate emissions from erosion and run-off at agriculture areas as well as different type of nitrogen emissions due to fertilizer, manure and dung use. The modelling of NOx emissions from fuel combustion, which depends e.g. on the technology standards applied in a specific region, could be another issue for a regionalized model.

Other aspect of consideration is the sensitivity of different methods for the calculation of the impact categories. For example, climate change or eutrophication is quite robust since the most influential substances are directly related to the primary data. However, other impacts like ecotoxicity or resource depletion are very dependent on the background data, therefore, the differences in the selected database could lead to great differences between LCIA. Regional background data when available should be implemented in the SENSE tool as recommended and regionalized impact assessment and regional emission models which may affect the result will need to be further developed and implemented when available in the future versions of the SENSE tool.

5. Conclusion

The most relevant KEPIs for food supply chains have been selected and implemented in the SENSE web-based tool. The tool is currently being validated by comparing the outcome of the SENSE tool with calculations performed by commercial software (SimaPro and GaBi). The validation is based on using as input only the selected KEPIs. Furthermore, additional case studies where the SENSE tool is tested by users are currently ongoing in the project in at least 30 companies and their supply chains. The harmonized SENSE-tool based on the selected KEPIs is designed to be flexible and adaptable to other food types and will thus be applicable to motivate an LCA based approach and support self-assessment of environmental performance in other food supply chains.

The benefit of a simplified environmental assessment as the SENSE tool can provide will be further assessed in the project by interviews and on-line surveys in companies that will test the SENSE tool.

ABSTRACT

Large uncertainties in the life-cycle greenhouse gas (GHG) emissions of biofuels could offset their potential savings. These arise from the difficulty in taking into consideration land use change effects and N_2O emissions, which are strongly dependent on local pedoclimatic conditions and technological options for feedstock cultivation. Here, we used an crop model (CERES-EGC) to simulate crop growth and C-N dynamics in the cultivation fields at the regional scale for a wide range of lignocellulosic feedstocks. Bioethanol made from cereal straw achieved the largest GHG reduction compared with fossil fuels (at 74%). Among the dedicated energy crops investigated, Miscanthus had the highest GHG abatement potential, ranging from 63 to 72% depending on crop management. A combination of feedstock sources (straw, Miscanthus and triticale) stroke the best compromise to fulfill sustainability criteria, secure the supply and limit the pressure on land and competition with food.

Keywords: lignocellulosic biomass, 2nd generation (2G) bioethanol, emission modeling, Miscanthus, greenhouse gas (GHG)

1. Introduction

Following its ratification of the Kyoto protocol, the European Commission set up directives to promote the development of biofuels in the transport sector, with a 10% target for the share of renewable fuels by 2020. Sustainability criteria were also introduced for conversion units coming onto the market after 2017, to ensure a minimum greenhouse gas (GHG) abatement of 60% compared to fossil equivalents (European Parliament 2009a; European Parliament 2009b). Biofuels are currently produced from agricultural sources. The agricultural sector, however, represents 15% of French GHG emissions, and 89% of N_2O emissions (CITEPA 2013). N_2O shows a high global warming potential (GWP), 298 higher than CO_2 (IPCC 2007). It is thus essential to accurately estimate GHG emissions from biomass crops to supply bioethanol conversion units.

Life cycle assessment (LCA) is an objective and holistic tool, commonly used to estimate the environmental impacts of biofuels. Whereas the uncertainty band in the GHG balance of fossil fuels typically amounts to 4 g CO_2 eq MJ^{-1}, it can be 2.5 to 10 times higher for first generation (1G) biofuels (10 to 40 g CO_2 eq MJ^{-1}) (Edwards et al. 2011) and not estimated for second generation (2G) biofuels due to the lack of data. Even if guidelines have been proposed (ADEME 2010), the methodology for GHG accounting lacks consensus on two crucial aspects: N_2O emissions and land use change (LUC) effects. Both of them could offset the conclusions on GHG savings (Searchinger et al. 2008; Hoefnagels et al. 2010; Cherubini and Strømman 2011; Smith and Searchinger 2012). In most cases, LUC is ignored or minimized, but recent studies encourage the integration of this factor within the biofuel sustainability criterion (ADEME 2012; De Cara et al. 2012; European Parliament 2012). N_2O emissions are mostly calculated from IPCC generic factors without considering any local pedoclimatic variations, which generates large uncertainties (Hoefnagels et al. 2010; Smith and Searchinger 2012).

As shown in recent publications (Dufossé et al. 2013), crop modelling can overcome these problems by a better consideration of local soil and climate variations and their effects on yield and GHG emissions. Combined with scenarios of bioenergy crop establishment, crop modelling makes it possible to define multi-sources feedstock supply scenarios and minimize GHG emissions from biofuel feedstocks. Whereas it is now obvious that the GHG abatement potential of 1G biofuels is limited (ADEME 2010; ADEME 2012; Humpenöder et al. 2013), 2G biofuels are still under technological development and their feedstock (lignocellulosic biomass) remains to be fully evaluated. In particular, different types of feedstock have to be compared to define the most reliable and sustainable mix for a given conversion unit.

The aim of this paper is thus to evaluate feedstock supply scenarios, through a LCA, for a unit of production of 2G bioethanol, considering field emissions, agricultural operations, agricultural input (fertilizers, pesticides, herbicides) manufacturing, as well as input and biomass transportation.

2. Methods

2.1. Crop modeling

Regional modeling was based on the crop model CERES-EGC (Gabrielle et al. 2002). The model requires meteorological and management data as forcing variables, as well as soil and vegetation data as input factors and runs at a daily time step. CERES-EGC comprises a physical sub-model which simulates the transfer of heat, water and nitrate down the soil profile, as well as soil evaporation, plant water uptake and transpiration in relation to climatic demand (Gabrielle et al. 2002). A biological sub-model simulates the growth and phenology of the crops and a microbiological sub-model simulates the turnover of organic matter in the ploughed layer. Direct field emissions of CO_2, N_2O, NO and NH_3 into the atmosphere are simulated with different trace gas modules (Lehuger et al. 2009; Lehuger et al. 2010). The nitrous oxide emission module simulates the production of N_2O in soils through both the nitrification and denitrification pathways. N_2O emissions resulting from both processes are soil-specific and are proportions of total denitrification and nitrification (Lehuger et al. 2009). CO_2 exchanges between the soil-plant system and the atmosphere are modeled from net photosynthesis and soil organic carbon (SOC) mineralization (Lehuger et al. 2010).

Soil input factors include physical properties, soil texture characteristics and biological parameters for nitrification and denitrification processes. At regional scales, these inputs are inferred from the 1:1 000 000 soil map of the European soil map, in which the twenty soil classes occurring in France were reduced to fourteen main soil types after an aggregation based on their characteristics (Dufossé et al., 2013). The model was run on simulation units (SU) defined by overlaying the soil map with geo-referenced databases on meteorology, land cover, administrative borders and crop management, as detailed in Dufossé et al. (2013). The area of the SU varied from 2.5 ha to 30 000 ha, with a median value of 1 210 ha. Administrative borders of regions and departments were given by IGN-GEOFLA and InfoSIG Cartographie (2010) and were used to determine crop management by deriving regional statistics (Agreste 2008). Corine Land Cover dataset (European Environment Agency 2006) provided the detailed area of utilizable agricultural land (UAL) within each SU, broken down into arable lands, fragmented lands and grassland areas. Meteorological datasets were provided on a 8km-mesh (SAFRAN grid, (Pagé et al. 2009)), each SU being associated to the closest grid point. The results presented in this paper at regional supply-area levels resulted from the weighted means of individual results from the SU involved.

2.2. Study domain and system boundaries

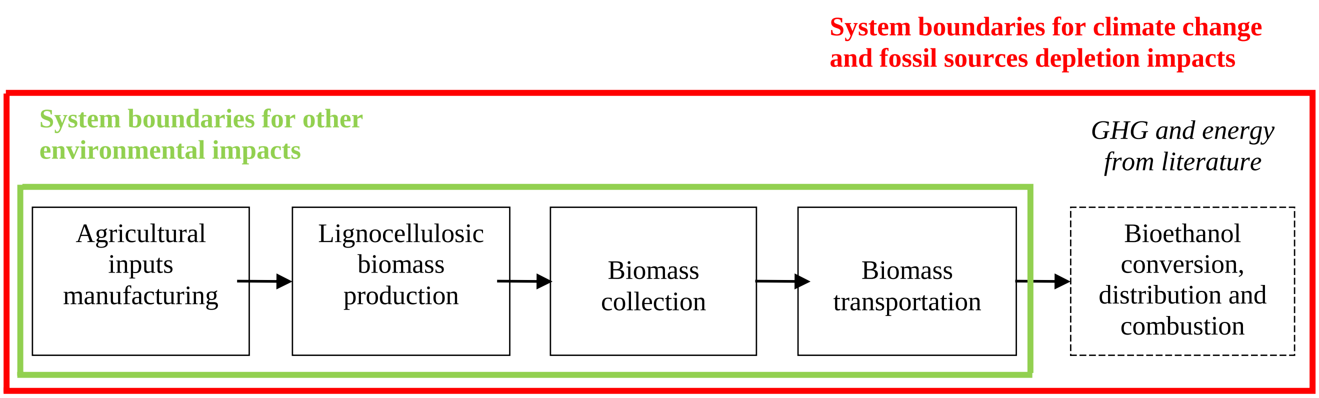

Figure 1: System description and boundaries for climate change and fossil resources depletion impacts (red) and other environmental impacts (green)

The LCA methodology applied in this study followed the ISO 14044 standard requirements. The biomass supplied to the bioethanol conversion unit represents the downstream boundary (green boundaries, Figure 1). The system was extended to the production of bioethanol to allow a comparison with a reference fossil fuel, in terms of GHG and energy balances. Data of the biomass conversion process were extracted for the theoretical unit presented by the National Renewable Energy Laboratory (Aden et al. 2002), for which emissions and consumptions were evaluated by a later study (Edwards et al. 2013) (Figure 1).

This unit can produce 600 t ethanol d^{-1} [annual production of 219 000 t ethanol], from a biomass supply of 730 000 t DM yr^{-1} [i.e. with a process mass efficiency of 30% kg EtOH kg $biomass^{-1}$]. These estimations were based on a single biomass source of woody short rotation coppice (SRC). Because of the lack of adequate data in the literature, we assumed this conversion efficiency to be independent of the type of input biomass.

The Burgundy region (Northeastern France) was thus selected as representative of the agricultural situation of France, presenting in particular a supply area large enough to supply the bioethanol conversion unit. Besides, a simulation period of 20 years appeared to be a minimum to capture inter-annual climatic variations and take into account a whole life-cycle of perennial crops. For these reasons, the 2010-2030 time slice was selected for the climate data. All results presented in this paper are thus annual means from the whole 20-year life cycle. Several biomass sources were studied: crop residues (cereal straw) and dedicated crops, either annual (sorghum and triticale) or perennial (Miscanthus). A feedstock composed from a mix of biomass sources, based on wheat straw, Miscanthus and triticale, was also examined.

2.3. Life cycle assessment (LCA)

2.3.1. Methodological aspects

Table 1 sums up the methodological choices made for the LCA study. N_2O emissions estimates LUC effects are more detailed within the life cycle inventory section below. As infrastructures represent a t

Table 1. Summary of methodological choices for the LCA

Methodology aspect	**Choice**	**Reference**
Functional unit	Feedstock supply at the conversion unit entrance (730 kt DM yr^{-1}) and 1 MJ of producted and used biofuel for GHG and energy comparison	(European Parliament 2009a)
LCA software and database	Simapro 7.3.3 and Ecoinvent 2.2	(Frischknecht et al. 2007; PRé Consultants et al. 2010)
Allocation rules between products and byproducts	Energetic prorate applied in the NREL process calculations, from biomass to bioethanol No byproducts were considered in the biomass production	(European Parliament 2009a)
GHG emissions calculations: - Biogenic carbon - Emissions factors - N_2O emissions	- GWP (biogenic CO_2) = 0 and GWP (fossil CO_2) = 1 - IPCC 2007 GWP considered for 100 years - Direct N_2O emissions from CERES-EGC model outputs - Indirect N_2O emissions from CERES-EGC model outputs (NH_3, NOx and NO_3^-) combined with IPCC 2006 equations	(IPCC 2006; IPCC 2007)
Land use changes (LUC)	Both direct and indirect LUC were considered: - Direct LUC estimated from CERES-EGC model outputs and scenarios - Indirect LUC from literature	(European Parliament 2009a; ADEME 2012; De Cara et al. 2012; European Parliament 2012)
Infrastructures consideration	Infrastructures were neglected (roads, buildings)	(European Parliament 2009a; ADEME 2010)

2.3.2. Life cycle impact assessment (LCIA)

The IMPACT 2002+ (Jolliet et al. 2003) method was selected, since it allows to evaluate midpoint and end-point impacts and also since it is based on the IMPACT 2002 model (Pennington et al. 2005), the Ecoindicateur 99 method (Goedkoop and Spriensma 1999) and the CML method (Guinée et al. 2002). As midpoint impacts are estimated from substance equivalences, they present fewer uncertainties than end-point impacts, based on models and strong hypotheses. The results presented in this study are therefore derived mainly from mid-point impacts.

A particular effort was carried on GHG balance and climate change impact to evaluate the sustainability of biofuels. The time horizon in IMPACT 2002+ is set to 500 years to consider long term impacts, especially for CO_2 that contributes to climate change for such a period. However, a time horizon of 100 years for the substances impacting the greenhouse effect is usually considered into the other methods, even if it does not reflect the whole impacts caused by these substances. We chose a time horizon of 100 years in this study.

In order to consider the energy efficiency of produced biofuels, the non-renewable energy consumption has to be estimated. Finally, since these fuels are based on biomass production, impacts specifically linked with agricultural production and affecting the ecosystems were considered, such as terrestrial and aquatic acidification, ecotoxicity, aquatic eutrophication and land occupation.

GHG balance uncertainties were estimated from modelling outputs (yield, N_2O, NO_x, NH_3 and NO_3^-) as N_2O emissions have the highest weights in biofuel GHG balance (Cherubini and Strømman 2011), excluding uncertainties from biomass conversion to bioethanol. They were calculated for individual SU from standard error of the annual results on a 20-year period (2010-2030), and then aggregated to region scale weighted by area.

2.4. Life cycle inventory (LCI)

2.4.1. Cropping management

- Agricultural residues

A reference crop succession was determined in Burgundy from statistical data and experts' knowledge, as follows: winter barley – oil seed rape – winter wheat (Agreste 2008; Lesur 2012). The cropping management of reference crops was determined through regional studies (Agreste 2008) with a unique level of fertilization for the whole region. Straw exportation rates varied from 33% (one removal every three years) to 50% and were determined for each soil type and crop succession to maintain soil C stocks (FRCA Picardie et al. 2009), by assuming that the rates determined in Picardy were applicable in Burgundy. Wheat straw was favored due to its high yield, and sometimes, completed by barley straw. Livestock requirements, estimated from literature (FCBA and PNRB 2009), were first subtracted to the straw thus produced, before assessing the amounts of straw available for bioenergy.

- Dedicated annual and perennial crops

As sorghum and triticale are annual crops, they can easily be inserted in crop succession, and thus be grown on any arable area within the region. Barley was thus substituted by the annual energy crops within the succession. Sorghum and triticale crops were silage-harvested (with a biomass at 70 and 60% of moisture respectively) while both early (autumn) and late (spring) harvests were simulated for Miscanthus (RMT Biomasse 2013). An organic variant for the management of this crop, without chemical inputs, was also implemented ("Misc.-0input", Table 2). In order to minimize the inputs, crop management was adapted to estimate crop yields and the resulting nutrient export rates (Table 2) (Cadoux et al. 2012; Béjot 2013). Early harvests ("Misc.-early") lead to higher yields with higher moisture content (around 60%), whereas late harvests ("Misc.-late") increase nutrient recycling within the rhizomes, while decreasing fertilizer requirements (Table 2) and the moisture content of harvested biomass (15%). As no data was available on the removal phase of Miscanthus, experimental measurements were used to apply the LCA on GHG emissions and measurement uncertainties were added in the miscanthus GHG balance (Dufossé et al. 2014).

- Mix of biomass sources

To provide an alternative perspective, a feedstock supply mix composed of three biomass sources in equal proportions (243 kt DM yr^{-1}) was assessed. It comprised cereal straw, triticale (which came out as the best annual energy crop in this study) and Miscanthus. In order to approach real establishment of energy crops, hypotheses on area restriction were carried Miscanthus and triticale. No hypothesis on area restriction was carried for straw. Miscanthus was assumed to be planted exclusively on marginal lands, as set aside land, to avoid competition with food crops. Protected areas were excluded. A late harvest and adapted fertilization rates were applied to Miscanthus ("Mix-Misc.", Table 2). Triticale was assumed to be on the less productive arable lands to minimize competition with food crops ("Mix-triti.").

Table 2. Mean fertilization rates applied to the crops for simulations. Mean annual rates, weighted by arable area within the SU. Three management for Miscanthus were simulated: early harvest with fertilization ("Misc.-early"), a late harvest with fertilization ("Misc.-late") and a late harvest without fertilization ("Misc.-0input"). Two annual crops were also simulated ("Sorghum" and "Triticale"), as well as a mix of biomass composed of a third of Miscanthus with fertilization and late harvest on set aside lands ("Mix-Misc.") and a third of triticale on low productive land ("Mix-triti.").

	Misc.-0input	Misc.-late	Misc.-early	Sorghum	Triticale	Mix-Misc.	Mix-triti.
N fertilization (kg N ha^{-1})	0	54	120	144	145	49	110
P fertilization (kg P ha^{-1})	0	7	14	24	25	6	18
K fertilization (kg K ha^{-1})	0	83	160	200	140	78	106

2.4.2. Direct and indirect emissions

Emissions of nitrogen compounds (N_2O, NOx, NH_3 and NO_3^-) in soil, water or atmosphere were simulated from the CERES-EGC model (Table 3). Indirect N_2O emissions were estimated from IPCC emission factors applied on simulated emissions of NOx, NH_3 and NO_3^- (IPCC 2006). Heavy metals inputs related to fertilization, and their transfer to soils were estimated from fertilization rates and emission factors proposed by Nemecek and Kägi (2007). Because of the lack of reliable data on heavy metals inputs through pesticides and exports by biomass, these fluxes were ignored.

Table 3. Main outputs of the CERES-EGC simulations, as inputs of the LCA. Mean annual rates, weighted by arable area within the SU.

	Misc.-0input	Misc.-late	Misc.-early	Sorghum	Triticale	Mix-Misc.	Mix-triti.
Yield (t DM ha^{-1})	16.13	16.69	22.56	13.46	13.73	15.6	9.0
Direct N_2O (kg N ha^{-1})	0.27	0.43	0.55	1.57	0.97	0.45	0.17
NO_3^- (kg N ha^{-1})	12.55	11.46	15.18	45.90	40.42	13.15	78.70
NH_3 (kg N ha^{-1})	-0.14	0.12	3.15	3.44	0.99	-0.01	0.16
NOx (kg N ha^{-1})	0.59	0.58	0.81	0.76	0.64	0.54	0.61
Net soil C variation (t C ha^{-1})	0.54	0.57	0.65	-1.11	0.19	0.91	0.07

2.4.3. Transportation

Because the lack of information on transportation, especially for the Burgundy region, the following hypotheses for distances were applied: 25 km between the farm and the regional storage where agricultural inputs (seeds, fertilizers, pesticides, fungicides and herbicides) are stored, and 100 km between fields and the region where the biomass is stored for the conversion unit supply, as in the JRC/EUCAR/CONCAWE study for European biomass (Edwards et al. 2013). All vehicles were selected among the most efficient vehicles in the Ecoinvent database (complying with the EURO5 standard, Frischknecht et al. (2007)).

2.4.4. Land use changes

Direct and indirect LUC (dLUC and iLUC, respectively) were considered separately, in a second part of the study. Firstly, dLUC from land conversion were estimated from variations in soil C stocks caused by the integration of bioenergy crops within the crop succession. These soil C stock variations were estimated from modeling outputs. Then, variations in soil C stock from the reference crop succession were withdrawn to obtain net stock differences (Table 3). These differences were transformed into CO_2 emissions according to the IPCC equations (IPCC 2006). For cereal straw, the dLUC was neglected since the exportation rates applied for modeling allowed to maintain soil C stocks (FRCA Picardie et al. 2009). To estimate the dLUC effects of converting set aside to cropland, the soil C variations of the reference crop succession were replaced by those estimated by simulating a set aside land with CERES-EGC before been subtracted to the soil C variations of energy crop succession.

Indirect LUC effects were mostly related to the displacement of food crops, because of the implantation of bioenergy crops. They were estimated at global scale, based on a recent meta-analysis (De Cara et al. 2012). For annual crops (sorghum and triticale), the CO_2 emissions due to iLUC were assessed at 37 g CO_2 eq MJ^{-1} (Al-Riffai et al. 2010; De Cara et al. 2012), whereas they were assessed at 27 g CO_2 eq MJ^{-1} for Miscanthus. These values correspond to the top of the range of values for every type of biomass from the meta-analysis. In scenarios where crops were established on set aside lands, no CO_2 emissions from iLUC were considered.

2.4.5. Biomass conversion into bioethanol

Emissions for the conversion of lignocellulose to ethanol were taken from the 2G bioethanol conversion unit described in the JRC/EUCAR/CONCAWE study ('WW/WFET1' scenario), as 15.6 g CO_2 eq MJ^{-1} including also conditioning and bioethanol distribution (Edwards et al. 2013).

This 2G bioethanol conversion unit also consumes 1.97 MJ of energy to produce 1 MJ of bioethanol (1.97 MJ $MJ(EtOH)^{-1}$). This consumption was split into multiple sources: non-renewable energy sources (0.28 MJ $MJ(EtOH)^{-1}$), nuclear power (0.01 MJ $MJ(EtOH)^{-1}$), biomass itself and heat recycling within the process (Edwards et al. 2013). In this study, for an equivalent conversion process, the energy consumption related to feedstock supply (poplar SRC) was estimated at 0.11 MJ $MJ(EtOH)^{-1}$. As non-renewable energy consumptions were not detailed according to bioethanol production steps, we assumed that the energy used in the agricultural phase was only non-renewable energy. For the bioethanol conversion phase, the non-renewable energy consumption was thus assumed at 0.18 MJ $MJ(EtOH)^{-1}$.

3. Results and discussion

3.1. GHG balance of bioethanol production

3.1.1. Global GHG balance

Figure 2 shows the GHG balance of bioethanol production from different lignocellulosic biomass sources. Thanks to the integration of local pedoclimatic variations in modeling crop production, the uncertainties on biofuel LCA results decreased from 1 to 4 g CO_2 eq MJ^{-1} for biomass production, excluding uncertainties from biomass conversion to bioethanol. The uncertainties were thus reduced ten-fold compared to recent studies (Edwards et al. 2011), improving the accuracy of estimates of GHG savings for 2G biofuels.

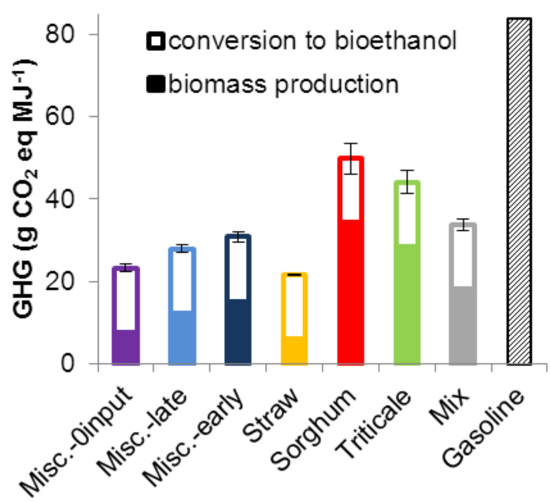

Figure 2. GHG balance of bioethanol produced from crop residues (straw), annual crops (sorghum and triticale), perennial crops (Miscanthus) and the mix of three biomass sources (straw, triticale and Miscanthus). GHG emissions of gasoline is also presented as the fossil reference. Error bars show the standard deviation of errors due to spatial and temporal variability within the region.

In terms of feedstock, Miscanthus (whatever its management) or cereal straw achieved larger GHG savings than annual crops, both reaching the 60% GHG threshold set by the RED Directive for 2017 (European Parliament 2009a).

The production of Miscanthus without fertilizer inputs (Misc.-0input) emitted 7.7 g CO_2 eq MJ^{-1}, which is similar to the 7.2 g CO_2 eq MJ^{-1} estimated as GHG emissions for poplar SRC cropping (with 25 kg N ha^{-1}) within JRC/EUCAR/CONCAWE study (Edwards et al. 2013). Both other Miscanthus management (Misc.-late and Misc.-early) received fertilization and emitted twice GHG than the one without inputs (12.4 and 15.2 g CO_2 eq MJ^{-1}). However, the required amount of area converted to Miscanthus (2.5% of UAL) seems unrealistic to supply the conversion unit with Miscanthus as a unique source of 2G bioethanol in the near future.

Since straw was considered as a crop residue, all impacts from wheat growing were attributed to grain production. Therefore, only impacts for biomass collection were attributed to straw, which minimized its GHG balance. In the JRC/EUCAR/CONCAWE study (‘STET1’ scenario), GHG emissions from straw were estimated to 3.8 g CO_2 eq MJ^{-1}, which is in the same order of magnitude as our findings (6.0 g CO_2 eq. MJ^{-1}). Since the study did not consider livestock in the estimation of available straw, yield per unit area should have been higher (in our study: 0.8 t DM ha^{-1} yr^{-1}) and therefore emissions due to collection, lower. Besides, due to these high livestock requirements (748 kt DM yr^{-1}), the amount of available straw could only supply 50% of the biomass required by the conversion unit (372 kt DM yr^{-1} produced for 730 kt DM yr^{-1} required).

Annual crops showed mediocre results when combining their high fertilizer requirements, high GHG emissions and moderate yields (around 12.5 t DM ha^{-1} yr^{-1}) in Burgundy. However, their introduction into crop successions could suffice to fulfill the biomass requirements of the conversion unit. A mix of biomass sources (residues, annual and perennial) is likely to be an interesting compromise to supply the conversion unit by ensuring feedstock supply while maximizing GHG savings (60% of GHG reduction for fossil reference, Figure 3).

Field N_2O emissions were the main contributor to GHG emissions for all biomass sources excluding Misc-0input, followed by emissions due to biomass transportation and fertilizer production (data not shown). Therefore, changes in land use have to be carefully thought to optimize biomass performances, by selecting fields which produce high yields and minimize N_2O emissions while located close to the conversion unit. Selecting annual crop variety with low input requirements is also a worthy option for improving biomass GHG balance, as also recommended by Smith and Searchinger (2012).

3.1.2. Effects of land-use changes (LUC) on GHG balance

The results presented above did not consider the effect of LUC on the GHG balance of feedstocks and bioethanol. Direct LUC effects were positive for Miscanthus (Figure 3b), as Miscanthus stored large amounts of C in soils. GHG savings from Miscanthus-based ethanol were between 63 and 72% without LUC effects and between 79 and 90% with them. However, due to significant and negative dLUC effects, sorghum GHG savings became negative (-4%), which means that, in Burgundy, producing and using bioethanol from sorghum results in higher GHG emissions compared to the reference fossil fuel.

When considering dLUC and iLUC, only straw biomass ensured biofuel GHG savings larger than 60% (Figure 3c). Miscanthus managed without inputs and the mix of biomass presented interesting results (58 and 57% of GHG savings respectively). Misc-0input had an overall acceptable GHG balance thanks to low N_2O emissions and the absence of fertilizer inputs. The mix of biomass sources compensated the poor GHG performances of triticale (11% of GHG savings) by the excellent ones of straw (74% of savings) and the advantageous ones of Miscanthus: no inputs (minimizing GHG emissions), high soil C storage (positive dLUC effects) and implantation on set aside lands (no iLUC effects).

The iLUC values used in this study came from the literature. They were generic and taken in their upper range. Due to the weight of the iLUC effects, further studies would be necessary to yield conservative estimates of GHG savings from 2G biofuels. Marginal lands showed reliable potentials for bioenergy cropping since the biomass produced would not compete with food production, and generate little iLUC effect.

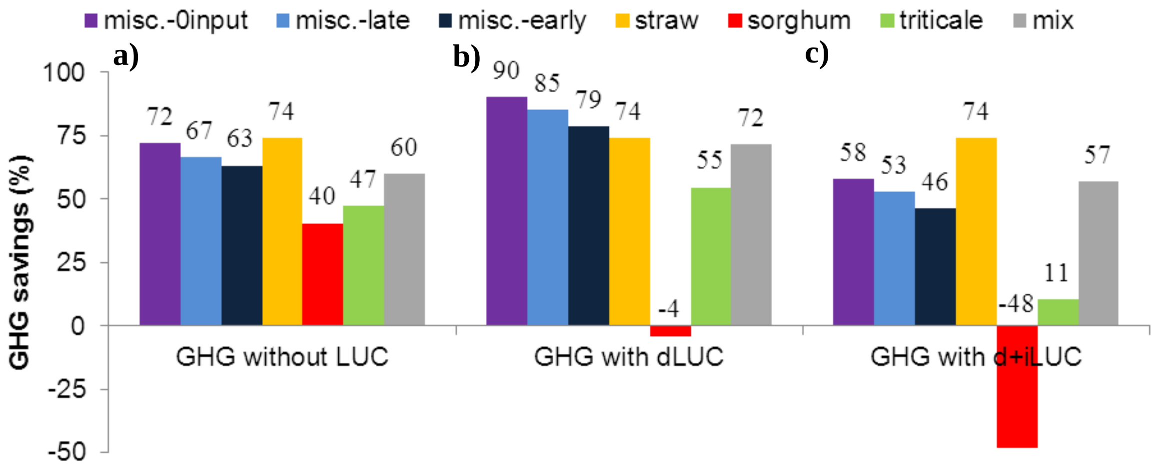

Figure 3. GHG balance of biofuels produced from different biomass sources, without considering LUC effects (a), with the integration of direct (dLUC, b) and indirect LUC (d+iLUC, c) effects in Burgundy.

3.2. Energy balance

Figure 4 showed the non-renewable energy consumptions for bioethanol production from different lignocellulosic biomass sources. Compared to the fossil reference, energy savings ranged from 65% for sorghum to 78% for Miscanthus without chemical inputs. These savings were highly dependent of the amount of cropping operations and chemical inputs. Biomass yields also played a role for these estimates as straw required few field operations but also produced low mean yields per hectare. Even if the conversion process was assumed to be similar for all studied biomass sources, the energy efficiency of 2G bioethanol was high in all cases and likely to increase as industrial processes are improved.

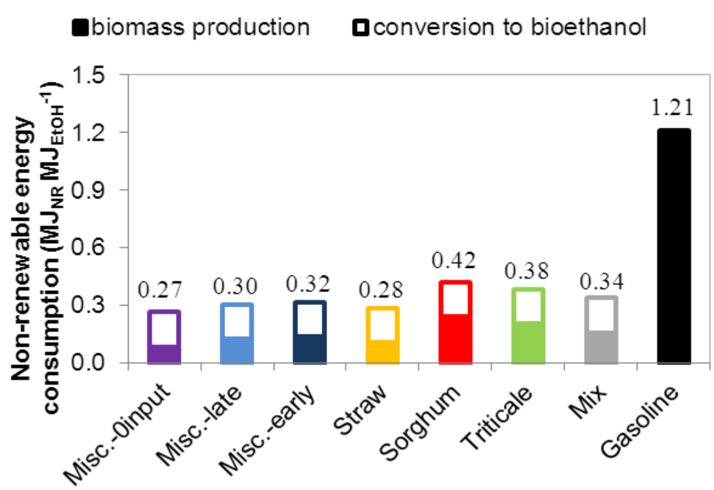

Figure 4. Non-renewable energy consumptions of 2G bioethanol produced from different biomass sources in Burgundy and comparison with fossil reference.

3.3. Other environmental impacts

Since few details were available on the conversion process for 2G bioethanol, the assessment of other environmental impacts focused exclusively on the biomass production to compare the various feedstocks. Crop receiving higher chemical inputs (herbicides, fungicides, fertilizers and associated heavy metal inputs) showed larger impacts on the ecosystem (scores of 63 to 100% of maximum impacts for eutrophication, aquatic and terrestrial acidification and ecotoxicity). Land occupation was directly related to crop yields. Sorghum and triticale were thus more harmful for the ecosystem (Figure 5). Compared to its other management, Miscanthus with early harvest turned out to affect notably the ecosystem, even if land occupation impact was lessened (Figure 5) thanks to high yields (averaging 23 t DM ha^{-1} yr^{-1}, Table 3).

Within the unique score assessed with the IMPACT2002+ method, damages on ecosystem had the bigger share compared to all endpoint impacts (data not shown). Since these impacts are strongly related to fertilizer input rates and in order to reduce the environmental impacts of bioethanol, it is crucial to select biomass sources that require the lowest chemical inputs, such as Miscanthus or agricultural residues. It is also possible to mitigate impacts if choosing a feedstock supply composed from a mix of biomass sources with straw, Miscanthus and triticale in equal shares. The considerable impacts of the last one (scores between 63 to 100% of maximum impacts) were mitigated by the limited impacts of Miscanthus and mainly straw to moderate impacts (scores of 35 to 79%).

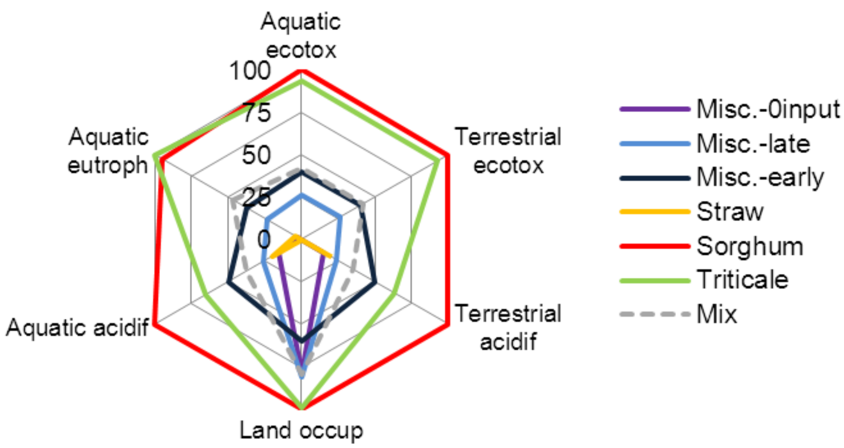

Figure 5. Results of midpoint impact assessment, of the damages on ecosystem endpoint impact, for different biomass production in Burgundy. Impacts are presented as a proportion of the highest score in the midpoint impact category.

4. Conclusion

Using a crop model to integrate the local pedoclimatic variability within a supply area made it possible to provide more accurately GHG balances for a conversion unit of 2G bioethanol from different sources of biomass. The estimated GHG savings, obtained with the LCA thus produced, could help for biomass selection and ensure the potential GHG reduction of 2G bioethanol from agricultural residues and Miscanthus. These bioethanol chains could fulfill the sustainability criteria set by the European Parliament. Sorghum and triticale, used as unique feedstock source, showed the lowest GHG savings. Nonetheless, if they are integrated in a feedstock mix with straw and Miscanthus, they can contribute to ensure the biomass requirements and limit biomass storage at the conversion unit, while their mediocre environmental performances could be mitigated by the other sources of biomass.

As shown by the previous results, the integration of LUC effects (direct or indirect) could offset the conclusions on GHG savings. When dLUC and iLUC were included in the GHG balance, only straw could ensure GHG savings higher than 60%. Since amounts of cereal straws are limited in the studied area, other biomass sources have to be considered. It is thus essential to accurately evaluate emissions, especially due to iLUC, and guide the establishment of energy crops towards zones that minimize emissions, such as set aside or marginal lands with low productivity in food cropping. However, these low productive lands may also show mediocre environmental and yield performances for energy crops, especially for cereals such as triticale.

Bioethanol from all energy crops presented in this study showed non-renewable energy consumptions reductions higher than 65% compared to fossil fuels. Best performances were obtained by straw and Miscanthus. The main environmental impacts of these crops on ecosystems were directly linked to the use of chemical inputs (fertilizers or herbicides). Biomass sources requiring the lowest chemical inputs rates should be favored in order to limit environmental impacts.

The study of innovative energy crops, such as Miscanthus, switchgrass or SRC, is likely to be critical to the optimization of biomass feedstock. Before widening the portfolio of biomass feedstocks for 2G bioethanol, we suggest using a mix of biomass sources for feedstock supply, made up of highly performing crops (Miscanthus), residues (straw) and commonly produced agricultural crops (triticale). Also, a particular interest should be paid to crop establishment patterns, and to the location of the biofuel conversion unit. Maps of potential yields, N_2O emissions and soil C sequestration rates, such as generated here with the ecosystem model, would be very useful and practical tools to guide public and private stakeholders in this direction.

5. Acknowledgments

This study was funded by BPIFRANCE as part of the FUTUROL project. The authors are grateful to Fabien Ferchaud, Stéphane Cadoux, Hubert Boizard and Claire Lesur for their data on crop successions and management as well as Nathalie Gagnaire for her support.

ABSTRACT

Agri-footprint is a new life cycle inventory database that focuses on the agriculture and food sector. The goal of this database is to support life cycle assessment practitioners to perform high quality assessments. The database contains a methodologically consistent dataset for a large number of crops, crop products, animal systems and animal products. These inventories can be used as secondary data in LCAs. Non-LCA models were used to calculate a wide array of elementary flows (such as land use change, water use, fertilizer application rates), to support assessment on a multitude of environmental issues. To safeguard relevance and data quality, the database will be updated regularly. As the public interest in food LCAs is expected to increase in the near future, Agri-footprint will be a helpful resource for practitioners in this field.

Keywords: Life cycle inventories, food, agriculture, food processing, crop cultivation

1. Introduction

The goal of the LCI database Agri-footprint is to facilitate life cycle assessments (LCAs) in the domain of food and agriculture by making life cycle inventory (LCI) data available in a single, internally consistent database. LCA studies of food have become more frequent in the last few years, although studies of food and agriculture have been undertaken almost since the emergence of the LCA method. The first agricultural LCAs were performed in the early 1990s. Pioneering food LCA case studies include LCAs about tomatoes, by Gysi and Reist (1990), ice cream, by Bolliger and Zumbrunn (1991) and Margarines, by Unilever (Vis, Krozer, van Duyse, & Koudijs, 1992). The proportion of published agriculture-related LCAs in the international Journal of LCA increased considerably at the end of the 2000s and has remained around 25% since then (Figure 1). Some reasons for this increased share are:

- Public interest in the first edition of the FAO report ‘Livestock’s Long Shadow’ (Steinfeld et al., 2006) which put the environmental impact of agriculture and especially animal production on the agenda.
- Pressure from retailers to provide carbon footprint information on food products since around 2007.
- The introduction of European biofuel legislation in 2009 (European Commission, 2009) and its related policy issues on fuel, feed and food competition.
- Specific agricultural related impact categories and related methodological solutions came up, such as water resource depletion and land use change.

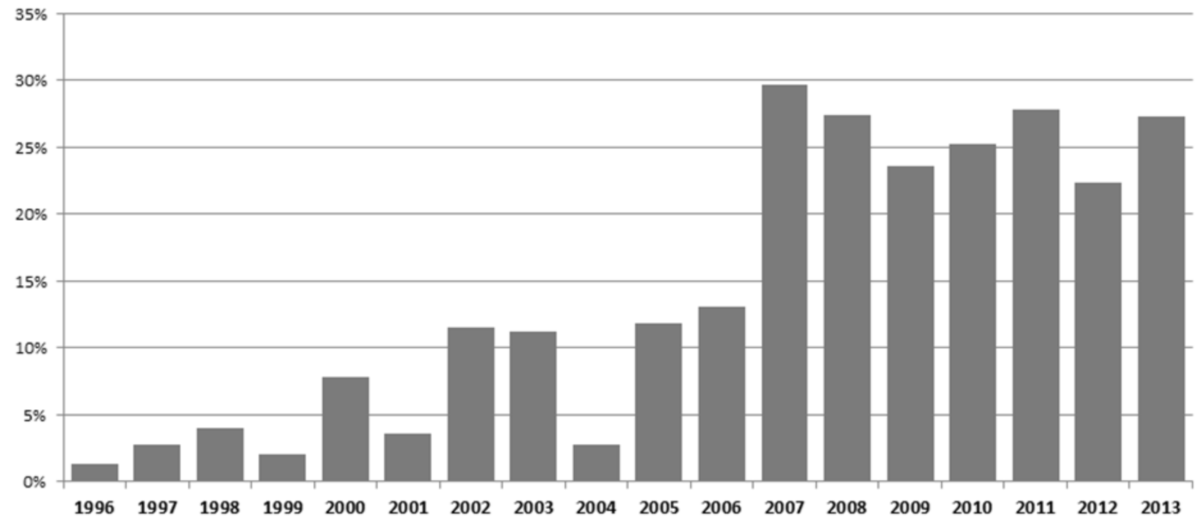

Figure 1. Share of agricultural related LCAs in the International Journal of LCA. Based on our survey of published articles.

In coming years, many food related LCAs will be performed due to the special attention from the European Commission for food, feed and beverages in the Product Environmental Footprint (PEF) program. Also the European research and innovation program Horizon 2020 focuses on more sustainable food production systems which have to include a sustainability assessment in line with the ILCD handbooks.

Therefore there will also be more and more demand for reliable and consistent secondary data in this field. The aim of Agri-footprint is to fulfill this demand by bringing data and methodology together and make it easily available for the LCA community. By having these generic LCIs readily available, future LCAs can be conducted more efficiently and also more reliable.

Although there are already a number of extensive LCA databases available (such as Ecoinvent, (2013) and ELCD (JRC-IES, 2012)), agricultural (processing) and food production LCIs only represent a small fraction of the data covered. Relevant information from a large number of food LCIs and food statistics (e.g. from FAO) are not yet implemented in LCA databases.

In addition, agricultural and food production companies find it often difficult to find a practical way to share their environmental information with the LCA community. Agri-footprint aims to combine information from these disparate sources (scientific literature, statistics and company specific data), into a single internally consistent LCI database. Therefore, Agri-footprint will also serve as a platform for companies to communicate their specific LCI data to a relevant audience. Already, some company specific life cycle inventories are included in Agri-footprint (currently Nutramon fertilizer from OCI and sugar products from Suiker Unie). By making the better performance of specific companies visible, LCA users can more easily identify improvement options in a lifecycle assessment.

The release date of the first version of the database is spring 2014. The database is intended to be used in the public domain and is available to LCA and sustainability experts who have a SimaPro license.

Agri-footprint is intended to be used as a secondary data source or background data for another LCI or LCA (comparative/ non-comparative). More specifically, potential applications of Agri-footprint may be:

- the identification of key environmental performance indicators of a product group
- hotspot analysis of a specific agricultural product.
- benchmarking of specific products against a product group average.
- to provide policy information by basket-of-product type studies or identifying product groups with the largest environmental impact in a certain context.

2. Methods

Agri-footprint includes linked unit process inventories of crop cultivation, crop processing, animal production systems and processing of animal products for multi-impact life cycle assessments. Agri-footprint also contains inventory data on transport, fertilizers production and auxiliary materials. Agri-footprint uses some background data that was sourced from ELCD (JRC-IES, 2012) and USLCI (National Renewable Energy Laboratory, 2012) datasets. Detailed reports are available for the methods and guiding principles (Blonk Agri-footprint BV, 2014a) and the sources and treatment of data (Blonk Agri-footprint BV, 2014b).

2.1. Guiding principles

During the development of Agri-footprint, the first step was to create data that was of consistent quality for all crops and regions covered. For example, all fertilizer application rates, fertilizer types, water use are based on the same methodologies for all crops. To create this consistent baseline dataset, data were derived from documented expert data or data from statistics.

Agri-footprint contains attributional LCIs of crop production, crop processing, animals systems, transport and other background processes (see Figure 2 as an example of types of processes included in database). Generally average mixes are considered that are representative for the specific product and location.

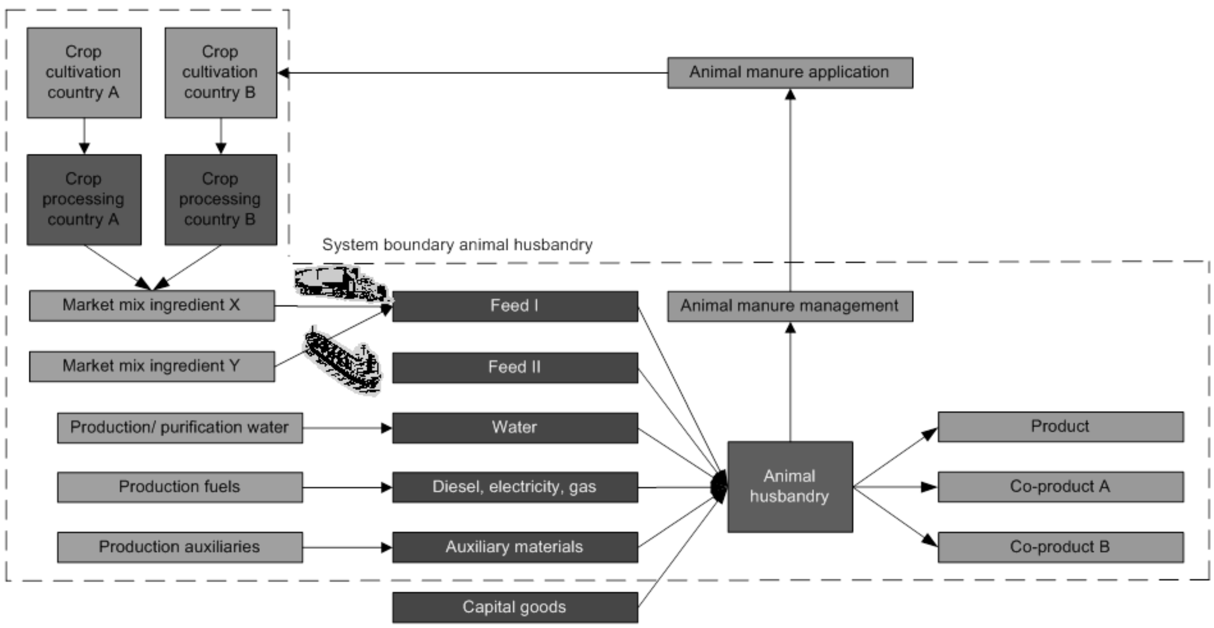

Figure 2. System boundaries of an Animal husbandry LCI in Agri-footprint.

The main baseline data source is the public domain (scientific literature, statistics from (FAOstat, Eurostat, IFA, etc.), using rolling 5 year averages. Data from the public domain are assessed based on representativeness (time-related coverage, technical coverage and geographical coverage), completeness, consistency and reproducibility. When data from public or confidential research by Blonk Consultants are more representative, complete and consistent, these data are used. Where possible, the data have been reviewed by industry experts and, where fit, an uncertainty range and a distribution type has been attributed.

The data in Agri-footprint are derived from different sources. The LCIs for animal husbandry, transport, auxiliary materials, fertilizers etc. have been developed based on previous reports/studies by Blonk Consultants.

Fertilizers production was modeled based on the latest available literature and a specific fertilizer product was based on primary data from a large Dutch fertilizer producer (Calcium Ammonium Nitrate produced by OCI Nitrogen in the Netherlands). Auxiliary materials were based on the ELCD 3 database or literature sources. For some (deep) background processes, estimates had to be made (e.g. the production of asbestos which is used in sodium hydroxide production which is used in vegetable oil refining), and these processes are of lower quality and representativeness.

Processing inventories were drawn from the feedprint study (Vellinga et al., 2013). These inventories are generic for all provided countries and regions. These processes are either largely similar between countries or the data available was not specific enough to create country/ region specific processes. These generic processes are regionalized by adapting the inputs for energy consumption to the country or region where the processing takes place. This means that the processing (in terms of mass balances, and types of inputs) is generally the same for all regions, except the input processes for energy consumption are specific per country. This means that the representativeness may have decreased for these processes. Transport distances and modes from and to the processing plant are also country specific. The geographical representativeness will be improved in future upgrades of Agri-footprint.

The aim is for the LCI data to be as recent as possible, which means that when better quality data or statistics on the processes/ systems are available these are incorporated in Agri-footprint,. To ensure the best time related representativeness, data will be updated regularly.

No specific choice of allocation approach is made, rather multiple options are presented to users. Two physical keys (dry matter and energy) and one economic allocation key are presented in Agri-footprint:

- Physical allocation: mass allocation
  For the crops and the processing of the crops, mass allocation is based on the mass of the dry matter of the products. For the animal products, mass allocation is based on the mass as traded.
- Physical allocation: gross energy allocation
  Water has a gross energy of 0 MJ/kg. The gross energy for protein, fat and carbohydrates are respectively: 23.6, 39.3 and 17.4 MJ/kg which are based on USDA (1973). Nutritional properties for gross energy calculations of products are based on a nutritional feed material list (Centraal veevoederbureau, 2010).
- Economic allocation
  For the crops and the processing of the crops the economic value of the products is based on (Vellinga et al., 2013).This allows users to choose an allocation that is most relevant for the context of their study. To ensure consistency in methodology and LCI modeling approach, Agri-footprint is reviewed by an independent external party.

System expansion is not applied in Agri-footprint because of the practical implications for the structure of the database. System expansion can be applied by the user by modifying processes. The allocation percentages of the unit processes can be set to 100% and 0% and the system can be expanded. In some specific situations avoidance of production is applied when the avoided product can be unambiguously determined such as electricity produced from a CHP delivered to a national grid.

2.2. Practical implementation – collection of data

The starting point of the inventory data development is information gathered in previous studies, particularly information gathered in the Feedprint project (Vellinga et al., 2013). The crop cultivation and processing inventories in that project contained only data to support carbon footprinting calculations. These inventories were further extended to include additional environmental flows to cover more impact categories. The additional flows were determined using a number of non-LCA models and data sources. Other environmental flows were added during the course of the development of Agri-footprint, to support assessment on other environmental impact categories. The LCIs have thus been extended to allow impact assessment on all impact categories of ReCiPe (Goedkoop et al., 2009) and ILCD (JRC-IES, 2011) impact assessment methods. Other impact assessment methods may also be supported, but naming of substances has aligned specifically to these two methods.

2.2.1. Crop cultivation

To expand the data from covering just greenhouse gas (GHG) related emissions, to coverage of a broader environmental scope, a number of models were developed, targeting specific environmental themes, relevant for all crop cultivation systems. These models focused on the themes land use change, fertilizer application, water use and heavy metal emissions. Other environmental themes were investigated using conventional literature or data survey, e.g. pesticide application rates (from a large volume of literature sources). How these models were used to create crop inventories is summarized below.

Fossil CO_2 emissions resulting from direct land use change are estimated using the "Direct Land Use Change Assessment Tool (Version 2014.1 - 21 January 2014)" that was developed alongside the PAS 2050-1 (BSI, 2012) and has been reviewed by the World Resource Institute (WRI) and WBCSD, and has, as a result, earned the ‘built on GHG Protocol’ mark. This tool provides a predefined way of calculating greenhouse gas (GHG) emissions from land use change based on FAO statistics and IPCC calculation rules, following the PAS 2050-1 methodology. GHG emissions arise when land is transformed from one use to another. This tool can be used to calculate these emissions for a specific country-crop combination and attribute them to the cultivated crops.

The tool provides means of estimating the GHG emissions from land use change based on an average land use change in the specified country. For Agri-footprint, the option “calculation of an estimate of the GHG emissions from land use change for a crop grown in a given country if previous land use is not known” was used. This estimate is based on a number of reference scenarios for previous land use, combined with data from relative crop land expansions based on FAOStat data (FAO, 2012). These FAO statistics then provide an estimate of the share of the current cropland (for a given crop) which is the result of land use change from forest and/or grassland to cropland. This share is calculated based on an amortization period of 20 years, as described in the PAS 2050-1. This results in three scenarios of land transformation (m2/ha*year): forest to cropland, grassland to cropland, and transformation between perennial and annual cropland, depending on the crop under study. The resulting GHG emissions are then the weighted average of the carbon stock changes for each of these scenarios. Further details and documentation can be found in the calculation tool itself (Blonk Consultants, 2014). The calculated CO_2 emissions from land use change (LUC) have been added in the database, the substance flow name is “Carbon dioxide, land transformation”. Note that land use change is also reported in m^2. By including the land use change in m^2, the impact categories ‘Land use: Soil Organic Matter (SOM)’ in the ILCD method and ‘natural land transformation’ in the ReCiPe method are supported.

Water use is based on spatially explicit water use methodology developed by Mekonnen & Hoekstra (2010). Water is used for irrigation of crops as well as during processing. The amount of (artificial) irrigation water is based on the ‘blue water footprint’ assessment (Mekonnen & Hoekstra, 2010b). The estimation of irrigation water is based on the CROPWAT approach (Allen, Pereira, Raes, Smith, & Ab, 1998). The blue water footprint refers to the volume of surface and groundwater consumed as a result of the production of a good. The model takes into account grid-based dynamic water balances, daily soil water balances, crop water requirements, actual water use and actual yields. The water footprint of crops have been published per country in m^3/tonne of product (Mekonnen & Hoekstra, 2010b). Combined with FAO yields (2007-2011) the blue water footprint is calculated in m^3/ha.

For the fertilizer application rates (in terms of kg NPK) the values of the Feedprint study are used. The majority of these fertilizer application rates are derived from data supplied by Pallière (2011) for crops in Europe, and data from Fertistat (FAO, 2011) for crops outside of Europe. Data from Pallière was preferred, because it was more recent. To match these total N, P and K application rates, to specific fertilizer types (e.g. Urea, NPK compounds, super triple phosphate etc.), a model was developed using data on country specific fertilizer consumption rates from IFA (IFA, 2012). In the analysis, it is assumed that the relative consumption rates of fertilizers are the same for all crops within a certain country. Some fertilizers supply multiple nutrient types (for example ammonium phosphate application supplies both N and P to agricultural soil). In IFA statistics, the share of ammonium phosphate is given as part of total N and also as part of total P supplied in a region. To avoid double counting, this dual function has to be taken into account.

Therefore the following calculation approach was taken: the fertilizers supplying K were considered in isolation. The relative shares of the K supplying fertilizers was calculated for a crop (e.g. if a crop A in Belgium requires 10 kg K/ha, 35% is supplied from NPK, 52% from Potassium Chloride and 11% from Potassium Sulfate). NPK however, also supplies a certain amount of N and P. The amounts of N and P supplied are subtracted from the total N and P requirements. Next, the share of P supplying fertilizers was calculated (however, the share of NPK in the P mix is not included as it is already accounted for during the calculation of K requirements). As in the P mix there are also fertilizers that contribute to the N supplied, this is also subtracted from the N requirements. For the remaining N required, the purely N supplying fertilizers are used (as NPK and ammonium phosphate are already considered during P and K calculations).

2.2.2. Processing of crops and animal products

Also, the starting point for crop processing was data gathered in the Feedprint project. Here the inventories have been extended to include non-greenhouse gas emissions, to cover more environmental impact categories. For example, additional data was gathered for water use in processing.

Unfortunately, the quality and availability of processing data is far from perfect. In some cases, the data are of quite good quality, meaning that they are representative for the region in scope, recently collected and accurate. In many other cases the data are of lower quality, and improvements are necessary.

Luckily some recent efforts by industry organizations are reducing this data quality issue. For example FEDIOL has recently published data on oil crushing and refining (Schneider & Finkbeiner, 2013). In addition, the Dutch meat processing industry has recently published data that was used to create inventories for slaughterhouse processes (for chicken beef and pigs) (COV & VNV, 2012). Also, some high quality company specific primary data on sugar processing from Suiker Unie has been collected and implemented in the database. As this producer of sugar and sugar products is the only major sugar producer in the Netherlands, the data is representative for Dutch sugar products. All this recent high quality data is included in Agri-footprint. Still collection of high quality processing data is an ongoing effort, and will be a main topic in future updates.

2.3. Data quality and review

Agri-footprint is externally reviewed by the Centre for Design and Society, RMIT University, Melbourne, Australia. This review is not a full ISO 14044 review. Rather, the external reviewers check the consistency and transparency of the methodology applied and completeness and transparency of data documentation.

PRé Consultants, the developers of SimaPro, did a thorough review to check technical database aspects, but also the transparency of the data (for example documentation and annotation of the Agri-footprint data within the software environment, and alignment of naming and structure to other databases already present in SimaPro).

3. Results

The first release of the database covers ~30 crops, ~100 (intermediate) products from processing, ~80 feed compounds, ~35 food products, 4 animal production systems and ~85 background processes (transport, auxiliary inputs for processing, fertilizers), with different versions for a number of countries/regions in the world and three pre-defined allocation systems. The total number of products in the database is ~3500. A full list of processes included in the database can be found on the Agri-footprint website (www.agri-footprint.com).

Also, two company specific LCIs are part of database, one for production of Nutramon (CAN) fertilizer from OCI, and sugar and sugar co-products produced by SuikerUnie.

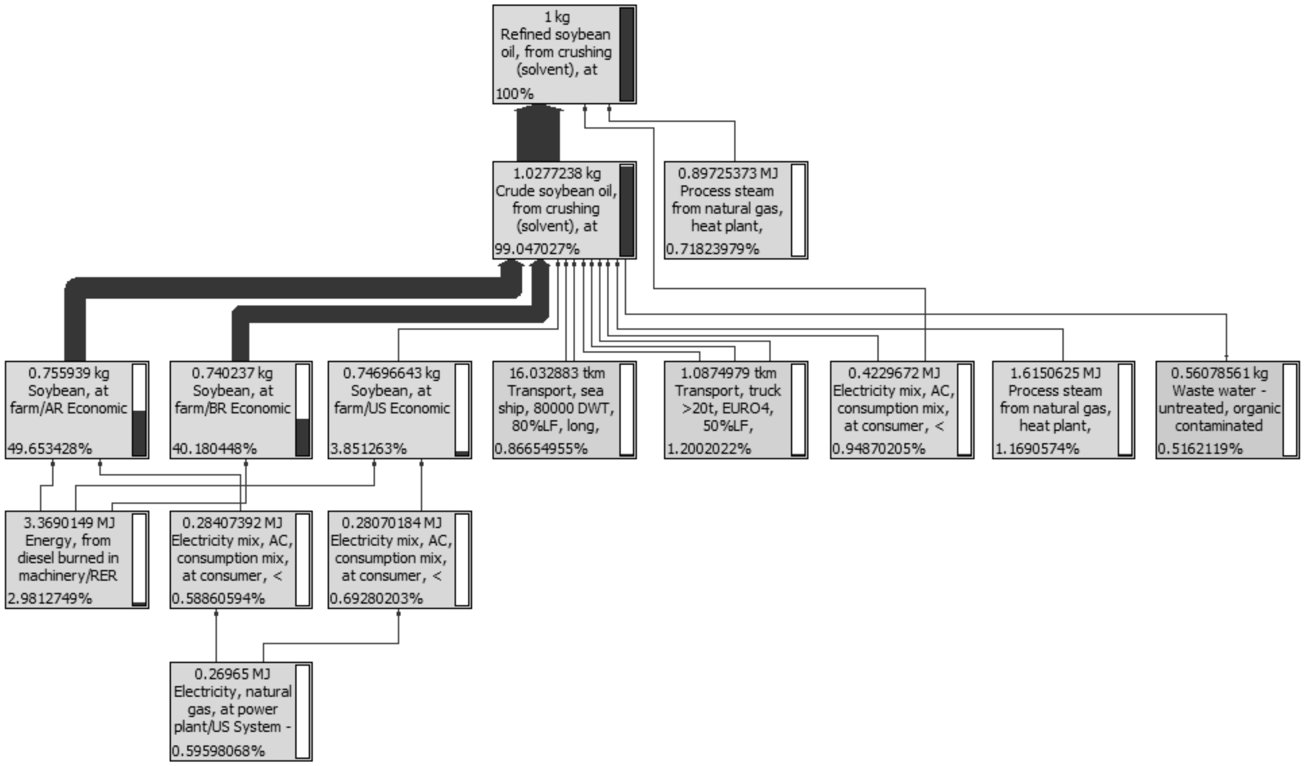

Figure 3. Example of a network diagram (in this case for refined soybean oil in the Netherlands) in Agri-footprint.

4. Discussion and conclusions

There are also a number of limitations that should be taken into account when using Agri-footprint. Internationally accepted LCA methodology for some agriculture specific environmental issues are still under development. For example, the methodology for assessment of loss of biodiversity due to land use or the estimation of direct and indirect land use change will probably evolve further. Due to limited methodology and data availability, elementary flows related to the environmental impact due to soil erosion and soil degradation are not included in Agri-footprint. The reliance on statistical data for crop yields, (artificial and organic) fertilizer application rates may not always appropriately reflect variability within regions and countries. Data availability of crop processing is also an issue that requires attention, as the use of older than desirable data sources and use of data from regions other than the region of interest is currently unavoidable.

To overcome these limitations, the database will be expanded and updated continuously. The aim is to yearly update data on crop yields, fertilizer use etc. Also the expansion to other crops and countries is important so that global production of some commodities can be better represented. Most importantly, the developers will continue to work with industry organizations to gather or gain access to new primary data for processing. Furthermore, additional non-LCA modeling approaches will be used to improve data quality on logistics and pesticide fates.

The database will be useful for LCA practitioners in the field of agricultural LCAs by providing relevant, transparent and consistent background data. As it provides an additional resource for LCA practitioners to use next to other currently available datasets, it will save time and facilitate the development of agriculture related LCAs. Agri-footprint will function as a platform for companies who wish to share their data. To ensure that the database will remain relevant in the future, there will be ongoing efforts to improve, expand and update the data.

ABSTRACT

Objective was to assess the environmental burden of food consumption and food losses in Germany with the aim to define measures to reduce environmentally relevant food losses. The assessment is based on a Screening Life Cycle Assessment and carried out from a consumer's perspective. Data have been taken from the German income and consumption sample and German production and trade statistics. In order to model the food baskets and its product chains some simplifications had to be done. The analysis shows that German food consumption emits 2.7 tons of greenhouse gases per person each year. 14 cubic meters of blue water are used for agricultural food production per person, and 2673 square meters of agricultural land are occupied each year per German for food consumption. In particular animal products cause high environmental burdens. Losses along the product chains have a share between 13 and 20 percent in environmental impacts.

Keywords: Screening Life Cycle Assessment, food consumption and losses, environmental impacts of German food basket, national origin of water and land use

1. Introduction

In recent years food waste is more and more of public interest. 2011 the documentary "Taste the Waste" came to German cinemas and its alarming message ("half of the food is spoiled") caused disgust about our way to deal with food in the public. In 2011 also the Food and Agricultural Organization (FAO) published a study on global food waste with the result that about one third of the food produced at global level is spoiled. This corresponds to 1.3 billion tons per year (Gustavsson et al. 2011). At the same time according estimations of the FAO 925 million people were starving.[1] Also in Germany a study on food waste was carried out on behalf of the Federal German Agricultural Ministry (BMELV). This study came to the result, that each year each German wastes 82kg food (Kranert et al. 2012).

In this context this study was carried out as part of a project aiming to reduce food waste in Germany on behalf of the Federal German Environmental Agency (Jepsen&Eberle 2014).

Aim of this part presented here was to assess the environmental burden of food consumption and food losses in Germany along the whole life cycle.

2. Methods

The assessment of German environmental impacts due to food consumption and food losses is based on a screening Life Cycle Assessment. Reference year is 2010.

The calculation is carried out from a consumer's perspective, meaning that the study starts from the consumer's food consumption (in-house and out-of-home) and analyzes every step of the various product chains. Drinks and candies haven't been considered. At the starting point the analysis differentiates between private consumers' food basket (in-house consumption) and the food basket of large scale consumers such as restaurants, and canteens (out-of-home consumption). Starting from in-house and out-of-home consumption the product chains are analyzed downstream as far as agricultural production. This includes storing and cooking in households respectively in canteens and restaurants, the shopping trip respectively food transportation to large scale consumers, retail and wholesale, food processing, agricultural production and all kind of transports along the products' life cycles. In order to provide information on the relevance and concrete impacts of food waste, environmental burdens are allocated to consumed and spoiled food on every step of the product chain. But for meat where food

[1] http://www.fao.org/mdg/goalone/en/; Status: 8. August 2012

losses due to slaughter by-products have been considered separately, all other food losses have been considered in the study without distinguishing between avoidable and unavoidable losses. [2]

2.1. System boundaries and modelling

The model was divided in four life cycle phases: agricultural production, food processing, retailing, and consumption.

System boundaries were set as follows:

For agricultural production energy, land, pesticide, fertilizers and water use for irrigation for production of plant products for direct human consumption but also for livestock feed have been taken into account. Land use and water consumption have only been taken into account in this life cycle stage. For livestock's breeding feed consumption, transports of feed and energy use were considered as well as direct emissions. Furthermore the necessary transports to food processing have been included within this life cycle phase.

For food processing energy use and direct emissions for all kinds of food processing like slaughtering, milling, baking, and processing of dairy products have been considered as have the transports to retail.

For retailing (wholesalers and/or retailers) energy use and freezing agent losses have been considered. Regarding in-house consumption also transports between wholesalers and retailers have been taken into account. Regarding out-of-home consumption transports from the wholesaler to the place of out-of-home consumption have been included.

For in-house consumption energy use for the shopping trip, the storing of purchased food, and cooking have been respected. For out-of-home consumption energy use for preparing of meals, food storing and air conditioning of restaurants have been taken into account; trips to the restaurant have been excluded. Customer transport to the place of out-of-home consumption has not been considered.

However, the production of seeds, water use outside agricultural production, all kind of packaging, and waste treatment haven't been considered within this study.

Modelling and the calculation itself were done with the software Umberto NXT LCA.

2.2. Data

Data for the composition of the two food baskets analyzed have been taken from statistical data such as the German income and consumption sample (Statistisches Bundesamt 2011) and German production and trade statistics (BMELV 2013). Also data from previous projects assessing the environmental impacts of German food consumption (Eberle et al. 2006, Wiegmann et al. 2005) have been used for this purpose.

Data for food losses have been used from two German studies carried out recently (Kranert et al. 2012, Peter et al. 2013) and from a study on behalf of the Food and Agricultural Organization (FAO) (Gustavsson et al. 2011).

Figure 1 and 2 show the material flows used as basis for the calculation of the environmental impacts of German food consumption.

Furthermore to calculate impacts it had to be estimated which share in the products was consumed cooked and which without cooking.

Most generic environmental data needed like electricity grids, transports, pesticides, and fertilizers have been taken from ecoinvent 3.01 database. Input and output data for agricultural production (including methane and nitrous oxide emissions from soils and animal production), food processing and retail have been taken from GEMIS 4.81 database. An exception has been made for water consumption data which are not included in GEMIS. These have been used from a study carried out by Mekkonen and Hoekstra (2010). In the study only data for the so called 'blue water' have been used.

To have the possibility to analyze where water consumption and land use is highest due to German food consumption and food losses, water consumption and land use in agricultural production were correlated with their national origins.

[2] This was done due to the reason that the characteristics 'avoidable' or 'unavoidable' are closely correlated with a value system that can change in the course of time.

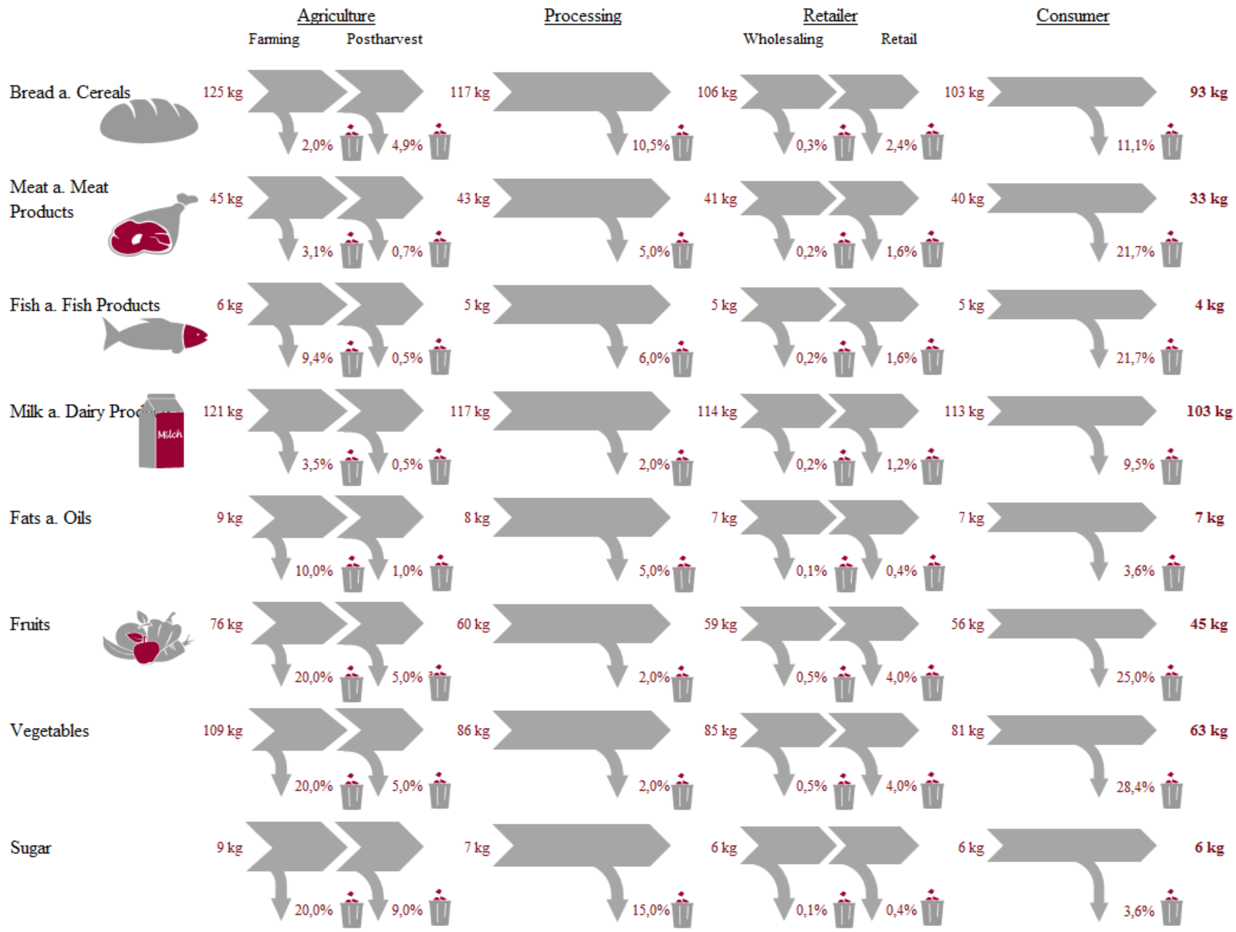

Figure 1. Material flows of in-house food consumption and food losses per person and year (number format: 0,2 = 0.2). Data are given in 'consumption' weight (e.g. boneless meat and w/o slaughter by-products).

Figure 2. Material flows of out-of-home food consumption and food losses per person and year (number format: 0,2 = 0.2). Data are given in 'consumption' weight (e.g. boneless meat and w/o slaughter-by products).

2.3. Simplifications and assumptions

In order to model the food baskets and its product chains some simplifications had to be done. Main reason for that was the lack of statistic and/or consistent environmental data, but also for modeling reasons (reduction of complexity of food production and distribution chains). The following simplifications have been made:

All food imports are modelled on agricultural level, thus also all food processing takes place in Germany. This simplification was done because statistical data don't show at which stage of the product's life cycle it is imported and also input/output data for processing in all the countries needed are not available.

Furthermore it was assumed that production of fodder components is done like in Germany with the same import countries and import shares for each fodder component. This simplification has to be done due to two reasons: one is the actual restrictions of the software program (which will be hopefully solved in next time); the other that import data for fodder components could not be looked into within this project. The composition of the livestock feed was modelled with respect to country specific data of the country where livestock breeding takes place.

Regarding poultry the assumption was made, that all meat is produced from broilers, the share of laying hens meat was not considered.

In addition, it was assumed that all food imports from overseas are carried out only by ship. This simplification was done with respect to the very low relevance of air freight transports of food to Germany which is about 0.12% of all food imports (Keller 2010).

Moreover, organic production systems are not included also due to their low relevance – only 6% of the agricultural land in Germany is cultivated regarding standards for organic production (BLE 2012) – and due to the fact that not all data needed have been available for organic production.

Besides, it was assumed that households buy all their food at retailers, purchases direct at the farm or at local markets haven't been considered. For out-of-home consumption it was assumed that all food is delivered by wholesalers.

2.4. Allocations

Most agricultural production systems have more than one output. Milk cows, for example are kept for milk as main product and meat as co-product. In LCAs environmental burdens need to be allocated to the products by different allocation methods (mass, economic, or commodity specific allocations). In order to reduce the complexity of the model and due to some data lacks allocations have been made only regarding food losses, where a mass allocation was applied at all life cycle stages. In case of meat a physical allocation was done to allocate burdens to meat and slaughter by-products. An economic allocation was renounced because prices in particular regarding by-products vary enormously with respect to time and geographical origin. Thus, regarding milk cow keeping an economic allocation was made with the result that 80% of impacts have been allocated to milk.[3] Also with respect to dairy production allocations have been made. Here an allocation with respect to milk solids was chosen, which is regarded as 'fairest' allocation method for dairy products (Lundie et al. 2007). Regarding the production of soy and rapeseed shred material flows have been allocated to oil and shred regarding their heating value equivalents, which was the approach chosen in the database used. In all other cases of agricultural production 100% product allocation was chosen. This approach leads to a slight overestimation of environmental burdens in agriculture.

In case of combined power generation burdens were allocated in relation to energy yield.

2.5. Impact assessment

The impact assessment methodology used is ReCiPe Midpoint (Goedkoop et al. 2008). The following environmental impact categories have been assessed: climate change, fossil depletion, freshwater eutrophication, marine eutrophication, metal depletion, ozone depletion, particulate matter formation, photochemical oxidant formation, and terrestrial acidification. Furthermore also the use of agricultural land and agricultural water use for food production have been analyzed. Toxicity indicators have not been assessed mainly because the input data for pesticide use available for the different foods have been very unspecific.

3. Results

The analysis shows that German food consumption emits 2.7 tons of greenhouse gases per person each year. 14 cubic meters of blue water are used for agricultural food production per person, and 2673 square meters of agricultural land are occupied each year for each German for food consumption. Table 1 shows total results for each indicator according to life cycle phases.

The results show that agricultural production and consumption are responsible for the main impacts of German food consumption and food losses. For all indicators analyzed these two life cycle phases cause more than 87 percent of the environmental burden. In contrast food processing and retailing have for all indicators and inventory parameters less environmental impact.

GWP-100, fossil depletion, freshwater and marine eutrophication, metal depletion and terrestrial acidification are mainly caused by energy use along the products' life cycles and in particular GWP-100 also by emissions directly from agricultural production. Particulate matter formation and photochemical oxidant formation originate mainly from transport emissions.

The biggest part of the impacts is caused by in-house consumption (61-80% for each indicator) which has also the highest share in amounts. Food losses due to in-house food consumption have a share in the total environmental burden between 8 and 14 percent, out-of-home food consumption 6 to 19 percent, and food losses due

[3] The remaining 20% have been allocated to mother cow meat, but haven't been considered further in the model.

to out-of-home consumption between 2 to 9 percent. Total losses have a share of 15 to 21 percent. Figure 3 shows the shares in in-house and out-of-home food consumption and food losses regarding environmental burdens of the different indicators and inventory parameters.

Regarding the consumed respectively wasted products results show that animal products like meat and dairy products cause most of the environmental burden of food consumption and food losses, although the share of plant products is higher regarding amounts of consumption or waste. This is the case for all analyzed impact indicators. Only regarding agricultural water use, plant products consume more water in total and per kilogram product (Table 2, Table 4).

Table 1. LCA results for life cycle phases and in total per person and year

Impact categories	Unit	Agriculture	Processing	Retailing	Consumption	Total
GWP-100a	kg CO2e	1.56E+03	1.19E+02	5.81E+01	1.02E+03	2.75E+03
Fossil depletion	kg oil-equiv.	2.69E+02	2.56E+01	1.51E+01	4.50E+02	7.59E+02

Photochemical oxidant formation	kg NMVOC	9.66E+00	4.19E+00	3.79E+00	4.51E+01	6.27E+01
Terrestrial acidification	kg SO2-equiv.	1.48E+01	2.00E-01	8.09E-02	2.58E+00	1.76E+01
Agricultural land use	m²*a	2.67E+03	0.00E+00	0.00E+00	0.00E+00	2.67E+03
Agricultural water use	L	1.40E+04	0.00E+00	0.00E+00	0.00E+00	1.40E+04

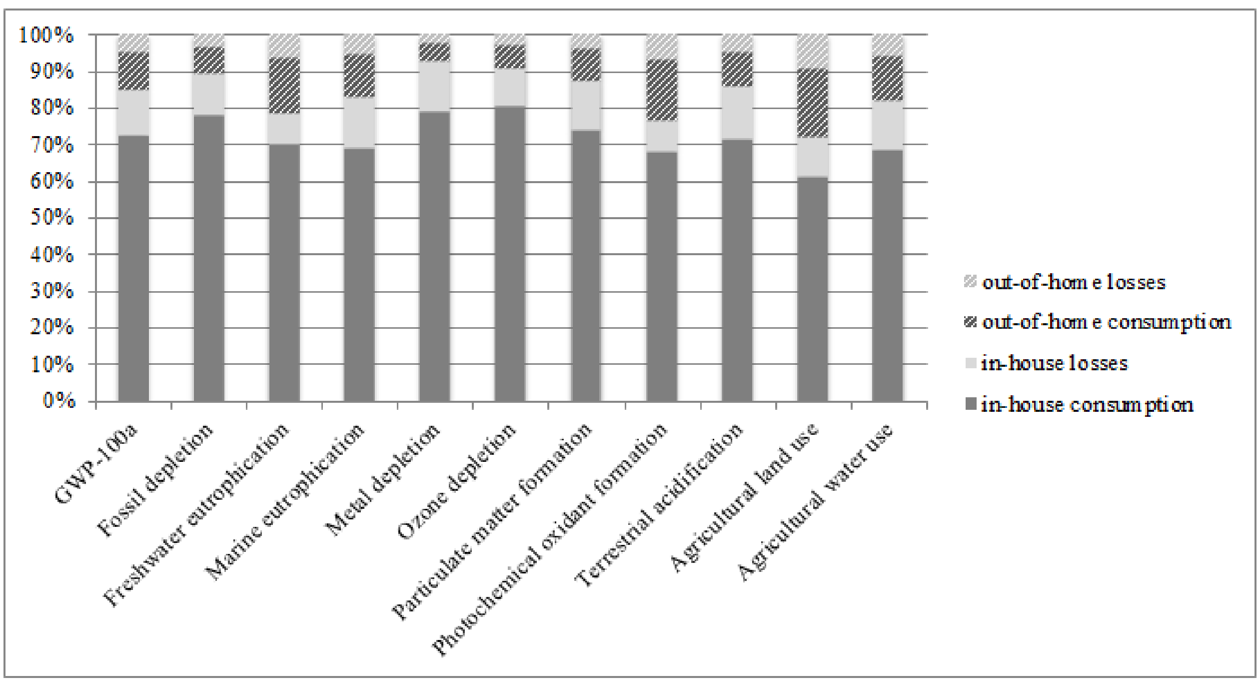

Figure 3. Shares of in-house and out-of-home food consumption and food losses regarding environmental burdens caused by German food consumption

Results per kg product (Table 2) show that animal products in the German food basket have a higher impact for all analyzed impact categories and parameters than have plant products in the German food basket. The only exception is water use. In particular in the case of agricultural land use for food production this is obvious: for the production of animal products eight times more land is needed per kilogram food than for plant products.Also with respect to the indicator terrestrial acidification differences are significant: the impact per kg consumed animal based food is nine times higher than that of products with a plant based origin. Also for marine eutrophication (six times higher), particulate matter formation (five times higher), and global warming (four times higher) the differences are similar. For all other indicators the impact of animal products is between 1.7 and 4.7 times higher than that of plant products. Only for agricultural water use (irrigation water) for food production the water use of animal products is lower as for plant products.

Results show that in total most water for German food consumption and losses is used in Germany (23%) followed by Spain (18%) and Pakistan (17%). Results for animal products show that also Germany is responsible for most of the water use (77%) followed by France (11%) and Argentina (8%). In contrast regarding plant based food most water is used in Spain (23%) followed by Pakistan (23%) and the US (9%).

Regarding land use most agricultural land is used in Germany (73%). This is also the case for animal (70%) and plant based food (75%). Germany is followed by Argentina and Brazil (both 9%). This is the same for animal-based products but not for plant-based products where the next highest shares have the Netherlands and the Czech Republic with 5 percent.

Table 3 shows the additional environmental impacts which are caused per kilogram consumed food due to food losses. These are much higher for out-of-home consumption than for in-house consumption[4]. This is mainly due to the fact that losses at out-of-home consumption are much higher than for in-house consumption but also for the differences in the composition of the consumed food. Thus, the high value for per kilogram consumed food for water use is mainly due to the fact that at out-of-home consumption regarding our data much more rice is consumed and spoiled than at in-house consumption. The value for land use is so much higher because of the higher share of waste but also due to the higher consumption and in consequence losses of meat.

Table 2. Average impact for German food consumption and losses per kg product

Impact categories		Animal products	Plant products
GWP-100a	kg CO2e	9.21	2.55
Fossil depletion	kg oil-equiv.	2.10	1.00
Freshwater eutrophication	kg P-equiv.	2.78	1.41
Marine eutrophication	kg N-equiv.	4.92	0.85
Metal depletion	kg Fe-equiv.	1.74	1.04
Ozone depletion	kg CFC-11-equiv.	0.53	0.26
Particulate matter formation	kg PM-10-equiv.	1.32	0.28
Photochemical oxidant formation	kg NMVOC	1.69	0.86
Terrestrial acidification	kg SO2-equiv.	7.15	0.80
Agricultural land use	m²*a	10.66	1.34
Agricultural water use	l	1.89	3.17

[4] Blumenthal&Göbel (2014) found out that in German communal feeding food losses add to 8 to 30 percent of food consumption in this sector. According to our data the share in food losses is 33.5 percent in out of home consumption (see fig. 2).

Table 3. Additional environmental impacts due to food losses per kg consumed food

Impact categories		in-house consumption	out-of home consumption	total consumption
GWP-100a	kg CO2e	0.9	2.8	1.1
Fossil depletion	kg oil-equiv.	0.2	0.6	0.3
Freshwater eutrophication	kg P-equiv.	2.3E-04	1.4E-03	3.6E-04
Marine eutrophication	kg N-equiv.	4.8E-04	1.5E-03	6.0E-04
Metal depletion	kg Fe-equiv.	2.5E-02	3.6E-02	2.6E-02

United States	l	0	925	925	m²*a	0	3	3
Viet Nam	l	0	293	293	m²*a	0	4	4
TOTAL	l	3333	10740	14073	m²*a	1861	425	2286

[5] Interpreting the results it has to be considered that results for animal based products depend on the assumption that production of fodder components is done like in Germany with the same import countries and import shares for each fodder component. Thus, shares of Germany are somewhat overestimated with respect to water and land use (see sections 2 and 4).

4. Discussion

Results show a high relevance of food consumption and food losses regarding environmental impacts: e.g. food consumption and food losses cause about 23 percent of the German greenhouse gas emissions per person[6] and the water used for German food production is about one third of the German households' water use (Destatis 2013).

In general, results show a similar dimension as results from previous studies which have been carried out to estimate environmental impacts of German food consumption. However, there are also differences. One reason for that is, that in this study both the whole life cycle from agriculture to consumption (including energy consumption for shopping trip, food storage and cooking) and also food losses at all life cycle stages have been considered which was not the case in previous studies

Wiegmann et al. (2005) calculated greenhouse gas emissions which are one quarter lower. They used a similar methodology but a different database. The results of Meier (2014) for greenhouse gas emissions are 9 percent lower. Meier also used a different database.

There are two main reasons for the differences: one is that Wiegmann et al. (2005) didn't calculate all food losses along the value chain, because data haven't been available in sufficient detail at that time. Meier (2014) didn't calculate energy consumption at household level for the shopping trip, cooling and cooking. The other reason is that both studies used the GEMIS database for basis data as electricity grid, fertilizer and chemicals production, transport. In contrast, in this study the ecoinvent database was used for basis data, GEMIS data were only used for material flows. Compared to the ecoinvent database greenhouse gas emissions in the GEMIS database are lower in most cases.

Regarding water consumption Meier (2014) calculated much higher water consumption. According to his results German food consumption is responsible for 32.5 m³ of water use per person and year which is more than twice as much as the results of this study. The main reason for that is that in Meier's study (Meier 2014) nuts count for about one third of water consumption of German food consumption. In this study nuts haven't been an own category, they have been subsumed in the category 'other fruits' and thus specific water use of nuts has not been taken into account. This and also other differences regarding the composition of the calculated food baskets explain differences in agricultural water use.

In contrast, with respect to land use results of Meier (2014), Wiegmann et al. (2005) and Kastner et al. (2012) are about 10% lower. There are two main reasons for this difference. One is that different data regarding land use have been used in the studies; the other that food losses have not been taken into account in all studies. Yield data in this study have been taken from GEMIS 4.81[7], which uses yield data from the Common Agricultural Policy Regionalized Impact Analysis (CAPRI) modelling system[8] in most datasets. GEMIS groups countries to Central, North, West and South Europe, and Germany has been assigned to Central Europe. Probably this leads to lower yields than typical for Germany.

Furthermore results of this study have to be discussed against the allocation methods used. For this purpose a sensitivity analysis has been carried out to analyze the influence of the allocation method used for milk cow keeping and processing of dairy products. In the sensitivity analysis both allocations have been changed to 100% allocation. Sensitivity analysis results show that this allocation influences results. With respect to all analyzed impact categories and inventory parameters results are 3 to 19% higher with 100% allocation. In particular regarding greenhouse gas emissions (8%), particulate matter formation (95%), terrestrial acidification (19%) and agricultural land use (18%) an effect of the chosen allocation can be shown (Figure 4).

[7] http://www.gemis.de
[8] http://www.capri-model.org/

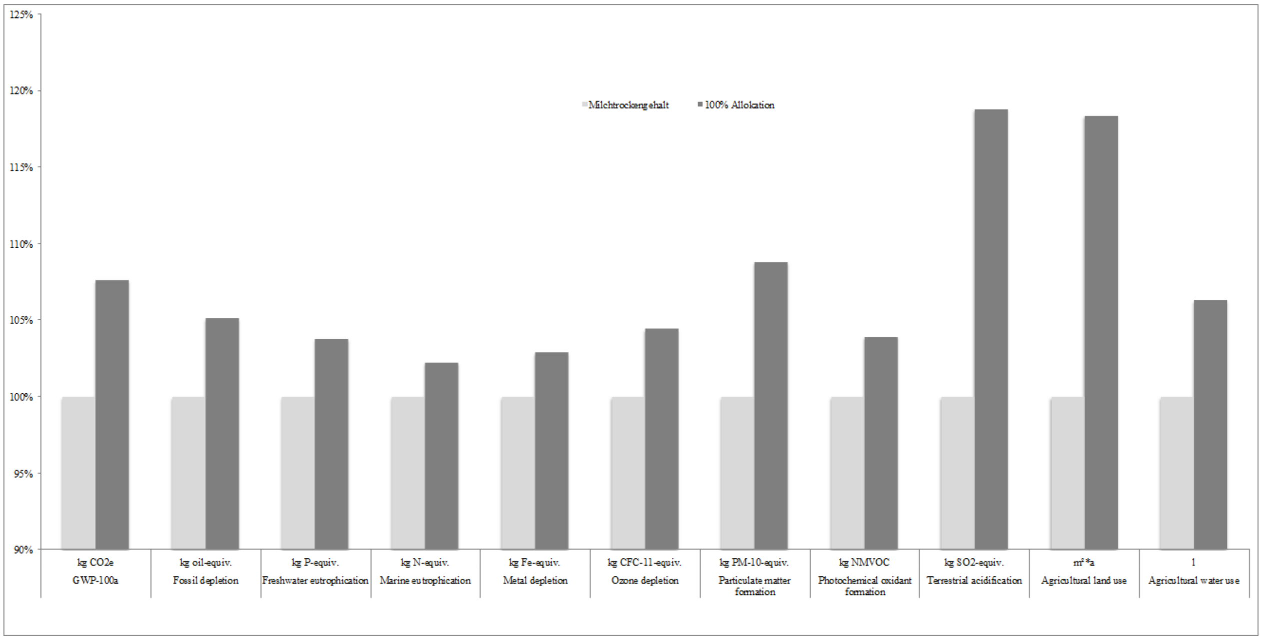

Figure 4. Differences in results with respect to allocation methods

Moreover, results have to be discussed against the assumptions and simplifications made. Thus, with respect to the chosen methodology it has to be considered that results for animal based products depend on the assumption that production of fodder components is done like in Germany with the same import countries and import shares for each fodder component. Thus, shares of Germany are somewhat overestimated with respect to water and land use.

Regarding the provenience of water consumption it has to be taken into account that in the case of rice no statistical data for the origin of consumed rice could be found. German trade statistics show only the import countries of processed rice (e.g. peeled rice). Thus, it was assumed that the world's largest rice exporters export rice to Germany at the same proportion as their share in the global rice market. Therefore, more precise trade statistics could change the results in the case of Pakistan.

5. Conclusion

The study shows the high relevance of food production regarding environmental impacts. In particular animal products are responsible for high environmental burdens in the German food basket. Losses (animal and plant based) along the product chains have a share between 13 and 20 percent in environmental impacts. With respect to reduce environmentally relevant food losses, measures should focus in particular to reduce food waste of animal origin like dairy products and meat. The most relevant points for reduction measures are agricultural production and consumption in households and out-of-home. In particular out-of-home consumption has a high share of spoiled food in relation to the total food used. Out-of-home consumption therefore also provides a good starting point for measures.

Nevertheless, better statistical and also environmental data are still needed to improve such kind of studies.

ABSTRACT

The lack of harmonized and regionally appropriate life cycle inventory databases is one of the main challenges limiting the use of life cycle analysis for decision making on food systems. The food and beverage sector in Chile is important for the country and is strongly focused on exports, where requirements for sustainable practices and value chain transparency are increasing, but there is a lack of technical capacity within companies to analyze and interpret sustainability assessment. In this context, Fundación Chile and Universidad de la Frontera are developing the EcoBase Food project, an environmental information management system for life cycle analysis, through a technological platform, to improve the sustainability and competitiveness of the food and viticulture exports industry. The following document presents a summary of the data collection methodology to create the life cycle inventories for the project, which corresponds to an adaptation from international best practices and is aligned to international initiatives.

Keywords: life cycle analysis, life cycle inventories, Chilean food and viticulture sector, LCI methodology, LCA tools

1. Introduction

The lack of harmonized and regionally appropriate life cycle inventory (LCI) databases is one of the main challenges limiting the use of life cycle analysis (LCA) for decision making on food systems (Heller, Keoleian and Willett, 2013). Several LCA and environmental information initiatives have been developed in recent years, but there is little coordination among them. Some of these initiatives are:

Table 1. Initiatives and sources of information

The food and beverage sector in Chile is an important sector, strongly focused on exports. It is the second largest sector for the Chilean economy and ranks 15th worldwide (US Commercial Service, 2012). Requirements for sustainable practices and value chain transparency are increasing (ProChile, 2012), both from international retailers (Walmart, Tesco, among others) and from within the country as a member of the OECD (OECD, 2005). Along with this, there is a lack of technical capacity within companies in Chile to analyze and interpret sustainability assessment.

In this context, Fundación Chile and Universidad de La Frontera (UFRO) are developing the EcoBase Food project, which has secured funding from a public grant presented with the following title: "Development of an Environmental Information Management System for Life Cycle Analysis, through a Technological Platform, to improve the sustainability and competitiveness of the Food and Viticulture Exports Industry". The project relies on the support and interest of 9 different trade organizations from the food and wine sector, along with the Environment and Agriculture ministries and the Chilean Promotion Bureau (ProChile due to its Spanish initials).

The aim of the project is to increase the competitiveness of food exporters and producers, including small to medium enterprises (SMEs).It is expected that companies will be able to increase their competitiveness by:

- Providing transparent and rigorous product sustainability information (e.g. environmental footprints) to clients.
- Demonstrating positive and competitive sustainability performance.
- Identifying hotspots, evaluating solutions and prioritizing sustainability improvements based on this information.

To achieve this, the project will deliver an environmental information platform, which will provide:

- A methodological framework and guidelines for consistent data collection and impact assessment
- Excel based data collection tool.
- 16 national product category (Table 2) data baseline models, with options to model different production systems per category.
- Instructions for selecting indicators, best practices and improvement opportunities associated with major environmental impacts.

The following document presents a summary of the data collection methodology to create the LCIs for food and wine products in Chile. The methodology is an adaptation from international best practices and aligned to international tools, standards and recognition schemes; balancing the generality and specificity of these to suit the Chilean industry requirements the best. The main sources for the methodology are:

- The International Organization for Standardization’s Life Cycle Assessment method (International Organization for Standardization (ISO) 2006a; International Organization for Standardization (ISO) 2006b)
- Ecoinvent Quality Guidelines (Weidema et al., 2012), as an important centre of expertise and support for the project, as well as the potential to provide the Ecoinvent database with information from the project.
- Shonan Guidance Principles (Sonnemann and Vigon, 2011), as a general guide for the methodology structure (Context, Unit process, Aggregation, Documentation, among others).

Along with the above, the methodology has been developed taking into account the different opinions of the trade organizations and ministries involved in the project, and will pass through a critical review before final publishing.

The methodology could be applicable to any food or beverage product, but the project will focus on 16 different product groups (Table 2), which are categorized into: Fruits & Wine, Aquaculture and Meat & Dairy. Collectively, in 2012 the considered product categories represented 62% of Chile’s food and beverage exports (Chilean Central Bank, 2012).

Table 2. Product categories in the project

Fruits & Wine	**Aquaculture**	**Meat & Dairy**
• Fresh Apples	• Salmon	• Pork
• Dried Apples	• Mussels	• Chicken
• Table Grapes		• Powdered milk
• Apple Juice		• Gouda cheese
• Wine		
• Avocado		
• Fresh Plums		
• Fresh Blueberries		
• Canned Peaches		
• Frozen Raspberries		

This project is being developed in parallel with the construction sector, in pursuit of a national project that aims to have a coordinated platform of information for relevant industries of the Chilean economy. Having databases which are coordinated and have similar structures facilitates information exchange and allows for improved decision-making at a country level, optimizing and making resource use more efficient. With the objective of having these projects as part of a more harmonized international network, Fundación Chile has become a member of UNEP/SETAC´s Life Cycle Initiative, and is actively participating in international developments.

2. Methodology

The present methodology aims to enable the quantification and reporting of environmental impacts associated with the agricultural/livestock/aquaculture production and processing stages, linked to upstream and downstream data. The project will create “cradle to gate" inventories and offer tool support to model “cradle to retail gate” scenarios.

The document includes:

- A methodological framework providing consistent data collection and impact assessment guidelines;
- Defined product categories (Table 2), with their respective lists of processes, inputs and outputs to facilitate data collection.

2.1. Scope

The goal of the project is to increase the competitiveness of food producers and exporters, including SMEs. It also aims to obtain better understanding of the impacts of the Chilean food and wine supply chains and to introduce and enable the industry to use life cycle thinking.

Therefore, one of the target audiences is exporting companies from the food and wine sector. Another key envisioned target audience for the sustainability information is future retailers at key export markets (e.g. French retailers in coming years). Therefore the functional units and scope need to be appropriate for use by retailers and cradle to retailer gate, which is why the functional unit will be a unit of mass or volume rather than a nutritional unit for example. This is useful from the consumer’s point of view but not from producers and retailers standpoint.

To this end, the methodology aims to generate national LCI baseline models that could be later used as a base for more complex LCA studies. Also, it will try to generate unit process inventories as disaggregated as possible, protecting minimum requirements of confidentiality.

The functional unit will be 1 kg of packaged product, except for wine which will be 0.75 l of packaged wine, since this is the most purchased format. Additionally, the most representative varieties or types of products (e.g. Royal Gala and Granny Smith apple varieties) of the Chilean industry will be employed. These measures will allow having consistent, comparable and representative information.

2.2. System boundaries

The stages covered are: i) raw materials, ii) agriculture, iii) livestock & aquaculture, iv) processing, v) packaging and vi) distribution.

A list of inclusions and exclusion per life cycle stage is given in Table 3.

Table 3. Life cycle stage inclusions and exclusions

Life cycle stage	Inclusions	Exclusions
Raw materials (secondary data)	• Agrochemical production • Other chemical input • Fuel production • Transportation[a]	• Manufacture, transportation, and end-of-life disposal of buildings, transportation and packaging infrastructure, capital equipment and auxiliary machineries • For crop production, it is not necessary to include the production of seeds as the relative contribution to environmental impact is

		small. The exception to this is where seed production would be expected to be, or shown to, represent more than 1% of the impact to any impact category (for example where small organic farms may be studied).
Agriculture	• Water use • Land use • Soil carbon sequestration • Agrochemical and fertilizers use • Fuels combustion and electricity • Machinery • Waste management • Transportation[a]	• Manufacture, transportation, and end-of-life disposal of buildings, transportation and packaging infrastructure, capital equipment and auxiliary machineries • Consumables • Staff transport • Noise and vibration, radiation, odor and waste heat
Livestock & Aquaculture	• Feed • Fuels combustion and electricity • Chemicals • Fugitive emissions • Water use • Land use • Soil carbon sequestration • Agrochemical use • Waste management • Transportation[a]	• Manufacture, transportation, and end-of-life disposal of buildings, transportation and packaging infrastructure, capital equipment and auxiliary machineries • Consumables • Staff transport • Animal welfare • Noise and vibration, radiation, odor and waste heat
Processing	• Fuels combustion and electricity • Chemicals • Fugitive emissions • Water use • Waste management • Transportation[a]	• Manufacture, transportation, and end-of-life disposal of buildings, transportation and packaging infrastructure, capital equipment and auxiliary machineries • Consumables • Staff transport • Noise and vibration, radiation, odor and waste heat
Packaging	• Source of plastics, paper, glass, aluminium, metals, etc. • Recycled content • Primary, secondary & tertiary packaging • Transportation[a]	• Manufacture, transportation, and end-of-life disposal of buildings, transportation and packaging infrastructure, capital equipment and auxiliary machineries • Consumables • Staff transport • Noise and vibration, radiation, odor and waste heat
Distribution	• Storage; • Distribution to retail outlets; • Transportation to retail outlets; • Cold storage and preservation processes	• Manufacture, transportation, and end-of-life disposal of buildings, transportation and packaging infrastructure, capital equipment and auxiliary machineries • Noise and vibration, radiation, odor and waste heat

[a]Transportation shall include all modes (road, rail, air, and by ship) occurring in-between the life cycle stages.

2.3. Allocation procedure

In LCA, environmental impacts and benefits are calculated for different materials, products, assemblies and services. These products are produced by a large diversity of production systems that make up a modern industrial economy. Whenever a single process produces more than one product or service (e.g. beef being produced as a co-product in the production of milk), an approach is needed to determine how the environmental impacts of the single process should be assigned to each of the products or services. This is commonly referred to as the allocation problem.

For the EcoBase project, sufficient data shall be collected to enable flexibility with regards to allocation between co-products. This includes co-product price information, mass/volume, etc. Where allocation between co-products cannot be avoided or based on direct causality, economic allocation will be used, in order to allocate inputs and outputs between the products and functions in a way which reflect their value. This is in line with the Handbook on LCA, which advises economic allocation as baseline method for most situations (Guinée et al., 2002).

This approach also allows allocating impacts between recycled products and waste-derived fuels.

2.4. Cut-off rules

No strict quantitative cut-off rule is followed in the project. The database shall be as complete as the knowledge of the data providers allow. In principle, all known inputs and outputs are recorded as such. All input and outputs within the assessment scope shall be included as far as practical and reasonable. However, for the purpose of prioritizing efforts, the following threshold can be applied:

- Strong efforts to collect high quality data shall be held when inputs are anticipated to make a material contribution (more than 1% normalized impact in the priority impact categories) to the total life cycle inventory per functional unit.
- Otherwise, data can be collected from conservative estimates.
- Where a single source of energy and water use and emissions accounts for more than 50% of the likely total life cycle inventory per functional unit, the above threshold rule (inclusion of at least 95%) shall apply to the remaining life cycle inventory.

Further information on data sources is given in section 2.5 below.

2.5. Data collection guidelines and tool design

For this project, one of the goals is to obtain data that represents the various realities (production technologies, raw materials, etc.) of each product. It will work with the principle of collecting the best available information, prioritizing completeness of systems, and basing the data collection efforts according to the following hierarchy of sources of information (adapted from Howard & Sharpe, 2010):

1. Primary information: Information obtained directly from companies
2. Secondary information:
   - Studies and other national projects related to each category.
   - Information available from the Clean Production Agreements from the National Council of Clean Production
   - Information available in the Chilean national environmental impact assessment database (e-SEIA).
   - Documented estimates from national experts.
   - International studies or other projects related to each category which could be complemented with international experts' contributions.
   - LCA databases internationally recognized, with the necessary and feasible adjustments to adapt them to the Chilean reality (energy matrix, transport distances, etc.).

Based on feedback by the trade associations supporting the project, the data collection tools developed have been designed to increase usability by the data providers. For each of the products in the database, a process list, with its inputs and outputs listed has been generated to guide the data collection process. These process lists are included within the data collection tools to facilitate the navigation and filling of the spreadsheets. Also, when information is available from literature review, some values are pre-filled to assist the data providers in case they don't have certain fields of information, or if they feel that the pre-filled values represent their production process; validating them. The data collection tools will be sent to private companies, through their respective trade association, with the project teams assisting the filling of the spreadsheets through visits to the facilities or farms, online workshops or other ways of more informal interaction.

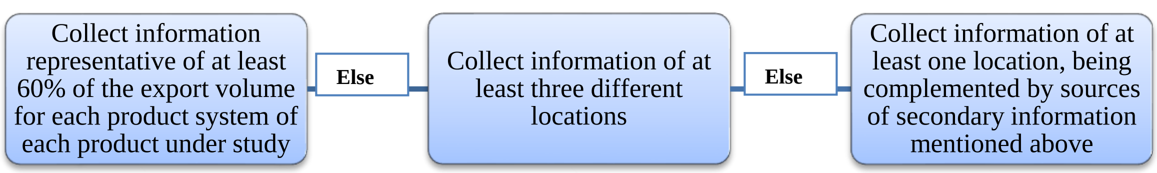
Data collection guidelines for each impact category have been developed and prioritized, based on literature and contribution analysis for several of the product categories. Data collection efforts will be focused according to the representativeness goals given in section 2.5.1 and the hierarchy of sources of information.

2.5.1. Representativeness

In order to maximize the usefulness of the LCI developed, a key aspect is representativeness (from a geographic, technological and productive point of view) of the most important product systems in term of market share exports.

Therefore, a hierarchy of objectives was defined and it is presented below

Figure 1: Hierarchy of objectives



For all cases, the export volume and relevance of the productive systems for national exports will be considered for selecting each location.

2.5.2. Averaging, aggregation and data confidentiality.

As one of the objectives of the project is to provide national baseline LCIs for the products under study, it is necessary to appropriately average and aggregate data from different companies.

In order to protect the confidentiality of individual company's data, the Project will allow for data to be published as aggregated from several sources into anonymous generic averages that are nonetheless representative of the Chilean industry. In general, inputs and outputs of several distinct unit processes are aggregated only if a) data is not available on a detailed unit process level, or b) unit process data is confidential.

The project will average data horizontally. This means that average inventory for each of the individual subprocesses in an inventory are weightily averaged and the sum of these then represents the inventory for the whole. This is preferred because it preserves data richness and it can be used to compare between similar processes from different industries. Also, it can even be used as a proxy process in another sector to fill a non-critical data gap. Maintaining data richness provides advantages such as the ability to see which parts of the processes contribute more to the impacts of their products. This can further help understand how to innovate to mitigate those impacts.

Two particular cases need special attention:

- Only one surveyed company: When only one company is surveyed in a product category, confidentiality will be ensured by combining their data with information from other national or international databases that are considered suitable.
- Various production locations per company: If a company has more than one productive location, LCI averages for each location will be weighted according to the percentage of production of the whole company. Special care will be held when different productive technologies exist inside one company.

The Project will estimate and document the extent to which data are representative of a market or a process, but will not exclude data that cannot achieve any particular threshold level of representativeness. The data used should derive from the most recent annual production data that it is feasible to compile. The data should represent the mean of Chilean production, reflecting differing efficiencies from production at different ages and scales of production.

2.6. Data quality

Data quality is one of the main aspects in the construction of a national LCI database. For this project, an adapted version of the Pedigree Matrix (Weidema et al., 2012) will be used, evaluating the aspects in Table 4.

Table 4. Data quality indicators. Adapted from Weidema et al., 2012.

Indicator	**1**	**2**	**3**	**4**	**5**
Reliability	Verified data based on measurement	Verified data partly based on assumptions or non-verified data based on measurements	Non-verified data partly based on assumptions	Qualified estimate (e.g. by industry expert)	Non-qualified estimate or unknown origin
Completeness	Representative data from a sufficient sample of sites over an adequate period to even out normal fluctuations	Representative data from >50% of the sites relevant for the market considered, over an adequate period to even out normal fluctuations	Representative data from only some sites (<<50%) relevant for the market considered or >50% of sites but from shorter periods	Representative data from only one site relevant for the market considered or some sites but from shorter periods	Representativeness unknown or data from a small number of sites and from shorter periods
Temporal correlation	Less than 3 years of difference to the time period of the dataset	Less than 6 years of difference to the time period of the dataset	Less than 10 years of difference to the time period of the dataset	Less than 15 years of difference to the time period of the dataset	Age of data unknown or more than 15 years of difference to the time period of the data set
Geographical correlation	Data from area under study (e.g. O'Higgins)	Average data from larger area in which the study is included (e.g. Central Valley Region)	Data from area with similar conditions (e.g. Chile or Argentina)	Data from area with slightly similar conditions (e.g. South Africa)	Data from unknown or distinctly different area (North America in- stead of Middle East, OECD-Europe instead of Russia)
Further technological correlation	Data from enterprise, processes, and materials under study	Data from processes and materials under study (i.e. identical technology) but from different enterprises	Data from processes and materials under study but from different technology	Data on related processes or materials	Data on related processes or materials but different technology

The project will have no strict data quality goals, and the LCI will be as complete as possible, having in mind completeness over depth of them. Therefore, all data will be reported with their respective quality indicators. These indicators will be available for the users, so they can judge how useful the information is in order to use it.

2.7. Life cycle impact assessment

Impact assessment models that are used to interpret LCIA data are still emerging and evolving internationally. Since the early 1990s, numerous LCIA methodologies have been developed. The widespread use of several different methodologies creates confusion over which methodology to use, and criticism arises when the use of LCA gives different results depending on the methodology chosen (European Commission – Joint Research Centre 2008)

ISO 14044, section 4.4.2.2.3.c, recommends minimizing value-choices and assumptions during the selection of impact categories, category indicators and characterization models for the LCIA method, which is why this project includes a recommended LCIA method to be used.

The recommended LCIA method is proposed based on the research documented in:

- A Life Cycle Impact Assessment Method for Use in Australia – Classification, Characterization and Research Needs (Bengtsson et al. 2010):
- Identifying best existing practice for characterization modeling in life cycle impact assessment (Hauschild et al., 2013):

In essence the key considerations are:

- Whether the impact assessment is conducted at mid-point, end-point, or both.
- Whether the impact assessment should be based on best practice scientific methods per impact category (i.e. the BP LCI and AgAusLCI approach in Australia and the ILCD work in Hauschild et al., (2013)) or to adopt a ready-made LCIA method such as World Impact +, ReCiPe or CML.
- Which approach offers the most regionally appropriate impact assessment method.

The interim preference is to adopt ReCiPe on the basis that it:

- Has the flexibility to calculate impacts at both mid-point and end-point,
- Includes global characterization and normalization factors which are deemed by the project team to have higher degree of acceptance by the intended audience than European or US-centric LCIA methods.
- Aligns in terms of impact category selection with the best practice research for the BP LCI and ILCD
- Is actively maintained and updated.

The ReCiPe impact for water depletion and toxicity shall be replaced with the consumptive water use method developed by Ruidoutt and Pfister (2012) and USE Tox (Rosenbaum et al, 2008), respectively. The latter, including minor adaptations to Chile based on contribution analysis and known used substances.

Ionizing radiation will not be covered, as it was deemed not to be relevant for Chile, based on a contribution analysis made for avocado, table grapes, wine and chicken where it represented less than 1% of the normalized impact. In addition, there is no nuclear energy in Chile.

3. Summary and next steps

A data collection and life cycle impact assessment methodology has been developed for the Chilean LCI food and wine database project EcoBase, built upon international best practices and considering several stakeholders' inputs. The methodology will be submitted for critical review to achieve scientific validation before final publishing. This review will be by the Chilean LCA Network nationally and Quantis internationally, with the interest of seeking alignment with the World Food LCA Database.

It is expected that after the initial stage, these developed guidelines will allow more and better databases and products to be incorporated into the database.

Currently, the project is in data collection stage, following the methodology covered in this document. Secondary data collection has mostly been completed, while primary data collection is in progress. As mentioned in section 2.5, the data collection tool has been sent to several companies through trade organizations that are part of the project, and workshops to facilitate navigation and learning of the tool are being carried out with companies for most of the product categories. By mid-2014, data collection will be finalized, and by the end of the same year, a first draft of the LCI and calculators for the 16 selected product categories will be ready. After a critical revision by project partners, a final version of the LCI and the calculators will aim to be ready by early

2015 following which, the process of dissemination will begin until August 2015, which is when the project is expected to finalize.

It is important to mention that all project deliverables including methodology, life cycle inventories, calculators etc. will be publicly available on an online platform operated by project partners.

EcoBase Food is one step towards a more transparent and sustainable food sector in Chile, but there is still a long way to go in this direction. While currently the project includes 16 products, the aim is to expand the scope in future both in terms of increasing the number of products and industries involved, as well as improving the quality of the results as and when additional information and/or methods become available. Another future step currently being evaluated is better communication of these results to consumers, possibly under an eco-labelling program or a similar initiative.

ABSTRACT

Although essential to understand the overall health impact of a food or diet, nutrition is not usually considered in food-related life cycle assessments (LCAs). As a case study to demonstrate comparing environmental and nutritional health impacts we investigate United States dairy consumption. Nutritional impacts, interpreted from disease burden epidemiology, are compared to health impacts from more traditional impacts (e.g. due to exposure to particulate matter emissions across the life cycle) considered in LCAs. After accounting for the present consumption, data relating dairy intake to public health suggest that low-fat milk leads to nutritional benefits up to one additional daily serving in the American diet. We demonstrate the importance of considering the whole-diet and nutritional trade-offs. The estimated health impacts of various dietary scenarios may be of comparable magnitude to environmental impacts suggesting the need for investigating the balance between dietary public health advantages and disadvantages in comparison to environmental impacts.

Keywords: dairy, dietary guidelines, LCA, nutrition

1. Introduction

Dietary guidelines, for instance suggested by the United States government, focus on improving health through dietary nutrition and do not consider environmental impacts occurring throughout the life cycle of the recommended diet (van Dooren et al., 2014). On the other hand, food-related Life Cycle Assessments (LCAs) assessing environmental and public health, tend to neglect nutritional advantages and disadvantages (Heller et al., 2013). In general, the assessment of emissions and nutrient intake is based on a functional unit relevant to the study question and the food system of interest. The selection of the functional unit is extremely important in LCA—specifically within food LCAs this point cannot be further emphasized, as it may change results when comparing two various food items or diets on different bases. Historically, there has been a large number of functional units based food LCAs (e.g. based on mass or volume of a single food type, quality corrected mass, a single nutrient, a full nutrient profile). Food oriented studies have mostly focused on environmental efficiency in crop or food production, for instance, how to decrease environmental impacts per unit output. (e.g. Garnett, 2013). In order to consider questions of impacts and benefits of dietary choices, i.e. consuming one food over another, assessment must be conducted in the context of the overall diet. These consumption oriented approaches (based e.g. on serving size, or full dietary or meal nutrients) are of growing interest as a means of informing consumer choices and policy decisions that affect dietary recommendations (e.g. Vieux et al, 2013).

Table 1 summarizes approaches to add nutritional impacts into environmental impact assessments the domain of application and limitations of each method, leading to the following statements: All present methods are impact oriented and do not enable a comparison of impacts with nutritional benefits. Several indices are themselves based on the contribution of the food to recommended nutrient intakes rather than based on epidemiological measures of health benefits and impacts. We expect in general when "quality" adjustments made including nutritional aspects, assessed impacts are reduced for items having positive nutritional benefits such as milk, fruit vegetables. This supports our thinking that if we can get to a better assessment of health benefits for products like milk then environmental impact in terms of expected negative human health impacts will be more balanced. However, trying to force various benefits and impacts associated to nutrition in the basis for comparison (the traditional functional unit) does not provide a clear view of the benefit of “positive” nutritional components versus the impact of “negative” nutritional components.

There is therefore a need to consider health benefits and impacts of nutrition in a parallel way to the latest quantitative development of the global burden of disease to incorporate diet-related risk factors, and consider Disability Adjusted Life Years as a basis for an improved index.

Table 1. Summary Table of Identified Approaches to Incorporating Nutrition in Environmental Impact Assessment

Approach	**Domain of application**	**Limitation / needs**	**Features of interest for framework**
a) Functional unit approaches			
Mass- or volume-based e.g. per kg or per liter	Internal (production oriented) assessments; identifying hotspots, evaluating abatement scenarios	Not appropriate for comparisons of different foods	Intermediary calculation step
Quality corrected mass e.g per kg FPCM	Normalizing product quality across different production practices; evaluating scenarios that affect product quality	Limited to simple nutritional quality assessments that can be related to a mass unit; not appropriate for comparison of disparate foods	Reconsideration of FPCM and impacts of allocated cream in overall diet scenarios
Single nutritional aspect, e.g. per g protein	Evaluating single nutritional dimensions across foods with related functions	Limited complexity; does not capture other nutritional differences	Impact and benefit of single nutrient could be estimated separately
Nutrient profile e.g. per index unit value	More complete nutritional picture; may be valuable in comparing foods	Negative impacts not adapted for functional unit; most current indices based on dietary recommendations rather than health outcome	Would be of interest to create a DALY weighted nutrient profile
Approach	**Domain of application**	**Limitation / needs**	**Features of interest for framework & next steps**
b) Consumption oriented approaches			
Serving size per serving size	Normalizes based on typical consumption quantities; can be used as a consumption-based unit for comparing individual food items, provided that health effects of nutrients are also considered	Does not link with nutrition or health; inconsistent definitions of servings	Testing scenario of one additional serving of milk
Diet-based for overall diet	Basis for consumption oriented assessment	Requires parallel assessment of nutritional quality/health; no basis to evaluate trade-offs	Basis for comparison framework at diet level
Equivalent nutrition diet for overall equivalent diet	Sound basis for comparing environmental impact of similar diets	Limited to nutritionally equivalent diets; definition of "nutritional equivalence" may be limited	Useful in considering isocaloric dietary substitution scenarios
Diet-level nutrient profile e.g. per index unit value of overall diet	May offer a comprehensive nutritional basis for diet comparisons	Negative impacts not adapted for functional unit; most current indices based on dietary recommendations rather than health outcome	Will be used as a comparative approach

To address these needs, we aim in this paper to 1) present a preliminary framework to show separately environmental and nutritional impacts together on a comparable scale, starting from serving size, 2) build on global burden of disease information and use of the DALY to compare human health impacts and benefits of nutrition, 3) provide a dairy case study to demonstrate the framework and analyze population-scale health effects of dietary changes.

2. Methods

2.1. Framework for comparing impacts and nutritional benefits of food

In an effort to bridge this research gap we build a preliminary framework and implement a dairy case study. Figure 1 schematically outlines the LCA framework to begin harmonizing nutritional and environmental impacts, where different food items within various diets may be associated with numerous environmental emission types which may influence population-scale health. Likewise, considered nutrients within those food items contribute to the nutrient index (i.e. nutrients consumed) and may also lead to various population-scale health impacts and benefits. To express human disease burden, many LCAs use the Disability Adjusted Life Year (DALY) (ILCD, 2010). Recently this metric has also been applied to quantify nutrition-based health impacts. For example, Murray et al. (2013) found that amongst a variety of health indicators and risk factors (e.g., smoking, violence, pollution etc.) inadequate diet generally accounts for 26% of deaths in the United States and 14% of DALYs. Benefiting from the implementation of the DALY metric in public health nutrition research and population-scale epidemiological evidence on minimum dietary risks, we build on work by Murray et al. (2013) and Lim et al. (2012) who performed large-scale epidemiological literature reviews on disease burden associated with specific food categories and nutrients, referring to both positive and negative health outcomes as nutritional impacts. Overall this approach offers an interesting possibility to compare nutritional benefits and impacts consistently with environmental impacts on human health.

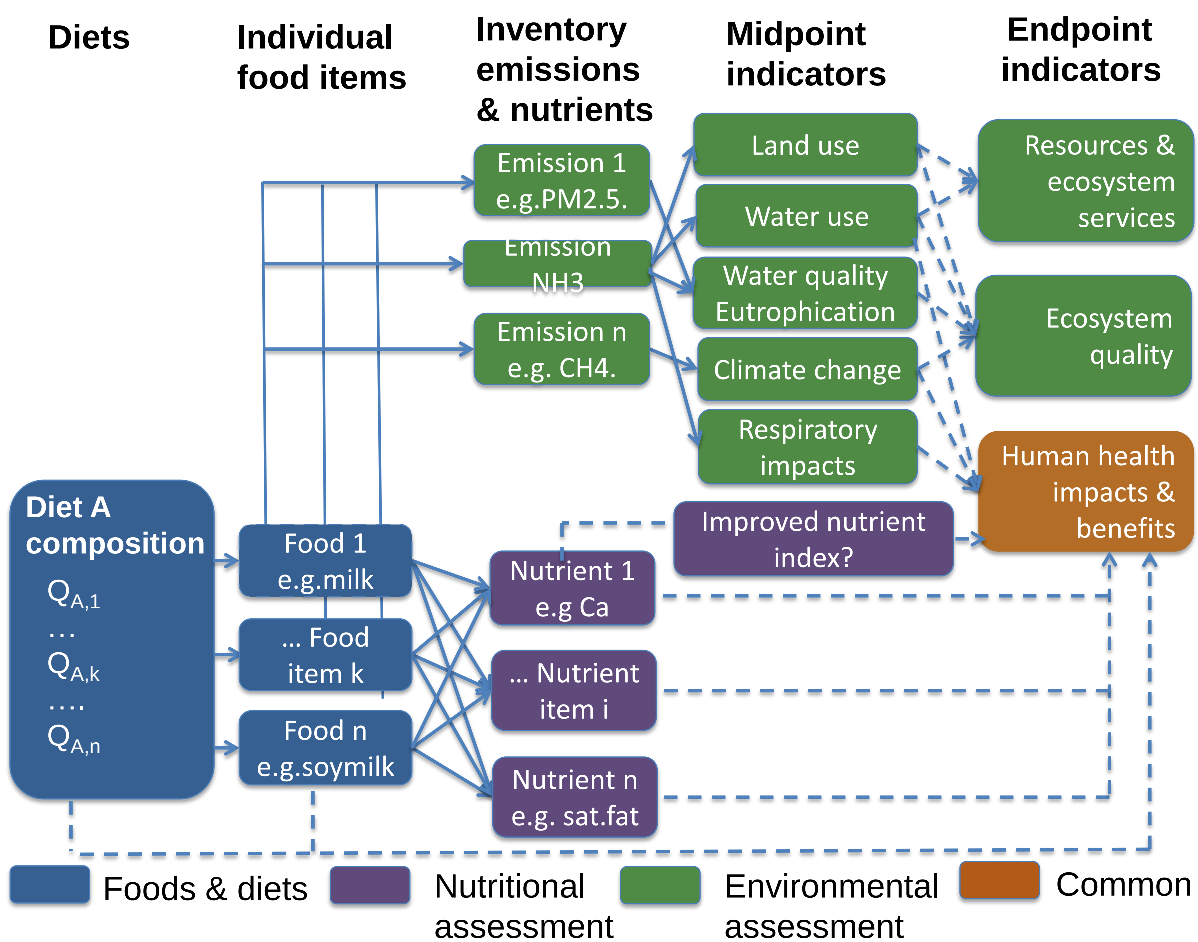

Figure 1. Framework to combine nutritional and environmental assessments. Dashed lines represent links that are useful to interpret midpoint categories, but whose quantification is also associated with a higher degree of uncertainty.

2.2. Dairy case study

a) Functional unit and scope

To test the LCA framework, which includes both nutrition and environmental impacts, we study a dairy case study. The Dietary Guidelines for Americans (USDA, 2010) recommends adult Americans consume 3 daily servings (≈740 g/day total) of low-fat or fat–free dairy products, close to doubling current consumption (USDA ERS. 2012). Previously performed LCAs (e.g. Thoma et al., 2013, Asselin-Balençon et al, 2013) have quantified various environmental impacts of dairy production in the US. Entirely missing from these LCAs, however, are the use phase nutritional impacts or benefits on human health due to dairy consumption. Building on the literature review from Heller et al., (2013), this research aims to incorporate nutrition related health effects of dairy into an LCA framework to compare them consistently with environmental impacts. We use the serving size as a common functional unit when combining nutritional and environmental impacts within LCA. This allows easy comparison with recommended dietary guidelines, based on serving sizes, and can also be easily converted to mass or volume, as well as to a corresponding nutritional intake or dietary function (e.g. calcium intake). We consider epidemiologically-based estimations of dairy's contribution to the global burden of disease and caloric intake to evaluate the health impacts due to nutritional components. For environmental impact, we focus on greenhouse gas (GHG) emissions and human health impacts of particulate matter (PM). We select these two impact categories because of their high relevance, and they have been extensively studied in relation to the dairy industry by Thoma et al. 2013 and Henderson et al. 2013. Additionally, human health effects of PM have also been assessed through various epidemiological studies (Pelucchi et al., 2009) and can thus be compared with nutritional impacts.

b) Defining the American diet and dietary context

In order to understand how a shift in dairy consumption may affect overall nutritional intake, we must first define the current "average" diet in the US. We assess two available datasets: The National Health and Nutrition Examination Survey (NHANES) and the USDA-maintained Loss Adjusted Food Availability (LAFA) data series (USDA ERS 2012). Survey-based approaches, like NHANES, are known to under-report food intakes; they are also comprised of as-consumed (e.g., processed) food items, with no consideration of the life cycle of a food item e.g. from the commodity or ingredient level. LAFA, on the other hand, measures the use of food commodities (e.g., wheat) by tracking the US marketplace. Generally, the available supply is the difference between the sum of production, imports and beginning stocks, and the sum of non-food use (e.g. industrial uses), exports, and ending stocks for a given calendar year. In the LAFA series, the available supplies for over two hundred commodities are adjusted by percent loss assumptions, for instance plate waste and food spoilage in order to account for various processes effecting food loss along the chain farm to retail. Availability adjusted for loss can serve as a useful proxy for per capita food consumption in the US. While LAFA data is presented at the food commodity level (i.e., raw farm products like wheat and corn rather than consumables like bread or tortilla chips), this level is far more manageable from the environmental impact perspective; LAFA data also allows to account for supply chain losses, which contribute to environmental impact but are not consumed (and therefore do not contribute to nutritional health effects).Therefore, we propose using a recent 2010 LAFA data series to define average US food consumption (the background average US diet) within this proof-of-concept case study. These data are available both on a weight and on a food pattern equivalent basis, permitting consistent connection between environmental impact and nutritional data.

c) Scenarios

In general, it is important to consider the nutritional and health effects from consumption of a single food item within the full dietary context. From average diet information we find that the average US adult diet includes 1.5 cup equivalents (with around 245 grams of milk per cup) of dairy consumed per person per day, about half the recommended value. To investigate the shift from average consumption to recommended consumption we evaluate three dietary scenarios. These are hypothetical examples to implement this framework; unfortunately there is limited data available to predict actual dietary changes. Starting from the average diet (scenario 0) at population-scale we investigate the effects if people generally will (Figure 2):

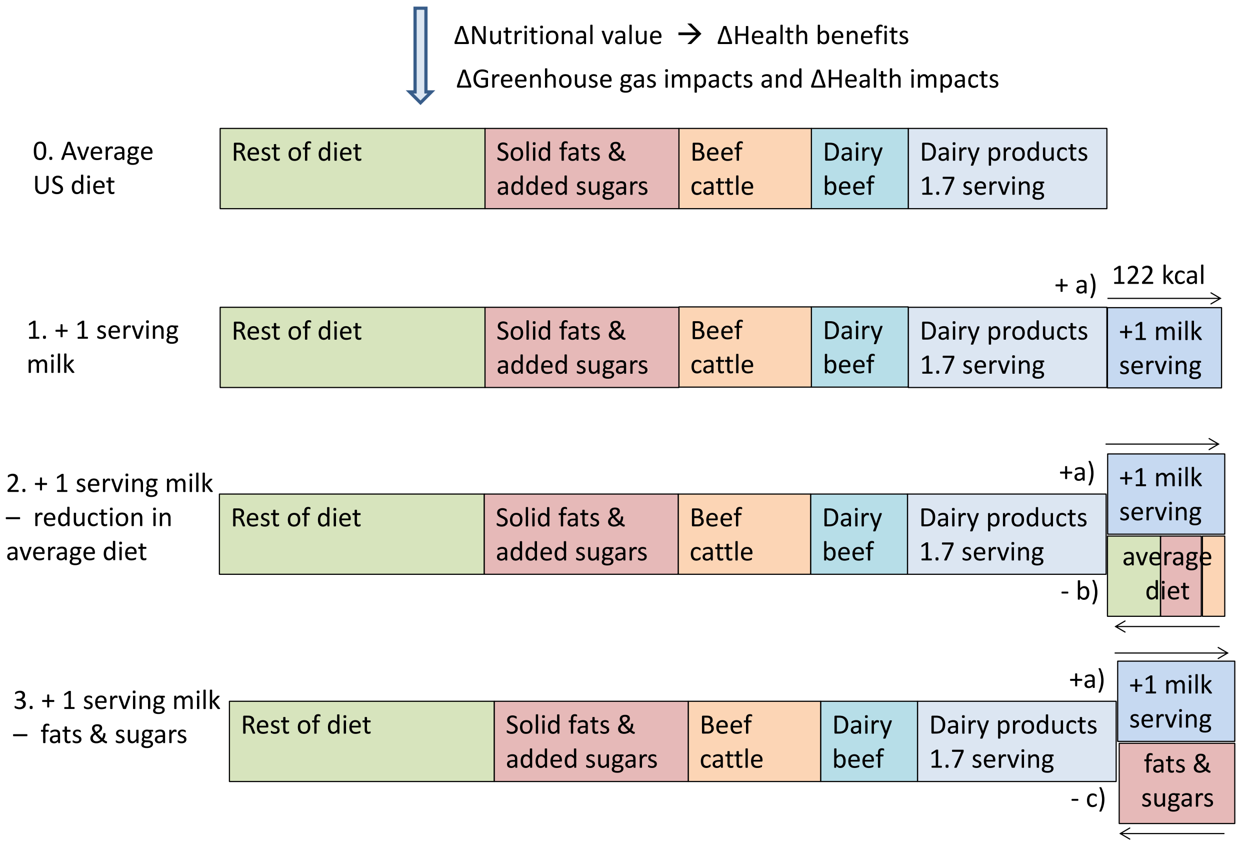

Figure 2. Scenario schematic: Changes in nutritional/health benefits and environmental impacts (greenhouse gas, example) associated with one additional serving of milk within the diet.

1. Add an additional serving (1 cup) of "2% milk," that is fluid milk containing 2% fat, (per capita per day) to the diet, with no change to the rest of the diet; i.e., this scenario would result in an increased caloric intake over the average diet baseline.
2. Add an additional serving of 2% milk while subtracting an equal caloric quantity from the overall average diet. Thus, the 1 cup of milk would be added to a diet that is proportionally reduced by ~122 kcals (the energy content in 1 cup of 2% milk). The resulting diet would be iso-caloric with the average diet baseline.
3. Add an additional 1 cup of 2% milk while subtracting an equal caloric quantity of "empty calorie" foods. This will likely be a proportional representation from the Dietary Guidelines' "solid fats and added sugars" category. The resulting diet would be iso-caloric with the average diet baseline.

We use these specific scenario decisions based on the following logic: In response to dissemination of dietary guidelines, consumers may acknowledge the governmental recommendation for increasing lower-fat dairy consumption, and chose to supplement their diet with a low-fat milk product (here considered 2% fat, because it is the most commonly consumed lower fat form of milk). This dietary change: 1) may not result in compensatory removal of equivalent calories from the rest of the diet (e.g. Duffy and Popkin 2007); 2) may result in compensatory removal of calories resulting in an a diet approximately iso-caloric to before dairy supplementation; 3) may result in removal of other beverages such as sodas from the diet (e.g. Cavadini et al. 2000).

3. Results compilation and case study

3.1. Nutrition-oriented assessment and relation to health

To assess nutrition-related health impacts, we use a global burden of disease (GBD) approach, building off of Murray et al. (2013) and Lim et al. (2012). Specifically, we build on the risk ratios from the GBD sources and minimum risk thresholds to extend nutrition-oriented work that associates nutritional/dietary benefits and risks with DALYs.

The benefits associated with increasing dairy consumption are dependent on the status-quo consumption or dairy products. Within the GBD risk framework, there are no additional health benefits to increase servings above the consumption threshold corresponding to the reported *minimum risk level*. Given the adult population (19+ yrs) in NHANES 2009-2010 had a reported milk intake of 0.87 cup per day (unpublished data), we can calculate the increase in amount of milk to reach the milk consumption threshold corresponding to the minimal risk level according to Lim, et al (2012). Assuming we standardize milk to 2% reduced fat milk with 236 g/cup, we estimate that currently American adults are consuming 205 g milk/day (the product of 0.87 cup and 236 g/cup). With a reported minimum risk threshold level of 450 g/day, we can deduce that adult Americans would need to consume *an additional* 245 g milk per day on average, which is about 1.04 cups (245 g milk/236 g per cup), to reach the minimal risk level outlined in Lim et al., (2012).

As a comparative exploration, we perform the same calculation based on nutrients instead of dairy or milk as a whole-food. The reported minimal risk for calcium intake is 1200 mg/day. Assuming a non-dairy calcium intake of about 385 mg/day (Fulgoni et al. 2011) and calcium from dairy as 516 mg calcium (1.72 cup equivalents of all dairy products from NHANES 2009-2010 with each cup equivalent having approximately 300 mg of calcium) we deduce we need an additional 299 mg calcium/day (1200-385-516=299) to achieve the minimal risk level outlined in Lim et al., (2012). Again, this corresponds to about one cup of 2% milk.

It appears Murray, et al., (2013) used ounces of weight rather than fluid ounces for their calculation for impact of milk (226.8g/8 oz=28.35g). To keep units similar to relative risks we can perform similar calculations; based on these relative risks, the change in milk in cup equivalents is 0.96 cup eq of 2% milk, which again corresponds to about one cup.

These different preliminary calculations suggest that an increase of *one serving of milk* will maximize health benefits for the primary dairy-related risk categories. Increases above this level would increase impacts without additional benefits in these categories. Further research will be needed to define minimal risks for other health categories (e.g., bone health, blood pressure).

3.2. Quantification of greenhouse gas emissions

Detailed results from the Innovation Center sponsored milk LCA studies (Thoma et al. 2013; Henderson et al. 2013) are used to estimate greenhouse gas emissions from the life cycle of fluid milk production. Additionally, to broadly estimate GHG emissions from the general diet we generate a dataset of 250 data points aggregated from a variety of published studies on greenhouse gas emissions from the production of specific foods in specific places. Where multiple emission factors exist in the dataset for the same food, an average is taken. For foods without specific data points, proxies are formed by averaging related foods. Several limitations exist in using this dataset: many studies are not specific to US production scenarios; significant variability can exist between studies of the same food; transport and other variables are not treated in a consistent fashion across studies. Still, the dataset is useful for a pilot level study; it captures most of the important foods in the LAFA dataset and is the most reasonable collection of data current available.

3.3. Quantification of Particulate Matter (respiratory inorganics) emissions and related impacts

The largest contributors in typical food and agricultural systems to respiratory inorganic impacts are particulate matter (PM) from internal combustion engines (i.e., tractor use, transportation) and ammonia emissions (a PM precursor), primarily from manure storage and handling. The Comprehensive LCA of Fluid Milk (Henderson et al. 2013) models these emissions (and impacts) related to PM for the US milk production chain, and will thus be used in this case study. Since most published LCA studies on foods do not report these emissions or impacts, we propose the following approach to provide a first order estimate of the PM associated with producing the average US diet. The majority of PM from food systems comes from direct ammonia emissions during agricultural production (generating secondary PM) and from tractor usage and from transportation (primary and secondary PM). A preliminary study carried out on the 4000 Ecoinvent processes shows that PM from all sectors can be interpolated from correlations between PM and greenhouse gas emissions (GHGE), with specific coefficients for agriculture production and for transportation. We estimate the proportion of GHGE from the production of individual food types using studies that report the contribution of field emissions, tractors and transportation to various food group GHGE (Weber and Matthews 2008; Hoolohan et al. 2013; Meier and Christen 2013). These studies will be combined with the Ecoinvent derived correlation to estimate direct emissions of PM2.5 (so-called primary PM) as well as emissions of precursors (NH3, NOx, SO2) of secondary PM (this important PM precursor for the average diet.

As described by Fantke et al. (2014), a starting point to determine the human health impacts associated with primary and secondary particulate is the effort of an earlier UNEP/SETAC working group that has designed a framework and proposed a set of default human intake fractions (iF) associated with PM emissions for use in LCIA (Humbert et al. 2011). This effort was consistent with other consensus building actions in the frame of comparative chemical assessments. However, this effort is limited to the part of the impact pathway from emissions to concentration and human intake, but does not cover the part from human intake to finally health effects. This will be complemented according to the latest recommendations of the LCIA guidance task force for PM related health impacts based on dose-response from the 2010 global burden of disease (Lim et al. 2012; Murray et al. 2013) as well as calculations based on the American Cancer Society Study of Particulate Air Pollution and Mortality (Gronlund et al. 2013; Pope III et al. 2002). Since nutrition impacts and benefits will also be mostly based on the 2010 burden of disease, this will ensure a good consistency between environmental impacts and nutrition.

3.4. Overall trade-offs

With considering only one serving additional in each dietary scenario, preliminary results show the following tendencies. The increase in calories may dominate, generating important additional impacts. In the iso-caloric scenario 2, the nutritional benefit of milk becomes important and will counter balance the human health impacts of PM over the life cycle. Dietary scenario 3 provides the most substantial nutritional advantage by also reducing the nutritional impacts of added sugar. We finally analyze the trade-offs between human health and global warming impacts for each scenario.

4. Discussion

Considering the present US consumption, and limited epidemiological data on disease burden, our results suggests that lower-fat milk leads to nutritional benefits up to one additional serving. Nutrition is a complex issue and we do not attempt to cover all intricacies in this case study. For example we do not consider non-nutritional health impacts such as social/cultural issues with dietary changes, or other health related issues such as bowel motility or indigestion related to lactose intolerance. We also do not consider possible variations in health impacts for different age groups (i.e. a health advantage of consuming dairy may be more measurable for children and teenagers than for elderly populations) and consider the general order of magnitude of potential impacts at the population scale and not the health impacts for a given individual. We also do not consider at this stage other potential benefits of dairy products on other risk areas such as bone health and blood pressure, whereas the Lim et al. (2012) and Murray et al (2013) studies consider only carcinogenic risks (e.g. balancing associations of dairy consumption with decreased risk of colorectal cancer and increased risk of prostate cancer).

It is important as population grows and food and environmental resources become strained that research continues on harmonizing nutritional and environmental public health impacts of foods and diets. This study assesses epidemiological data on disease burden in relation to one food group (dairy) and one associated nutrient (calcium) in the context of governmental dietary regulations and LCA. This type of analysis may help regulators in selection of dietary guidelines and promote holistic consideration of both the environment and the direct nutritional implications. Our findings emphasize a clear need for more research on dietary choices and for understanding whether or not shifts in the diet are compensated for by other food groups. Generally the framework we present provides the groundwork for considering both the nutritional and environmental impacts of a specific food, and for also considering the entire dietary context, which we find essential.

5. Conclusion

In all, this work suggests that in order to optimize public health dietary recommendations, nutritional impacts and benefits should be considered with respect to the entire diet as well as the food's life cycle. This work provides a stepping-stone for consistently incorporating nutritional effects into an LCA framework.

Accounting for the nutritional function of food is a perennial problem in assessing the environmental impact of food production in the LCA framework. The review presented here outlines a functional unit approach that also includes dietary context. We propose a novel framework for bringing environmental and nutritional aspects of food together using the global burden of disease approach to evaluating risk factors using the DALY metric. This approach allows expression of behavioral choices such as diet composition in terms of the associated disease risks. Under such a framework, nutritional and environmental health impacts of a dietary change may be evaluated in equivalent units, permitting a quantitative estimate of the complements and trade-offs between nutrition and environment. Regarding the limited epidemiological data relating food items to possible health impacts, these preliminary investigations do not offer exact calculations or the health risks for a given individual, but instead should be considered as an indication of the importance of balancing nutritional and environmental health impacts, as these may lead to contradicting conclusions depending on the population-scale dietary context.

ABSTRACT

Life cycle assessments (LCA) on the environmental and public health impacts of food and beverage packaging materials have found some advantages to plastic over glass. Entirely missing from these evaluations are the health impacts of possible chemical, e.g. endocrine disruptor, exposure through migration of chemicals from the packaging into the food product. We build a framework based on a life cycle perspective to predict which chemicals may be in a package that are not intentionally added ingredients, and we apply this approach to the US EPA's CPCAT database. In total we find 1,154 chemicals within the CPCAT database related to food-contact materials; out of these 107 are potential endocrine disruptors according to the TEDX list of endocrine disruptors. We also build a framework in an effort to begin harmonizing LCA to include health impacts of chemical exposure related to food packaging in conjunction with other traditional LCA environmental impact categories.

Keywords: Endocrine disruptor, exposure, food packaging, LCA

1. Introduction

Life cycle assessment (LCA) has long guided industry in selection of food and beverage packaging materials to minimize environmental and human health impacts (Curran 1993; Humbert et al. 2009; Marsh et al. 2007; Roy et al. 2009). Often, results suggest that plastic packaging has marginally better performance than glass, for instance for baby food containers (Humbert et al. 2009) or for alcoholic beverages (Smith, 2009). Packaging efficacy and chemical emissions during transport and disposal have been the focal issues in these LCAs. Although human health may be a relevant impact category in such LCAs, for instance due to inhalation of particulate matter or organic chemicals, lacking from these impact assessments is addressing the possibility of chemicals leaching from packaging into the ingestible products. Contamination of food products from packaging has been documented, and of particular concern are plastics and paper treated with fluorinated chemicals (Loyo-Rosales et al. 2004; Muncke et al. 2011; Tittlemier et al. 2007; Trier et al. 2011; Wagner et al. 2009). Some fluorinated and plastic-associated chemicals have demonstrated endocrine disrupting properties, meaning they may interfere with various natural hormone systems within the human body (Muncke et al. 2014; Zoeller et al. 2012). Endocrine disruptors are a chemical category of high exposure concern and are particularly complex to assess because of their atypical toxicology, often with non-linear dose-response curves and substantial low-dose effects, as well as various effects in exposed populations due to interference with hormone-dependent human development and functioning (Colborn et al. 1993; Vandenberg et al. 2012). To our knowledge, exposure to endocrine disruptors through ingestion of packaged foods has not been addressed in LCAs. In general, LCAs evaluating health impacts of consumer products, even food products, focus on health impacts due to exposure to and intake of environmental pollutants and health impacts due to chemicals embodied within the product are neglected.

Empirical evidence suggests that food contact materials, such as packaging, lead to human exposure to chemicals of concern (Loyo-Rosales et al. 2004; Tittlemier et al. 2007; Wagner et al. 2009). For example, significantly lower levels of potentially endocrine disrupting chemicals bisphenol A and bis(2-ethyhexyl) phthalate were observed in the urine of participants while undergoing a "fresh food diet intervention," where packaged foods were limited (Rudel et al. 2011). In all, substantial evidence suggests humans are exposed to chemicals within food packaging, and thus this exposure avenue must be considered in LCAs of food packaging materials in order to provide a holistic assessment of product impacts.

Risk assessment is a parallel field of study to LCA which also offers insight regarding the exposure to and human health risks of chemicals contained in e.g. consumer products. For instance, risk assessments of chemicals within consumer products tend to focus on risks associated with the product's ingredients (Wormuth et al. 2007). Although considering ingredients is an essential first step, this strategy neglects chemicals which may be in the food packaging product that are not added intentionally as a final ingredient (Muncke et al. 2014). Thus, whether product-associated health risks are considered from a risk or LCA perspective, considering the general life cycle perspective of a food package offers a more holistic consideration of what chemicals may end up in the food due to packaging that were not intentionally added package ingredients.

The present study aims to *provide a framework to incorporate toxicological health impacts due to exposure to chemicals in food packaging* that is harmonized with established LCIA frameworks used to calculate human toxicological health impacts due to life cycle environmental emissions. We consider the life cycle perspective in two distinct ways: 1) the life cycle perspective is applied in an effort to determine all possible avenues of chemical incorporation into a food package and thus into a food product and 2) the life cycle perspective is applied as an overall framework to calculate human health impacts which may result from different stages of the food product's existence.

2. Framework development

2.1. Life cycle consideration to identify chemical constituents

Literature review suggests human ingestion of chemicals due to food packaging may be influenced from various life cycle stages and through various avenues (Figure 1.). These influences were split into two distinct sequences representing before packaging and after and during packaging. For example, before a product was distributed to consumers, chemicals may be incorporated into food packaging because they: were the result of a chemical reaction or incomplete chemical reaction occurring during material acquisition or manufacturing (Muncke et al. 2014), they were ingredients of the raw materials or ingredients required for manufacturing (Lau et al. 2000; Tittlemier et al. 2007; Trier et al. 2011), or they were incorporated incidentally during manufacturing through contamination from equipment or the environment, as for instance is observed in other consumer products such as tampons (FDA, 2013). Likewise, during and after the packaging process, that is while and after the food was enclosed by the package, although contamination of the packaging material may now be negligible, migration or diffusion of chemicals from packaging into the food may occur. Migration may occur passively through the passage of time depending on temperature, pressure, and the physicochemical interactions of the food-package combination. Additionally, there are various processes which require further consideration. For example, food pasteurization through thermal sterilization often occurs within the packaging (Ranken et al. 1997), or a consumer may microwave the food within the package (Begley et al. 2005); these processes may increase migration of chemicals into the food item or cause a heat-dependent chemical reaction.

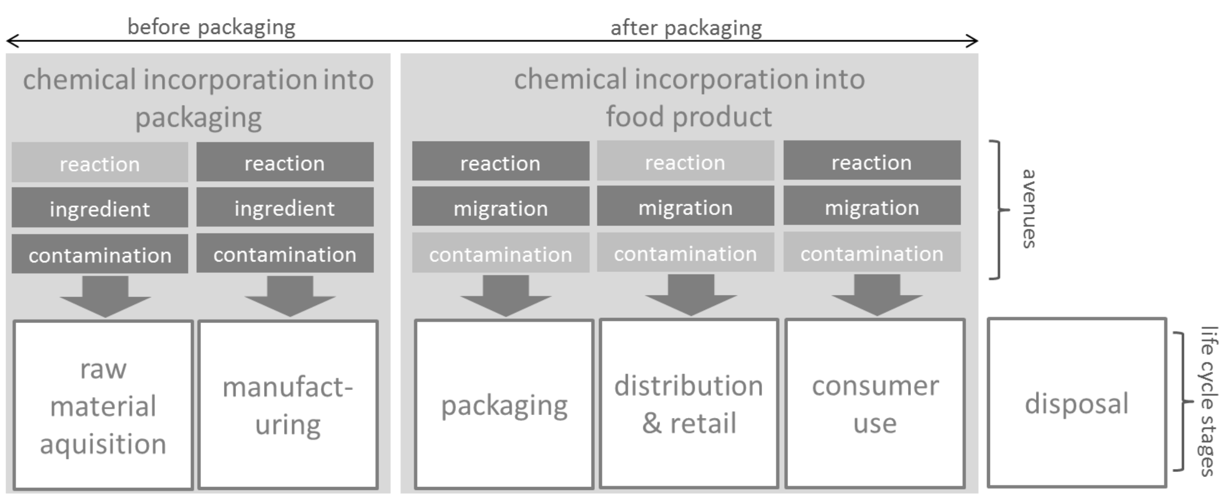

Figure 1. Relevant stages of a packaged food product life cycle, where (1) chemicals may be incorporated into the package, and (2) where these chemicals may be subsequently incorporated into the food product by various avenues (light shaded avenues are considered less relevant).

To obtain preliminary information from a life cycle perspective on which chemicals may be within food via food packaging, we mined the newly developed consumer product category (CPCAT) database publically available through the US EPA (Dionisio et al. 2014, in preparation) to look at chemicals known to be in food contact materials, as well as those known to be used in manufacturing, and as raw materials.

2.2. Development of a framework to incorporate chemical exposure to food packaging in LCA

In our framework development we considered that LCAs which include human health impacts of food packaging products may be performed using an ISO framework, generally with the following phases: 1) defining the goal and scope of the study and relevant life cycle stages; 2) collection and analysis of inventory, that is inputs and outputs of the product system; 3) assessment of impacts associated with outputs of the product system; and 4) interpretation of impacts. Typical relevant stages of a product's life cycle include, but are not limited to: the acquisition of raw materials, manufacturing, distribution, use of product, and disposal of the product. Throughout and between these life cycle stages there may be various processes also contributing to emissions such as due to transportation and waste streams.

In this study, we defined the goal and the scope around the need to include human exposure to chemicals within food packaging into an overall LCA framework in order to holistically quantify associated human health impacts. We therefore defined the relevant life cycle stages required to model this process slightly differently from traditional LCA life cycle stages. To summarize from Section 2.1, chemicals may end up in a food product via the packaging through acquired raw materials, while manufactured, while the actual packaging occurred, while the food was distributed and retailed, and while the consumer used the food product (Figure 2, top row of boxes and solid lines).

Likewise, each of these steps may lead to environmental emissions due to for example waste streams or energy use; further the disposal of the food packaging must also be considered to evaluate environmental emissions (Figure 2, top row of boxes and dotted lines). Disposal may also be important to evaluating the population-scale intake of chemicals within foods due to packaging, if food waste is significant. Inventory analysis needs to account for environmental emissions throughout the life cycle of the product, for instance from raw material acquisition to the disposal and any transportation processes occurring between and within different stages. Using the CPCAT database, a parallel inventorying process was performed analysing the various chemical inputs resulting from distinct life cycle stages in order to predict which chemicals and to what extent they may end up in a packaged food product.

In order to assess the impacts of these parallel inventories, exposure and intake of chemicals must be assessed. The intake fraction, iF, concept (Bennett et al. 2002) is often employed in LCIA models assessing human-toxicological impacts from chemical. Likewise, the product intake fraction, PiF, (Jolliet et al. 2014 in preparation; Ernstoff et al. 2014 in preparation) is a concept proposed for use in LCIA to estimate population-scale and product-user intake of substances contained in the product. The end goal was to assess the overall human health impact from exposure to chemicals in food packaging materials. This required consistent consideration of the health impacts due to environmental emissions (i.e. using the iF) versus health impacts due to use stage exposure and intake of chemicals in the food package migrating into the food product (i.e. using the PiF).

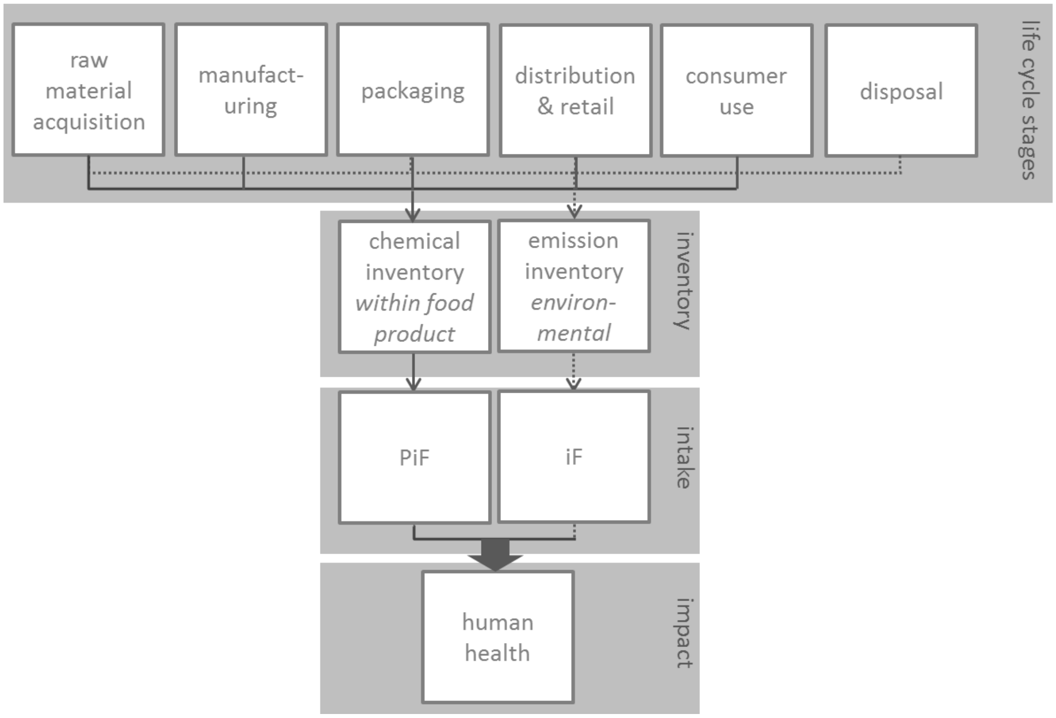

Figure 2. Contribution of relevant stages of the package's life cycle to human health impacts. Solid lines correspond to avenues in which chemicals may be incorporated into a food product, leading to human exposure and intake calculated as a product intake fraction (PiF) and dotted lines correspond to avenues in which chemicals may be emitted to the environment, leading to subsequent human exposure and intake calculated as an intake fraction (iF).

2.3.Issue of endocrine disruption

Many chemicals used within food packaging are known or suspected endocrine disruptors (Muncke et al. 2014). Perhaps due to their complicated and atypical toxicology (e.g. non-linear and non-monotonic dose response curves) (Vandenberg et al. 2012), to our knowledge, there are no methods to incorporate endocrine disruption toxicity into an LCIA framework for human-toxicological impacts, which currently relies on the assumption of a linear dose response (Rosenbaum et al. 2011). In an effort to begin including endocrine disruptors into LCIA we first employed a flagging method where chemicals were flagged if they are on lists of suspected endocrine disruptors (e.g. TEDX 2014). From here we investigated EPA approaches to approximate low-dose nonlinear chemical exposures, where at the population scale, due to tremendous individual variation, a near linear dose-response may be observed, Figure 3. (US EPA 2009).

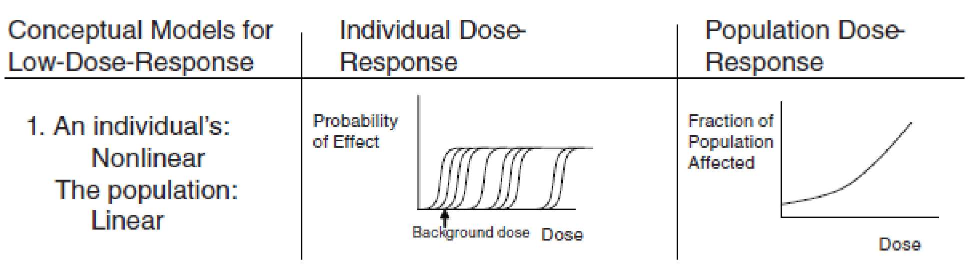

Figure 3. Demonstration of possible population scale linear dose response even when an individual's dose response may be nonlinear, taken from US EPA (2009).

3. Results

The main purpose of this paper was to develop a framework to consider exposure to chemicals within food packaging, as well as to better assess which chemicals may be incorporated into a food package and subsequently into a food product along the supply chain, therefore the main results were demonstrated in the framework development section above. Additionally, we mined the newly released US EPA consumer product category (CPCAT) database to begin understanding which chemicals may be in food products due to food packaging. In total we find 1,154 chemicals within the CPCAT database related to food-contact materials; out of these 107 are potential endocrine disruptors according to the TEDX list of endocrine disruptors. When distinguishing by life cycle stage, we find 235 chemicals associated with use as *raw materials* for food-contact products, such as packaging; 52 of these are potential endocrine disruptors. For the *manufacturing* life cycle stage we find 12 chemicals, 4 of which are potential endocrine disruptors. Table 1 shows all the manufacturing related chemicals and a sub-sample of the raw-materials related chemicals. When looking to understand the chemicals in a food package which may not be listed ingredients, raw material and manufacturing labels within CPCAT are the two distinguishable life cycle stages. All the other chemicals associated to food contact materials within the CPCAT database are listed in the database associated with the given product and thus are likely intentionally added ingredients.

Table 1. Example of chemicals likely used in food packaging manufacturing as they are listed in the CPCAT database as chemicals approved for manufacturing of food-contact materials.

Life cycle stage	CAS RN	Chemical Name	Potential endocrine disruptors
Raw material	106-89-8	1-chloro-2,3-epoxypropane	X
Raw material	126-99-8	2-chlorobuta-1,3-diene	X
Raw material	149-57-5	2-ethyl-1-hexanoic acid	X
Manufacturing	63148-62-9	baysilon	
Manufacturing	71-43-2	benzene	X
Raw material	117-81-7	bis(2-ethylhexyl) phthalate	X
Raw material	80-05-7	bisphenol A	X
Manufacturing	10043-35-3	boric acid	X
Raw material	84-74-2	dibutyl phthalate	X
Raw material	75-21-8	ethylene oxide	X
Raw material	96-45-7	imidazolidine-2-thione	X
Manufacturing	7664-38-2	orthophosphoric acid	
Raw material	131-57-7	oxybenzone	X
Manufacturing	25322-68-3	polyox WSR-N 60	
Raw material	25013-16-5	tert-butyl-4-methoxyphenol	X
Manufacturing	13463-67-7	titanium dioxide	
Manufacturing	108-88-3	toluene	X
Manufacturing	1330-20-7	xylene	X
Raw material	137-30-4	ziram	X

4. Discussion

The development of this framework is an iterative process and further insight will be gained for example, when case studies are implemented. In this discussion we focus on issues related to understanding chemical exposures due to food packaging, and do not address uncertainties related to the traditional LCIA approaches regarding environmental emission inventory of toxic chemicals.

It is difficult to identify the vast number of chemicals which may end up in a food product due to packaging because of the various contributions of the life cycle stages, and the CPCAT database is certainly not exhaustive. Further, once the chemical inventory is created and the majority of chemicals within food packaging are identified, large uncertainties are expected when estimating the subsequent concentration or migration potential of each chemical from the packaging into the food. A large amount of data is required on the variables and processes which may influence migration, for example on packaging strategies (e.g. if foods are pasteurized within the packaging), time and average storage temperature during the distribution and retail, and consumer use (e.g. if foods are microwaved within the packaging).

Further, even in the cases when the concentration of a chemical contaminant in the end food product is known perhaps due to analytical detection, data will be needed on population scale ingestion of the food product, and of course toxicity or dose response in the case of estimating resulting health impacts. Specifically for endocrine disruptors, where new information is being generated at a fast rate, we expect many years of research required to provide methods to consistently include such impacts within an LCA framework.

Aside from uncertainties in our analysis and within the defined system boundaries, there are also various considerations outside the scope of this study which may also influence the overall health impact related to a food package. For example, the food package's efficacy in controlling the growth of pathogenic bacteria on food items is an important contribution to human health.

5. Conclusion

In all, we suspect it is essential to include chemical exposures via food packaging in order to estimate the overall health impact of a food product. Many chemicals associated with food contact materials are potential endocrine disruptors and are therefore of particular concern. Insight gained through the life cycle perspective may help identify chemicals of concern which are not intentionally added ingredients, and also help consistently evaluate the extent of a food package's effect on public health both mitigated through environmental emissions and exposure occurring through consuming the packaged food. In this paper we provide the ground-work to advance future work addressing these necessary research gaps and a framework which must be iteratively developed with advances in knowledge.

Indirect Land Use Change and GHG emissions of two biodiesel pathways in Spain

ABSTRACT

Imported biodiesel has accounted for a large share of the total amount consumed in Spain, the main supplier of which was Argentina at least until anti-dumping duties on biodiesel imports from this origin were approved by the European Commission in November 2013. A consequential LCA is carried out in the present study to compare this pathway, which was the prevailing one until almost 2014, with the alternative of using domestic biodiesel from Used Cooking Oil (UCO). System expansion is performed in order to take the indirect functions of both systems into account, functions arising from interactions between co-products (protein meals) in the animal feed market. The marginal suppliers of these co-products in the international market are identified and emissions from direct and indirect Land Use Change (LUC) are calculated. When they are not considered, imported soybean biodiesel leads to lower GHG emissions, due to the carbon uptake by biomass. However, when global LUC is taken into account, UCO biodiesel generates a much lower impact, because it causes a contraction in the area diverted to biofuel feedstock production in other parts of the world. The results underline the importance of considering emissions from LUC when comparing biodiesel alternatives and, thus, interactions in the global market must be addressed.

Keywords: biodiesel, consequential LCA, greenhouse gas, land use change, Used Cooking Oil

1. Introduction

Over the last ten years, the worldwide consumption of biofuels has been on the rise for both economic and political reasons. Together with rising oil prices, public policies have been instrumental in promoting the use of non-petroleum based fuels in countries such as the United States (US), Brazil or the European Union (EU). Specifically, European Directive 2009/28/CE aims to reduce the greenhouse gas (GHG) emissions by introducing a blending mandate of 10% biofuel share in the motor fuel market of the Member States by 2020. However, despite the increased demand for biodiesel in Spain as a consequence of this Directive, the biodiesel sector is currently working at around 10% of its total production capacity. While the renewable energy target in transport, which was 6.5%, was nearly reached in 2012, in that very year imported biodiesel accounted for 79% of the market share (Datacomex 2013). Most of this biodiesel was imported from Argentina, providing almost half of the total consumed.

In addition, this Directive sets out a sustainability criterion requiring biofuels to emit at least 35% less GHG than the replaced fossil fuel; emissions must be calculated over the entire life cycle and must include the emissions from land conversion necessary for the cultivation of the raw materials. This phenomenon, known as Land Use Change (LUC), refers to potential changes in the carbon stock of the soil and biomass that take place when the land is diverted to biofuel production. Apart from the direct LUC (dLUC) as a consequence of an increased demand for biofuels, indirect LUC (iLUC) takes place through global market-mediated effects, prompted by the displacement of existing productive uses. In an attempt to promote the production of biofuels which do not lead to substantial losses of land carbon stock either in the producing region or elsewhere (known as *advanced* biofuels), the EU recently launched another proposal, COM 595 (European Commission, 2012), still under debate. It seeks to minimize GHG emissions from iLUC by limiting the contribution of conventional biofuels to that 10% target, and obliging Member States to report the estimated iLUC emissions from the biofuels they produce.

Against this background, the production of biodiesel from Used Cooking Oil (UCO) in Spain may help to increase the energy independence and boost the national industry, given the requirements imposed by COM 595. In fact, UCO was the second most commonly used feedstock for producing domestic biodiesel in 2011 (CNE 2013). Hence, it constitutes a viable alternative to the importing of biofuels, especially to those coming from feedstock used in the food and feed markets (known as *first generation* biofuels). The aim of this study is to compare overall GHG emissions –including those from iLUC– of two current pathways for biodiesel consumption in Spain: importing soybean biodiesel from Argentina and producing biodiesel from UCO. It must be taken into account though that the imports of biodiesel from Argentina have markedly declined during the first few months of 2014, as a consequence of the anti-dumping duties which have recently been approved by the European Commission (Regulation 490/2013). However, most of the biodiesel is currently produced from imported feedstock, and imports of vegetable oil into the EU have been increasing sharply. Soybean oil from Argentina accounts for a remarkable market share in Spain, only surpassed by palm oil imports from Malaysia and Indonesia. Therefore, this pathway for biodiesel consumption still has iLUC effects, similar to those arising from importing the manufactured product, with the only difference that now the transesterification takes place in Spain.

2. Methods

2.1. System description

A consequential approach is used to perform LCA according to the ISO standards (ISO 2006a, b); this is because crop displacement is the result of interactions among global agricultural markets and, as such, this is the way to quantify these future indirect responses. Economic modeling is a very useful tool with which to quantify these effects, and it has been used by authors such as Banse et al. (2010), Hertel et al. (2010) or Kløverpris et al. (2008) in the field of bioenergy. However, some practitioners have developed a methodology for quantifying the environmental consequences of increased biofuel consumption within the LCA framework (Dalgaard et al. 2008; Reinhard and Zah 2009, 2011; Schmidt 2010; Schmidt and Weidema 2008). It is based on system expansion, in order also to include interactions due to biofuel co-products such as protein meals, which may fulfill different functions in other markets. These studies are built on causal relationships, which model the substitution effects between those *marginal suppliers* affected by changes in the production system. The marginal supplier of a co-product is defined by Weidema (2003) as the most competitive in the international market. For each co-product, the marginal supplier of the substitute must be identified.

According to the procedure described by Weidema (2003), two scenarios are defined: Scenario 1, where soybean biodiesel is imported from Argentina, and Scenario 2, where it is produced from UCO collected in Spain. The functional unit is 1 MJ of biodiesel in regional storage in Spain. Scenario 1 mainly consists of *soybean farming*, *soybean oil extraction* and the subsequent oil refining, *soybean methyl-ester (ME) production* by transesterification and *soybean ME export to Spain* by tanker. Scenario 2 includes *UCO collection*, *UCO-ME production* and *transport within Spain*. Furthermore, due to market responses, a loop between co-products is identified and iterated against 0 to estimate the indirect effects of 1 additional MJ of biodiesel consumed in Spain, following the same principles used by Dalgaard et al. (2008) and Reinhard and Zah (2009).

In Scenario 1, it is assumed that increasing the production of soybean ME in Argentina to meet the Spanish demand reduces the amount of soybean oil in the international market, the shortage of which has to be compensated for by Malaysia as the marginal supplier of vegetable oil. According to the *ceteris paribus* assumption (Ekvall 2000), the demand for Malaysian oil expands 1:1, with the subsequent expansion in the agricultural land. As side effects, palm kernel meal production increases too, affecting the demand for Brazilian soybean meal in the animal feed market. The loop between the soybean meal and the soybean oil leads to a net increase in the production of palm oil in Malaysia (+25.27 g), and to a decrease in the production of soybean meal in Brazil (-3.44 g), as can be seen in Figure 1. The Argentinian soybean meal, obtained as a co-product of the oil extraction, is a stable commodity in the feed market, with a global demand which is assumed to remain constant despite the increase in demand for biodiesel in Spain. Hence, it is not involved in the loop.

In Scenario 2, using UCO to produce domestic biodiesel avoids the need to import crude palm oil from the marginal supplier, which is again assumed to be Malaysia, since palm oil stands out as the least expensive oil in the international market and Malaysia is the world’s largest exporter (MPOB 2012). Similarly to Scenario 1, it is assumed that this country reduces palm oil production, and less palm kernel meal is thus available. The gap left in the market supply is filled with meal from Brazil, with the subsequent LUC effects. The resulting loop causes a contraction of palm oil production in Malaysia (-26.31 g) and an expansion of soybean meal production in Brazil (+3.58 g), as shown in Figure 2.

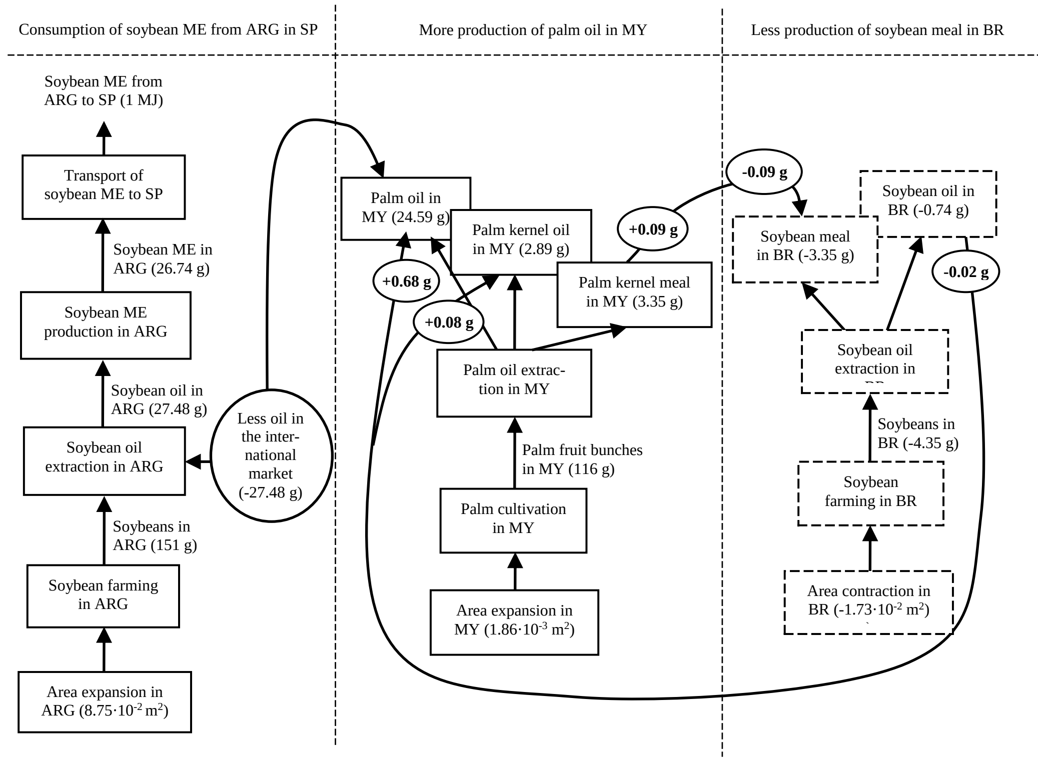

Figure 1. Delimitation of the system under study in Scenario 1. The loop between palm oil and soybean meal in the global market is iterated against zero and the resulting amounts of both are shown in the circles. SP: Spain; ARG: Argentina; BR: Brazil; MY: Malaysia.

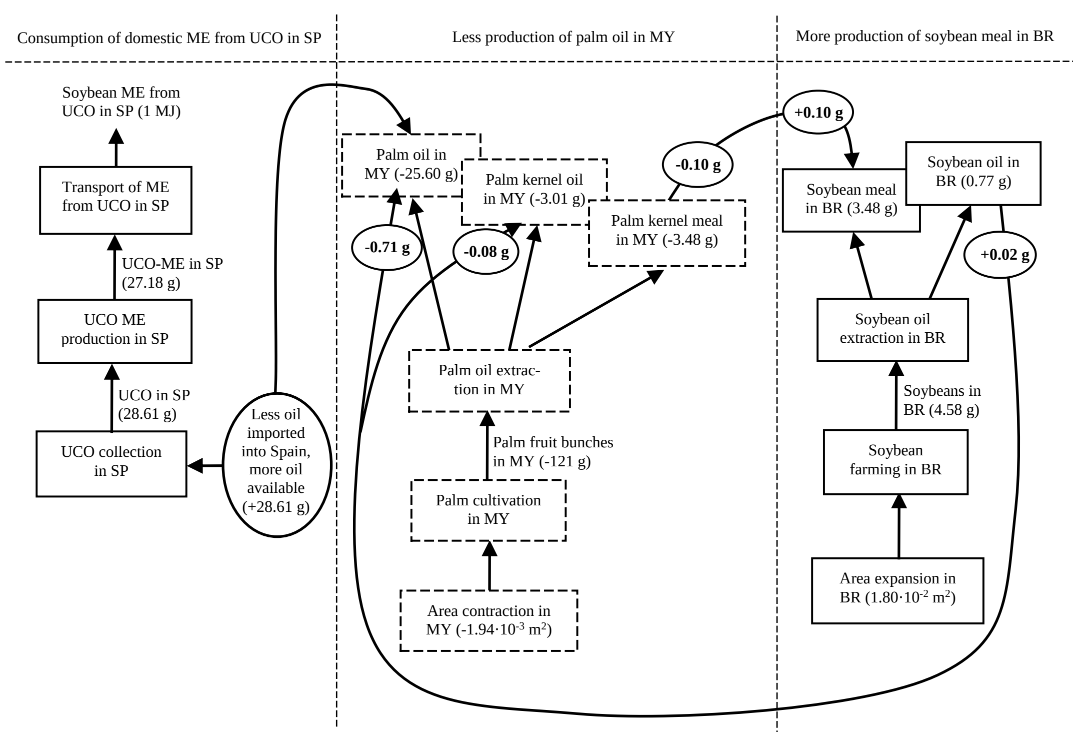

Figure 2. Delimitation of the system under study in Scenario 2. The loop between palm oil and soybean meal in the global market is iterated against zero and the resulting amounts of both are shown in the circles. SP: Spain; BR: Brazil; MY: Malaysia.

2.2. Inventory data

Inventory is drawn from primary and secondary data sources. In Scenario 1, the soybean ME pathway in Argentina is entirely gathered from the inventory of Panichelli et al. (2009). For the export sub-stage, it is considered that the biodiesel is transported first by lorry to the port of Rosario, then to Rotterdam (The Netherlands) by transoceanic tanker, and finally to Valencia (Spain) by lorry. In Scenario 2, all the data relative to the UCO-ME pathway in Spain is provided by the company Bionorte (Asturias, Spain), a representative company of the sector. The distance for the transport of UCO-ME within Spain is that between Bionorte and Valencia, whereas the UCO collection distance is estimated to be 100 km, the same as in the study by Vinyes et al. (2013) analyzing the system consisting of urban collection points. The processes for the production of palm oil in Malaysia and soybean meal in Brazil, common to both scenarios, are taken from the Ecoinvent v.2.2 database (Hischier et al. 2010). The production and provision of all the inputs, including fuel and energy, is included in each sub-stage and taken from the same database, as well as the average transportation systems.

The CML 2 impact assessment method (Guinée et al. 2002) is applied to analyze the impact category Global Warming (GW, 100 years). GHG emissions from dLUC and iLUC are calculated and taken into account for the GW assessment. With this aim in mind, the area diverted to arable land must be multiplied by different emission factors depending on its previous use (forest, grassland, shrub land or other crops). These area values associated with each land transformation are taken from Ecoinvent v2.2 for the palm oil production in Malaysia. Updated values from Prudêncio da Silva et al. (2010) are used for the soybean production in Brazil, since they represent the situation in the Mato Grosso, a state which accounts for 87% of the soybean area in the country. Area values from Panichelli et al. (2009) are considered for the soybean crop in Argentina. Emission factors for each land conversion in each country are calculated by following the guidelines of the IPCC (2006), for a baseline of 20 years. Carbon losses are the result of differences in the carbon content in biomass, soil and dead organic matter before and after the LUC. When deforestation takes place, biomass burning is included, following the process in Ecoinvent v2.2.

3. Results

The GW results show that, without considering the LUC effects, imported soybean biodiesel leads to lower GHG emissions. The contribution of each sub-stage to the impact is shown in Figure 3, depending on whether they cause net GW *input* or GW *output*. Overall, Scenario 1 causes a negative impact (carbon uptake), whereas Scenario 2 causes net CO_2-eq. emissions. As can be seen, this is due to the photosynthesis of the soybean plants and palm trees in Argentina and Malaysia, respectively, which makes GW *input* larger than GW *output* in Scenario 1. In Scenario 2, the only process causing carbon uptake is the soybean farming in Brazil, which is not enough to offset net CO_2-eq. from the decreased palm oil production in Malaysia (through plant photosynthesis) and emissions from the other processes in the system. Carbon uptake by Malaysian palm trees counts as negative GW *input* (implying net emissions) in Figure 3 because 121 g fewer palm fruit bunches are produced due to interactions in the global market. As a result, GHG emissions from producing UCO-ME in Spain are 139% higher, relative to the reference situation of importing soybean ME from Argentina.

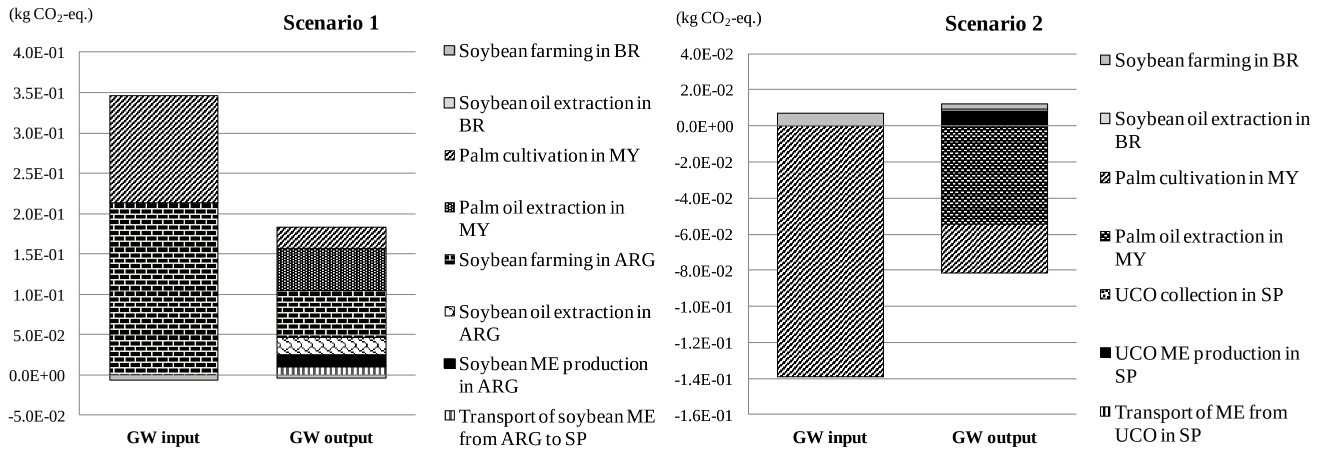

Figure 3. GW results of Scenario 1 and Scenario 2 without considering emissions associated with LUC. SP: Spain; ARG: Argentina; BR: Brazil; MY: Malaysia.

Figure 4 shows the GW results but includes GHG emissions from LUC in their calculation. The UCO-ME pathway then leads to an impact reduction of 103%. In Scenario 1, dLUC in Argentina releases 1137.5 g of CO_2 into the atmosphere, while iLUC in Malaysia is responsible for 221.1 g more, entirely caused by the deforestation of tropical forests; iLUC in Brazil generates an uptake (GW *input*) of 133.8 g of CO_2, because soybean production is falling. Emissions from the entire import chain of soybean biodiesel into Spain are 1028.6 g CO_2-eq., while compensating for the drop in the oil available in the international market with Malaysian palm oil releases another 35.1 g of CO_2-eq. into the atmosphere, even including net carbon uptake in Brazil. As a result, GW *output* is greater than GW *input*, and Scenario 1 generates 1063.7 g of CO_2-eq. On the contrary, Scenario 2 causes a negative overall GW (GW *input* > GW *output*). UCO-ME avoids the production of 28.6 g of CO_2-eq., mainly as a consequence of the area contraction in Malaysia, which causes an uptake of 230.6 g of CO_2, while increasing the agricultural land diverted to soybean in Brazil generates 139.4 g of CO_2.

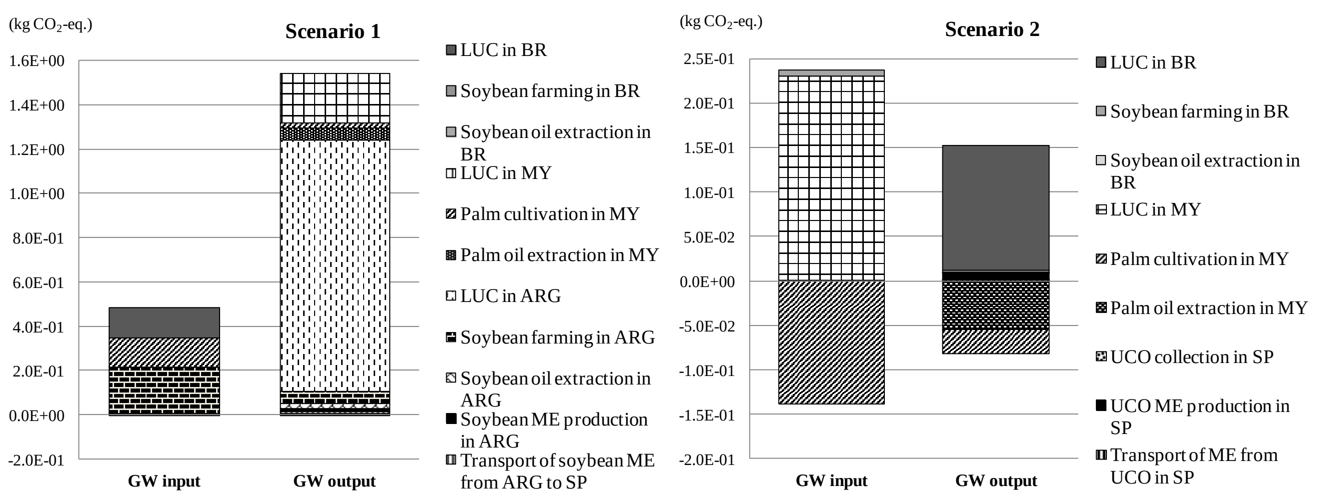

Figure 4. GW results of Scenario 1 and Scenario 2 by taking emissions associated with global LUC into account. SP: Spain; ARG: Argentina; BR: Brazil; MY: Malaysia.

4. Discussion

In Scenario 1, increasing the consumption of biodiesel in Spain by 1 MJ triggers market-mediated responses which, in turn, cause direct land transformation in Argentina, deforestation in Malaysia and area contraction in Brazil. As a result, $8.75 \cdot 10^{-2}$ m^2 of land are diverted to soybean in Argentina, which come from other crops (32%), forest (22%), pasture (27%) and shrub land (19%), according to Panichelli et al. (2009). Similarly,

$1.86 \cdot 10^{-3}$ m^2 of forest are diverted to palm in Malaysia, whereas in Brazil there is an area contraction of $1.73 \cdot 10^{-2}$ m^2. These values are reported in Table 1. Scenario 2 causes an increase of $1.80 \cdot 10^{-2}$ m^2 in the agricultural land in Brazil, while there is a contraction in Malaysia of $1.94 \cdot 10^{-3}$ m^2, as shown in Table 2. Emissions from iLUC are responsible for 92.8% of the GW *input* in Scenario 2, whereas iLUC emissions account for only 8.2% of the overall CO_2-eq. released into the atmosphere by the system in Scenario 1. The most influential sub-stage in Scenario 2 is thus related to an indirect function.

Table 1. LUC results per MJ of biodiesel consumed in Spain in Scenario 1, including direct (in Argentina) and indirect effects (in Malaysia and Brazil).

	Soybean farming in ARG	Palm cultivation in MY	Soybean farming in BR
Transformation from arable land, non-irrigated crops [m2/MJ]	$2.80 \cdot 10^{-2}$	0	$-1.65 \cdot 10^{-2}$
Transformation from forest, clear cutting [m2/MJ]	$1.93 \cdot 10^{-2}$	$1.86 \cdot 10^{-3}$	$-1.73 \cdot 10^{-4}$
Transformation from pasture and meadow [m2/MJ]	$2.36 \cdot 10^{-2}$	0	0
Transformation from shrub land [m2/MJ]	$1.66 \cdot 10^{-2}$	0	$-5.88 \cdot 10^{-4}$
Land Use Change, transformation to arable land [m2/MJ]	$8.75 \cdot 10^{-2}$	$1.86 \cdot 10^{-3}$	$-1.73 \cdot 10^{-2}$

Table 2. LUC results per MJ of biodiesel consumed in Spain in Scenario 2, in terms of only indirect effects (in Malaysia and Brazil).

	Palm cultivation in MY	Soybean farming in BR
Transformation from arable land, non-irrigated crops [m2/MJ]	0	$1.72 \cdot 10^{-2}$
Transformation from forest, clear cutting [m2/MJ]	$-1.94 \cdot 10^{-3}$	$1.80 \cdot 10^{-4}$
Transformation from pasture and meadow [m2/MJ]	0	0
Transformation from shrub land [m2/MJ]	0	$6.12 \cdot 10^{-4}$
Land Use Change, transformation to arable land [m2/MJ]	$-1.94 \cdot 10^{-3}$	$1.80 \cdot 10^{-2}$

These land transformation values for Malaysia correspond to the estimations of Jungbluth et al. (2007), based on historical data for different bioenergy crops. From this, it follows that 100% of the LUC in Malaysia takes place at the expense of tropical rainforests. This type of land conversion leads to substantial carbon losses according to the IPCC (2006), mainly due to the changes in the carbon stock in aboveground and belowground biomass, including dead organic matter, such as wood debris, whose presence is remarkable in areas of tropical rainforests. On the contrary, the establishment of palm oil plantations can generate a gain in the soil carbon stock if it implies reduced tillage with low input, which can even improve the characteristics of the prevailing acidic soils. As can be seen in Figure 4, GHG emissions from iLUC in Malaysia make a significant contribution in both scenarios, since they are enough in themselves to offset the carbon fixation by palm trees during the photosynthesis after the land conversion. However, it must be taken into account that the land transformation values associated with each bioenergy crop are subject to change depending on the temporal and spatial framework considered. As an example, Germer and Sauerborn (2008) found that establishing palm oil plantations in anthropogenic grasslands, which are readily available in Southeastern Asia (long ago converted from forest), can significantly improve the GHG balance of palm oil, after rehabilitation.

Similarly, in our case study, LUC in Brazil occurs at the expense of other arable crops in almost the entire area, but also at the expense of forest (1%) and shrub land (3.4%), according to the situation described by Prudêncio da Silva et al. (2010) for the Mato Grosso. These values are based on historical data for the period 2005-2008. However, soybean expansion has also taken place in Southern States, such as Paraná or Rio Grande do Sul, with a long-standing tradition of agriculture. According to estimations by the same authors, if this second possibility was considered, there would be neither transformation from rainforest nor from savanna. This would even improve the GHG balance of Scenario 2, since the GW *output* would decrease, whereas the GW *input* would be lower in Scenario 1.

As regards LUC in Argentina, land transformation values assumed by Panichelli et al. (2009) are based on 2000-2005 data (Gasparri et al. 2008), a period of great expansion in soybean production in Argentina due to the consolidation of the biodiesel sector in regions such as the EU. It can be assumed though that this situation barely changed during the 2005-2008 period (consistent with data for Brazil). In fact, deforestation still takes place in the region of El Chaco (Aide et al. 2013; Gasparri and Grau 2009). However, considering LUC patterns in the central region of the country (Buenos Aires, Córdoba and Santa Fe) would lead to different results, since there are no native forests and soybean expansion mainly occurs at the expense of other crops.

Considering LUC in Indonesia instead of in Malaysia may have led to different transformation values in Tables 1 and 2 as well, although the emission factors calculated from the IPCC (2006) guidelines for tropical forests should be the same. According to data from the UN-RED programme launched by the United Nations and with the support of the Food and Agriculture Organization (FAO) –among other partners–, in the 20 years from 1983 to 2003, there was a reduction of about 4.9 Mha of forest cover in Malaysia, or an average of 250,000 ha of forest lost annually. However, a recent study by Margono et al. (2014) reveals a loss of primary forest in Indonesia of over 6.02 Mha from 2000 to 2012. Only in 2012, Indonesia lost 840,000 ha of its primary forest, becoming the world's third largest producer of GHG behind China and the US, with 85% of its emissions coming from forest destruction and degradation. This shows that deforestation rates can be highly variable depending on the period considered, and highlights the need to update conversion rates (in terms of ha/year) for each country in databases such as Ecoinvent, in particular for tropical regions in which the palm industry is still expanding. Thus, new rates should be consistent with spatially and temporally explicit observations, since they ultimately determine overall LUC.

This discussion may also contribute to the debate on land use transitions. This concept simply refers to any change in land use systems from one state to another one, while trying to understand the ecological, social and economic circumstances which trigger specific transitions observed in different regions. Specifically, forest transitions have been widely studied, firstly in Europe and the US, and more recently in tropical and sub-tropical regions, in order to explain alternating periods of deforestation and reforestation. According to Lambin and Meyfroidt (2010), LUC is a non-linear phenomenon, which is associated with other biophysical and societal changes and must thus take into account both socio-ecological and socio-economic considerations. For the present study, it has been assumed that LUC effects occur on a global scale, implying that reforestation in one region must be compensated by deforestation in another region, in order to produce the commodities which are no longer produced in the first region. The globalization of timber and agricultural markets is also mentioned by Lambin and Meyfroidt (2010) as an example of a socio-economic force influencing land use transitions. However, due to its dynamic nature, a transition is not a fixed pattern and other political, technological or demographic scenarios could be considered, also including micro-economic considerations about the land tenure system in each region. For instance, it still remains to be seen what will happen with that degraded grassland declared available by Germer and Sauerborn (2008) in Southeastern Asia, whether it will be converted to palm plantations or to tropical forest, depending on government initiatives.

5. Conclusion

As could be expected, biodiesel produced in Spain from domestic UCO performs better than imported soybean biodiesel from Argentina in terms of GW. However, these environmental benefits are not detected if emissions from LUC are not taken into account for the LCA, which can be used as biased results in favor of first generation biofuels, arguing that feedstock production causes carbon uptake due to the photosynthesis and soil carbon storage. Fortunately, most of the recent biofuel policies have mainstreamed iLUC concerns, arising from the increase in the worldwide production of bioenergy. Addressing iLUC effects is thus not temporary, and the consequential approach appears to be an appropriate way of quantifying them within the LCA framework, although there is no consensus on the methodology to apply. The present study shows a case study by using a methodology already developed and accepted within the LCA community, which can contribute to the promotion of the use of biofuels from non-edible biomass (as required by COM 595). This procedure provides additional insights in the analysis of ILUC effects due to a biofuel mandate at country level, which can be used for policy analysis. The results underline the importance of considering indirect effects of biofuel pathways; for this purpose, an analysis of interactions between co-products in the international market is required. A thorough analysis of the uncertainty is recommended in order to reinforce confidence in the comparative assessment, including the variability in land transformation values.

ABSTRACT

The extensive outdoor pig production systems in Corsica are quite different from the conventional production of Europe. Because of the longer lifetime of pigs and the lower technical performance of animals, the environmental impacts of a kilogram of pig until it leaves the farm gates could be expected to be greater. The diets of pig have to be considered because the animals are fed partly with natural feed like acorns and chestnuts. The hypothesis is made that those feedstuffs which grow naturally without any human mediation do not have any environmental impact. Three Corsican systems with an increasing amount of natural feed in the diet were assessed using Life Cycle Assessment (LCA). The results per kg of pig indicate a decrease of 62-81% for selected impacts from the system with the least amount of natural feeding to the more extensive system. By comparison, the conventional production systems of Europe previously assessed by Dourmad et al. (2012) have intermediate results.

Keywords: outdoor pig production, LCA, natural feed

1. Introduction

The extensive outdoor pig production systems in Corsica are quite different from the standard production systems of Europe which have been described and assessed by Dourmad et al. (2012). The animals are raised outdoors, on extensive areas and partially fed with chestnuts and acorns that have fallen directly from trees. Animals can also be left free in the mountain for a transhumance period. Compared to standard production, the technical performance of the pigs is lower, and their lifetime (18-24 months) longer. Therefore, the Corsican pigs are expected to have a higher environmental impact per kilogram of pig, despite an improved quality (Edward 2005).Their natural feed could partially reduce the environmental impact. It is not cultivated or transported by humans. The chestnuts and acorns grow naturally on trees, with no maintenance.

This study performed an environmental assessment by Life Cycle Assessment (LCA) of three outdoor pig production systems in Corsica. The objectives were to quantify the environmental gain on the kilogram of pig produced, reached by the use of natural feed, and also to identify the specific data to collect on such systems to be able to make an evaluation (Webb et al. 2014).

2. Methods

2.1. Description of the three Corsican pig systems

Three extensive outdoor pig production systems in Corsica were investigated (Table 1) and compared to the average conventional system in Europe (Dourmad et al. 2012). The technical data of husbandry methods was collected from farms. Two systems (Farm1 and Farm2) keep the animals on extensive areas where produced feedstuffs are regularly provided to the pigs by the farmer. The pigs supplement their diet by taking acorns and chestnuts from the ground. In a third system (Farm3) a part of the fattening pigs (64%) goes into the mountains for a transhumance period of 135 days per year. During this period, the pigs are not fed at all by the farmer and are dependent on natural feed found in the mountains.

Animal products sold by the Corsican farms are diverse: fattened pigs, piglets and maiden sows. The systems were compared on their common product with results expressed for fattened pigs and sows.

The systems differed by the type and the proportion of produced feedstuffs in the pig diets: grains from crops cultivated in Corsica (maize, barley …), feeds produced in Corsica with Corsican feedstuffs, and feeds coming from metropolitan France. Their amounts and characteristics were considered to estimate the ingestion by the pigs of purchased feeds (Table 2). The Corsican feeds given to the pigs are specific to extensive diets. It is elaborated to complement the seasonal starchy diets with chestnuts and acorns. It takes into consideration the growing characteristics of the pigs and their energy needs. For this reason, the crude protein content of the feeds is higher than in standard production (average content of 13.4% given by Dourmad et al. 2012).

Per sow and compared to Farm1, the amount of produced feedstuffs given to the pigs is respectively lower by half for Farm3 and higher by 18% for Farm 2 (Figure 1). The main difference between Farm1 and Farm2 is the type of diet and its protein content. Farm1 gives mainly concentrated feeds to sows with less quantity of feed and more protein content than in Farm2. Farm 2 gives grains (barley, maize) which correspond to higher quantities of feed with less protein content. For the three systems, the amount of feedstuffs and protein is largely below the amount given in the conventional system of Dourmad et al. (2012) (1330 kg of feed /sow/year and 28 kg N/sow/year). This could be partly explained by the fact that the pigs also ingested natural feed (chestnuts and acorns) which was not considered. But the total protein amount ingested by sows (even with the natural feed included) is known to be less than in standard conditions.

Table 1. Description of the three Corsican pig production systems assessed and comparison with the average conventional system of Europe described by Dourmad et al. (2012)

Units	Description data	Farm 1	Farm 2	Farm 3	*Conventional system of Europe (Dourmad et al. 2012)*

	- Corsican diet 60-20-20		28%		

[a] without natural feed which corresponds to a part of the diet for the Corsican pigs

For the fattening pigs, from weaning to selling, Farm3 is still the most extensive system with lower quantities of produced feedstuffs and nitrogen given to pigs. Farm1 and Farm2 give a close amount of nitrogen coming from the produced feedstuffs, but with half as many feedstuffs for Farm1. This is due to the type of feedstuffs provided with mainly concentrated feeds in Farm1 and with grains in Farm2. The comparison with the European standard production of Dourmad et al. (2012) (267 kg of feed/pig and 6.8 kg N/pig) shows higher amounts of feedstuffs and nitrogen given to the pigs for Farm1 and Farm2 (Figure 1). This is due to the lifetime of the pigs which is three times longer (18-24 months) than in standard production. The amount of feed could also be explained by lower technical performances and a lower adaptation of the feeds to the physiological needs of the animals. However, Corsican pigs also eat natural feed which is not presented on figure 1. By considering it, the difference with conventional production would be greater. Farm3 has lower amounts of feed and nitrogen per pig compared to conventional system because the proportion of natural feed is greater.

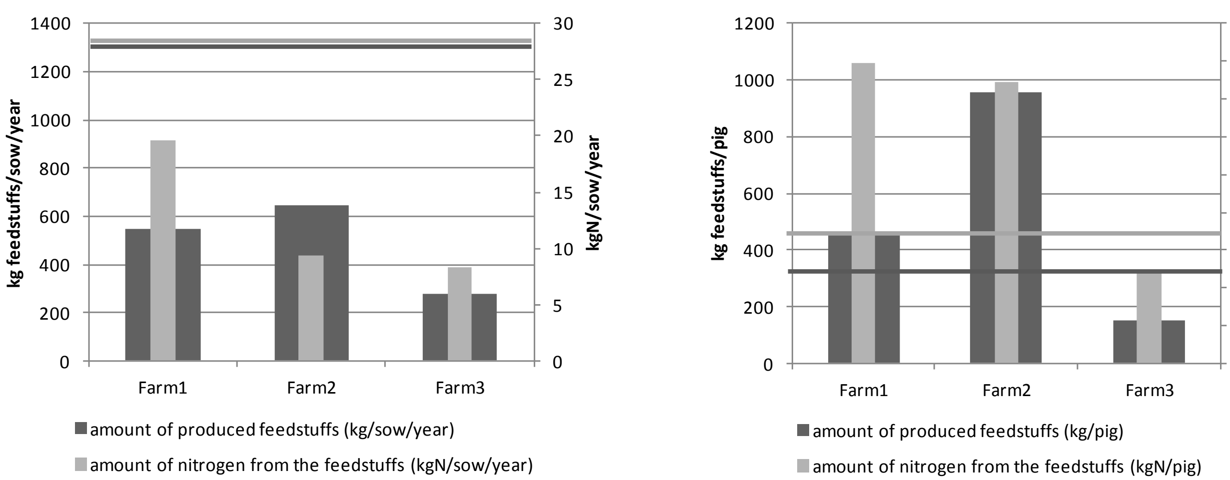

Figure 1. Produced feedstuffs in the diet of sows and fattening pigs of the Corsican systems compared to the standard production of Dourmad et al. (2012)

2.2. LCA assessment

The three extensive outdoor pig production systems in Corsica are assessed, using Life Cycle Assessment (LCA) for the impacts: climate change (kg CO_2eq), acidification (kg SO_2eq), eutrophication (kg PO_4^{3-}eq), energy consumption (MJ) and land occupation ($m^2.year^{-1}$). The environmental impacts are calculated at farm gate, including the production and supply of inputs (feedstuffs, sheds, primary sows, and boars) (Figure 2). The results are expressed per kg of live weight of the two co-products (sows and fattening pigs). At the farrowing unit, an allocation was made between culled sows and piglets and corresponded to the energetic valorization of the feed (Gac et al. 2014): 60% for the culled sows and 40% to the piglets.

The ingestion of natural feeds (chestnuts, acorns) is not considered in the Life cycle perimeter because the fluxes linked to their production are natural (not linked to human activities) and those due to their degradation (NH_3, N_2O and CH_4 gaseous emissions, NO_3- and P losses) would occur without the presence of the pigs.

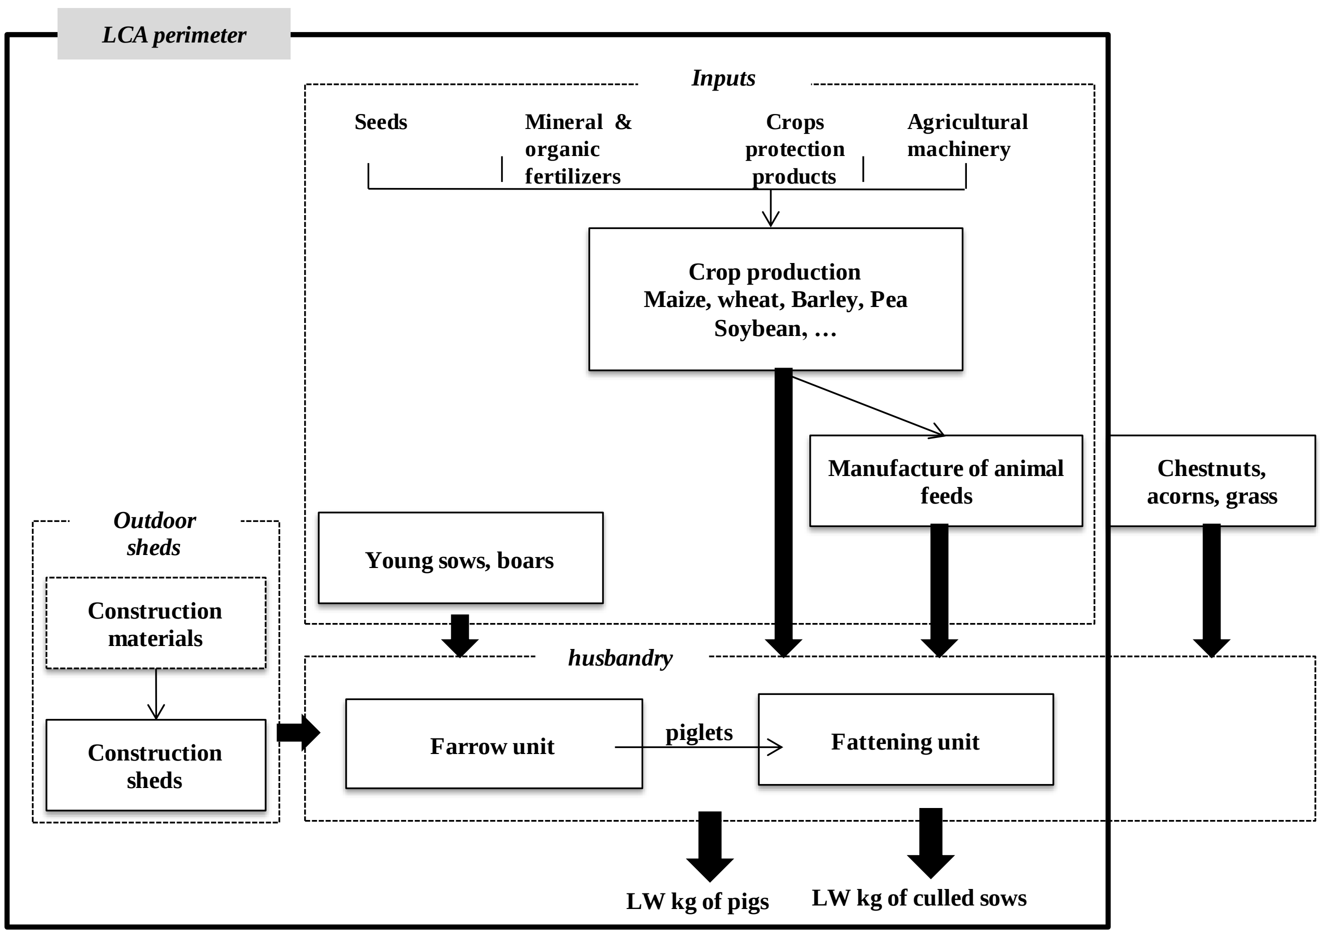

Figure 2. LCA perimeter

Details of the amount and characteristics of the feedstuffs given to the pigs were collected at the farm, and provided by the farmers. The LCA data of metropolitan ingredients of the diet were chosen from a national database (Bouter et al. 2012) and LCA was performed for Corsican barley and maize considering the key data presented in Table 3. For the barley, the straw in Corsica is sold as the grain. An economic allocation was made to consider this specificity: 60% for the grain and 40% for the straw. For the other crops, all the impacts were allocated to the grain.

Table 3. Characteristics of Corsican barley and maize (collected at farm)

Description data	Corsican barley	Corsican maize
N mineral (kg/ha)	40	253
P_2O_5 (triple superphosphate) (kg/ha)	100	139
K_2O (potassium oxide) (kg/ha)	100	
Seed for sowing (kg/ha)	175	26.2
Pesticide (active ingredient) (kg/ha)	0.9	1.23
Diesel (l/ha)	40	91.6
Irrigation water (m^3/ha)	31	2900
Electricity consumption (kWh/ha)		1131
Yield (q/ha)	45	127
Straw (kg/ha)	60	

Sheds were considered for the sows and piglets of the farrowing units with 160 kg of galvanized steel sheets and 0.5 m^3 of concrete per shed. No other infrastructure is used in the three farms. No direct energy consumption is needed for the pig units.

The environmental emissions linked to the excretions of the pigs were assessed with emission factors applied only on the part of the excretion due to purchased feed. The excretion due to natural feed was not considered. The ammonia emissions were calculated with the emission factors of the EMEP/EEA Tier 2 (2009) (eq.1). The method of IPCC Tier 1 (2006) was used to assess, the nitrous oxide emissions (eq. 3.), the methane emissions from enteric fermentation (eq 4.) and the nitrogen leaching (eq. 2.). The IPCC tier 2 (2006) method was used for the methane emissions from the manure management (eq.5). The equation of Nemecek and Kägi (2007) estimated the phosphorous losses.

$$NH_3 = N\ excreted_{\ produced\ feed} \times 0.7 \times EFNH_3 \times 17/14 \qquad eq.1$$
$$NO_3 = N\ excreted_{\ produced\ feed} \times EFNO_3 \times 62/14 \qquad eq.2$$
$$N_2O = (N\ excreted_{\ produced\ feed} \times EFN_2O + NH_3 \times 14/17 \times 0.1\% + NO_3 \times 0.1\%) \times 44/28 \qquad eq.3$$
$$CH_4\ enteric = EFCH_4\ enteric \times AAP \qquad eq.4$$
$$CH_4\ manure = VS_{\ produced\ feed} \times 0.65 \times 0.67 \times EFCH_4\ outdoor \qquad eq.5$$

Where NH_3 emitted = annual ammonia emitted, kg NH_3
NO_3 leached = annual nitrate leached, kg NO_3
N_2O emitted = annual nitrous oxide emitted, kg N_2O
N excreted $_{produced\ feed}$ = annual nitrogen excreted by the pigs coming from produced feed ingested, kg N
0.7 = kg TAN $_{produced\ feed}$ /kg N excreted $_{produced\ feed}$
$EFNH_3$ = emission factor of NH_3, 25%
$EFNO_3$ = emission factor of NO_3^-, 30%
EFN_2O = emission factor of N_2O, 2%
$EFCH_4$ enteric = emission factor of CH_4 enteric, 1.5 kg CH_4/pig /year
$EFCH_4$ outdoor =emission factor of CH_4 from manure, 1%
AAP = Annual Animal Production
VS $_{produced\ feed}$ = volatile solid excreted by pigs coming from produced feed ingested, kg dry matter
0.65 = maximum methane-producing capacity for manure produced by livestock category T, m^3 CH_4 kg^{-1}
0.67 = conversion factor of m^3 CH_4 to kilograms CH_4

The N and P excretions of the pigs were calculated by a mass balance approach considering the nutritional characteristics of the produced feed and the animal performances. The excretion is the difference between the ingestion of produced feedstuffs (the natural feed is not considered) and the body retention of the produced feedstuffs (eq.6 and eq.7 for respectively N and P, Corpen (2003)).

$$N\ Body\ (kg) = e^{(-0.9385 - 0.0145\ Lean\%)} \times (0.915BW^{1.009})^{(0.7364 + 0.0044\ Lean\%)} / 6.25 \qquad eq.6$$
$$P\ Body\ (kg) = 5.3\ BW \qquad eq.7$$

Where BW = body weight, kg

3. Results

3.1. Life cycle inventories

The environmental fluxes are given in Table 4.

The N fluxes (ammonia, nitrous oxide and nitrates) are correlated to the N excretion which is correlated to the N ingestion. Because of this, the relative ranking of the three farms is the same as for the N ingestion (Figure 1).

For the fattening unit, Farm3 which has the most extensive management has N fluxes lower by 86% for ammonia, nitrous oxide and nitrates compared to Farm1. Farm2 has higher nitrogen fluxes of 14% compared to Farm1.

The P fluxes are also reduced for Farm3 compared to Farm1 and Farm2. The methane fluxes are linked to the lifetime of pigs for the enteric component, and to the volatile solid excreted (which is a function of the gross energy intake) for the manure management component. The methane fluxes give less difference between farms than the other environmental fluxes because the methane fluxes are mainly due to enteric emissions (instead of emissions linked to the manure) and the lifetime of the pigs is very close between the three systems.

Table 4. Direct environmental fluxes of the pig units

	Farm1		**Farm2**		**Farm3**	
	Farrowing unit (/sow)	Fattening unit (/pig)	Farrowing unit (/sow)	Fattening unit (/pig)	Farrowing unit (/sow)	Fattening unit (/pig)
N excreted[a] (kg N)	18.4	13.4	6.4	11.5	5.3	2.1
P excreted[a] (kg P)	2.0	1.5	1.3	2.3	0.7	0.1
VS excreted[a] (kg VS)	118.2	98.0	86.2	100.8	79.2	50.3
Ammonia (kg NH_3)	3.6	2.8	1.4	2.5	1.0	0.5

[a] part of the excretion linked to the digestion of the produced feedstuffs (without natural feed)

3.2. Life cycle assessment

The LCA results per kilogram of live fattening pig and culled sow are given in Table 5.

Farm3 obtains lower impacts for all the indicators (per culled sow and fattening pig). Compared to Farm1, the result per kilogram of fattening pig are reduced by 64%, 81%, 77%, 62% and 67% for respectively the impacts of climate change, acidification, eutrophication, energy consumption and land occupation.

Farm2 compared to Farm1 has a reduction of impacts of 25%, 24% and 21% for respectively the impacts of climate change, acidification and eutrophication. The result is similar for eutrophication and higher for the land occupation impact.

Table 5. LCA results of the three Corsican farms and comparison with the average conventional system of Europe described by Dourmad et al. (2012)

	Farm1		**Farm2**		**Farm3**		***Conventional system of Europe***
	/kg culled sow	/kg fattening pig	/kg culled sow	/kg fattening pig	/kg culled sow	/kg fattening pig	*/kg fattening pig*
Climate change (kg CO_2eq)	6.9	4.09	6.1	3.03	2.11	1.47	*2.25*
Acidification (g SO_2eq)	87.0	51.5	67.2	38.7	17.0	9.7	*44*
Eutrophication (g PO_4eq)	91.0	53.8	98.9	53.3	25.4	12.3	*19*
Energy consumption (MJ)	35.5	20.2	32.1	15.8	12.4	7.7	*16.2*
Land occupation (m^2year)	11.35	6.43	15.17	7.83	3.78	2.14	*4.13*

For the impacts climate change, acidification and land occupation the respective importance of three main steps in pig production on the LCA result for a kilogram of fattening pig is presented in Figure 3 : the production of the piglets (piglets), the production of the feedstuffs (feedstuffs), the fattening of the pigs (fattening units). The production of piglets on the farrowing unit has a minor incidence on the results. For climate change the step of feedstuff production and the fattening unit have an equivalent impact on the results. This is due to nitrous oxide emissions during the feedstuff production and to both nitrous oxide and methane emissions on the fattening unit. For acidification, the impacts occur mainly on the fattening units with the ammonia emissions while for land occupation it is the feedstuff production which uses land.

For all the differences between systems, both the reduction and the increase occur during the two main steps: production of feedstuffs and the fattening units (Figure 3). It comes from the fact that the feeding strategies impact hugely the excretion from which the environmental fluxes and the impacts are calculated.

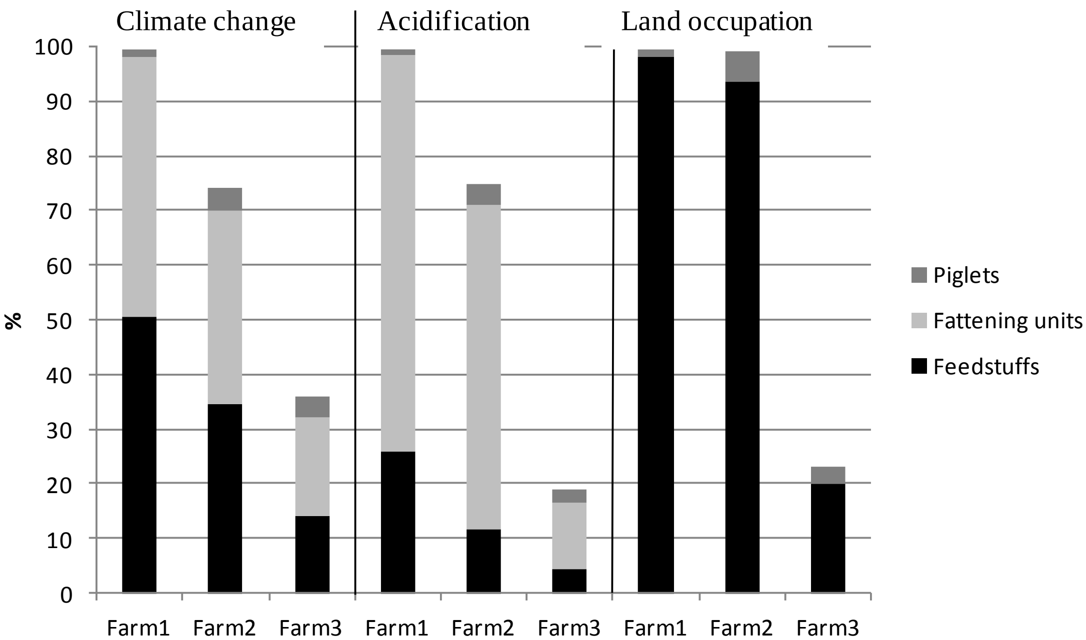

Figure 3. Contribution of the three main production stages to LCA results for a kilogram of fattening pig produced by the Corsican farms

4. Discussion

By comparing the LCA results of the Corsican kilograms of pig to conventional kilogram of pig (Dourmad et al. 2012), Farm3 obtained lower impacts, Farm1 had higher impacts and for Farm2 the results could be higher or lower depending on the impact. As expected, when the impacts for the farms are higher compared to the conventional system, this could be explained by the longer lifetime of the pigs and their lower technical performances. Dourmad et al. (2012) also obtained higher impacts for traditional systems of Europe compared to conventional ones: an increase of respectively 54, 79, 23, 50 and 156% for climate change, acidification, eutrophication, energy use and land occupation. The added value of this study is to have assessed three different extensive systems in which the proportion of natural feed varied. The result indicates that the increase in impact compared to conventional production could be compensated by the use of natural feed in the diet of the pigs.

This is due to the methodological choice of not considering the natural feed in the LCA perimeter. It was determinant in the results. It required being able to specify environmental fluxes without considering grazing and transhumance. The diets were detailed and the associated excretion estimated. The choice of the emission factors applied on the excretion was also a determining factor. Without information on the diets (amounts and composition), global emission factors (Tier1) would have been used, especially for ammonia and methane emissions from manure management. The environmental fluxes would have considered a global average diet without the possibility of extracting natural feeds from the assessment. The specification of the intake and excretion linked to manufactured feeds gave the information that made it possible to conclude on the specific impacts of extensive pig systems in Corsica. The more specific the system, the more detailed the information about the LCI should be, because average references are not valid.

5. Conclusion

This study shows the interest of natural feed in extensive pig systems. By not considering it in the LCA assessment, the environmental impacts of the kilogram of pig at farm gate are reduced and could reach a level below the impacts of conventional production. The results also underline a huge difference among the three systems studied which could change the conclusions of a comparison with conventional production. The sensitivity of the results to the diet of these systems is relevant because the importance of natural feed modifies all inventory data such as the amount of feed, the excretion and the associated environmental fluxes. To reach such a conclusion made it necessary to detail the diet without the natural feed and the associated excretion.

ABSTRACT

In a context where husbandries are questioned on their environmental impacts, optimized systems for the future should be devised to provide the milestones. Eight pig systems were constructed by experts by considering the use of best available techniques (BAT), the modernization of buildings and the improvement of technical performances. The kilogram of pig produced from each optimized system was assessed at farm gate using Life Cycle Assessment (LCA) and the results were compared to an average current pig system in conventional production. The results indicate a reduction of impacts which could reach respectively 39, 43, 26, 26 and 45% for climate change, acidification, eutrophication, land occupation and energy use. The implementation of BATs is limited by their cost. Husbandries should improve their technical performances more than those of the 10% best current husbandries to maintain the current cost of production.

Keywords: future models, pig farms, environmental optimization, LCA

1. Introduction

In a context where husbandries are questioned on their environmental impacts (Petit and van der Werf 2003 ; Krystallis et al. 2009), environmental assessments of pig systems are needed in order to inform makers on the recent situation and to initiate improvements. The results must concern different environmental impacts in order to promote a sustainable evolution by limiting the transfer of pollution. The assessments must also be explained under the agricultural practices which devise possibilities of action for the farmers. Best available techniques (BAT) are formalized and recommended to farmers (Bref 2003). Each one is efficient on at least one major environmental flux and concerns a specific part of the farm (building, manure storage, spreading). Pig systems applying these BATs have been assessed by LCA regarding different feeding strategies (Garcia-Launay et al. 2014) or different manure managements (Prapaspongsa et al. 2010). This study proposes to assess pig systems considering an environmental optimization applied on the whole life cycle of pig production. The purpose is to reach the possible global gain. Because the BATs could not all be applied on one farm (some of them concern the same part of husbandry and can't substitute for each other; costs also represent a limit), priorities must be found in improving pig husbandries. It results in a combination of BATs which could differ from one system to another. This study built eight configurations which resulted in eight models of future pig production systems. Environmental and economic assessments were performed among those systems to evaluate the improvement and its applicability.

2. Methods

2.1. Construction of eight models with an environmental optimization

Eight models of pig systems were constructed for the next 10-15 years by 35 experts with a goal of environmental optimization (Table 1). Experts from administration, research and industry were individually interviewed. They bring complementary skills which are necessary to devise sustainable models of production for the future. The experts took care of different environmental aspects (reduction of impacts on water, air and soil) in the regulation context, but also economic and social aspects (competitiveness, income, quality of life and labor). Their expertises enabled decisions to be made for each system of a combination of BATs.

Table 1. Characteristics of the eight optimized models on the environment

Logics	←---------**Combination of pig and crop production**--------→			←------------------------------**Specialized production**-----------------------------------→				**Outsourcing of farrowing activity**
Models	**1a**	**1b**	**1c**	**2a**	**2b**	**2c**	**2d**	**3**
Size of the pig unit	175 sows – 200 ha	225 sows – 225 ha	250 sows – 120 ha	475 sows – 70 ha	←------------------------1000 sows – 80 ha----------------------→			900 sows – 100 ha
Location in an area with high animal density			Yes		←-----------------------------------Yes ----------------------------→			
Mode of housing	Straw litter for sows and fattening pigs, open building with natural ventilation	←--Closed building, slatted floor and dynamic ventilation--→						
Pig feeding strategy	←--------------Feed production on the farm, use of feedstuffs produced on the farm, use of soy meal not linked to deforestation, substitution of a part of wheat and soy meal by pea ----------------→							Purchase of feeds
Manure management	Composting manure, spreading manure + exportation	Spreading slurry + small biogas plant at the farm with slurry and intermediate crops with energy value	Phase separation by a centrifugal decanter to reduce the excess of phosphorous + spreading the liquid fraction + exportation of the solid fraction	Spreading slurry + exportation	Biological treatment with centrifugal decanter. Spreading of the liquid fraction, exportation of the solid fraction and the sludge	V scraper in the fattening building. Exportation of the solid fraction. Spreading of the liquid fraction	Spreading slurry + participation to a large biogas plant for the excess slurry	Spreading slurry + exportation
Best available techniques applied		←--Bioscrubber--→						
		←---Cover of the slurry pit---→						
			←--Energy efficient equipments--→					
		Use of the heat produced by methanization to heat the buildings		Flare for the storage				

The eight pig models correspond to three logics of production which were identified for future innovative and competitive husbandries by Roguet et al. (2009): the combination of pig and crop production (3 models), the specialized production of pigs (4 models) and the outsourcing of farrowing activity (1 model). Other distinguishing criteria concerned the type of production (7 models with standard pork quality and 1 model 1a with improved quality) and the strategy of manure management in relation to the link of livestock to land (conventional storage and spreading, biogas plant, aerobic treatment). The model with improved quality was chosen to be smaller than the other by its size, with more autonomy for the feeding strategy and the manure management, and with the use of straw for the pigs. It corresponds to a model which is often well received by society as it has an environmental consideration. The level of access to land is determinant for manure management and depends on the agricultural area of the farm but also on its location. For this reason some models defined for territory with a high density of animal production treat their manure for abatement and exportation (1c, 2b, 2c and 2d). For the other models, spreading was considered to be the best way to valorize the manure.

2.2. LCA assessment

The kilogram of live pig at farm gate for the eight models was assessed by Life Cycle Analysis (LCA). The environmental impacts were: Climate change in kg CO_2eq (CC), Eutrophication in kg PO_4^{3-}eq (E), Acidification in kg SO_2eq (A), Energy consumption in MJ (EgC) and Land occupation in m^2year (LO). The LCA scope included the production and supply of inputs, the construction of the building, and the pig breeding (Figure 1). Concerning manure management, the system boundaries integrated the avoidance of the production and application of mineral fertilizer which would be applied on crops if manure were not spread, as described by Nguyen et al. (2010).

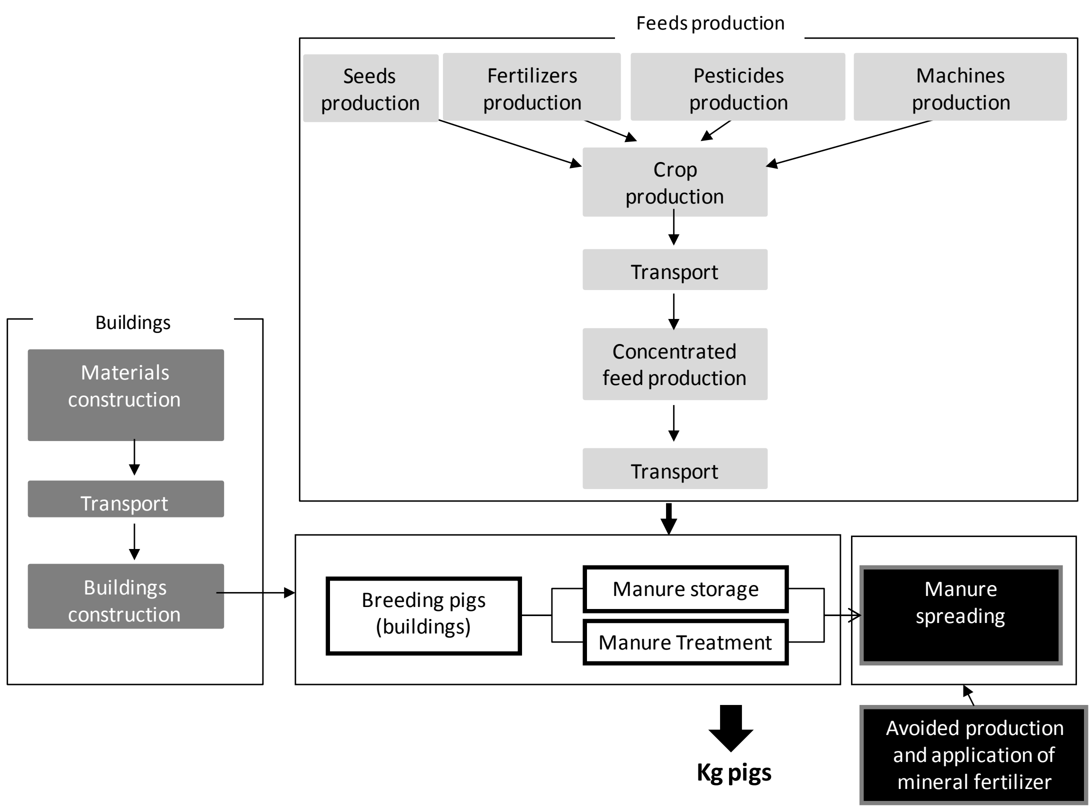

Figure 1. LCA perimeter

In order to measure the reduction of impacts, the optimized models were compared to an average current pig system defined by Espagnol et al. (2012), with the same LCA methodology. The reference system is a fully slatted floor with a classic management of manure (storage under the pigs in the building, external storage in a pit and spreading). Its technical performances are given in Table 5 (husbandries with less than 500 sows). No BAT was considered for this current average system. Its impacts per kilogram of live pig at farm gate are given in Table 4 and correspond to those of a current pig system with less than 500 sows.

Table 2. Models used in the LCI assessment of the optimized systems

Substance emitted / Resource consumed	**Source of emissions / consumer of resource**	**Literature reference for model used**
Ammonia (NH_3)	Animal excretion of nitrogen	CORPEN 2003
	Emissions of NH3 (buildings, storage)	CORPEN 2003
Combustion gas	CO_2	Ecoinvent® v2
Methane (CH_4)	Animal excretion of VS	IPCC 2006 Tier 2
	Emissions from manure management	IPCC 2006 Tier 2
	Emissions from enteric fermentation	IPCC 2006 Tier 1
Dinitrogen oxide (N_2O)	Emissions of N_2O (buildings, storage)	IPCC 2006 Tier 2
Phosphorus	Animal excretion of phosphorous	CORPEN (2003)
	Phosphorous losses	Nemecek (2007)

Table 3. Efficiency of the BATs considered in the optimized systems issued from Bref (2003) and national publication (Guingand et al. 2010)

Best available practices	**Application scale**	**Environmental flux**	**Efficiency at application scale (% abatement)**	**Cross effects**
Bioscrubber	Building	NH_3	50%	Increase of the nitrogen content in the manure
Pit cover	Manure storage	NH_3	70%	Reduction of the manure volume, increase of the nitrogen content in the manure
V scraper	Fattening building	CH_4 N_2O NH_3	100% 49% 40%	Increase of the nitrogen content in the manure
Flare	Storage	CH_4	100%	
Heat pump	Buildings	Energy consumption	65%	
Heat exchanger	Buildings	Energy consumption	30%	
Niches with underfloor heating	Farrowing building	Energy consumption	50%	
Niches for weaned piglets	Buildings	Energy consumption	75%	
Centralized ventilation	Buildings	Energy consumption	60%	
Efficient fan	Buildings	Energy consumption	50%	
Control of the ventilation rate	Buildings	Energy consumption	30%	
Trailing shoes, injector	Spreading	NH_3	Respectively 35% and 70%	
Biogas plant	Treatment	CH_4 and energy	Destruction of 100% CH_4 + production of energy sold and heat used for the building	Energy consumption for the biogas plant. Increase of the nitrogen and phosphorous content in the digestate to spread when there is the use of external inputs (2d)
Improvement of the production of crops	Feeds	Reduction of all the impacts	8.8% on the CC, 3.9% on A, 2.1% on E, 4.6% on EgC and 2.9% on LO	
Reduction of the excretions (N and P)	Excretion	N and P excretions	5% for N and P excretions of systems 1a, 1b and 1c 10% for N and P excretions of the others systems	Reduction of the N emissions of the manure and reduction of the area needed to spread the manure

For the Life Cycle Inventory (LCI) of the optimized models, some improvements were considered comparing them to the current situation. The technical performances of the optimized systems correspond to the 10% of the best French pig husbandries (Table 5). A reduction of nitrogen and phosphorous excretion was applied (Table 3) compared to the current situation considering pretreatment of the feedstuffs and multiphase feeding. The soy meal incorporated in the feeds was considered coming from Brazil but from a location not linked to deforestation (Mosnier et al. 2011). An increased incorporation of pea (10%) into the feeds was chosen instead of a part of wheat (5%) and soy meal (5%). An improvement in crop production was also taken into account based on the result of a prospective analysis by the French agricultural ministry (2011). The efficiencies of the BATs at their application scale are given in Table 3. The models used for LCI are given in Table 2.

For the models with biogas plant (1b and 2d), the emissions linked to the digester and pre and post storage were allocated between the kilogram of pig and the kWh produced considering the energetic content of the inputs in the digester.

3. Results

The results of LCA for optimized system and the baseline scenario are given in Table 4. The optimized models compared to the baseline show reduction of impacts that could achieve up to 39%, 43%, 26%, 26% and 45% for the respective impacts of CC, A, E, OS and EgC.

Table 4. LCA results of optimized pig systems

	LCA results / kg of live pig				
	CML, 2001				Recipe
	Climate change (kg CO_2eq)	Acidification (kg SO_2eq)	Eutrophisation (kg PO_4eq)	Land occupation (m^2.year)	Energy consumption (MJ)
System 1a	2.49	0.047	0.023	4.96	11.57
System 1c	1.54	0.029	0.018	6.49	10.07
System 2a	1.33	0.026	0.017	6.71	9.65
System 2b	1.88	0.027	0.017	4.72	11.97
System 2cb	1.51	0.026	0.017	6.34	10.21
System 3	1.69	0.027	0.018	6.07	11.33
System 1b	1.41	0.026	0.017	6.91	8.95
System 2d	1.31	0.025	0.017	6.21	8.98
Baseline	*2.14*	*0.044*	*0.023*	*6.46*	*16.29*

The reduction of impacts of a kilogram of pig at farm gate is performed mainly during the production of the feed and during the breeding of the pigs.

The improvement of the feeding strategy reduces the impacts among the optimized systems of a range from 18 to 20%, 4 to 6%, 5 to 8%, 2% and 11 to 21% respectively for CC, A, E, LO and EgC. It is due both to the improvement of the technical performances of the pigs and also to the reduction of impacts during the crops production.

The use of BAT in the pig husbandries reduce the impacts for all the optimized systems except 1a from 7 to 19%, 29 to 37%, 12 to 16% and 15 to 23% for respectively the CC, A, E and EgC.

The impacts CC, A and E of the system1a are higher than the other systems despite the fact that BATs are used. This is due mainly to the use of litter in the pig buildings which emitted N_2O (impact on CC) and to the fact that techniques like bioscrubber could not be used in natural ventilation conditions (emissions of NH_3 are not abated and have impact on acidification).

Concerning the spreading of the manure, the difference among the optimized systems and by comparison to the current husbandry shows less difference except for systems 1a, 2b and 2c. The systems 1a and 2b abate nitrogen with respectively composting and biological treatment. The content of nitrogen in the manure to spread is also reduced and changes the comparison with mineral fertilization.

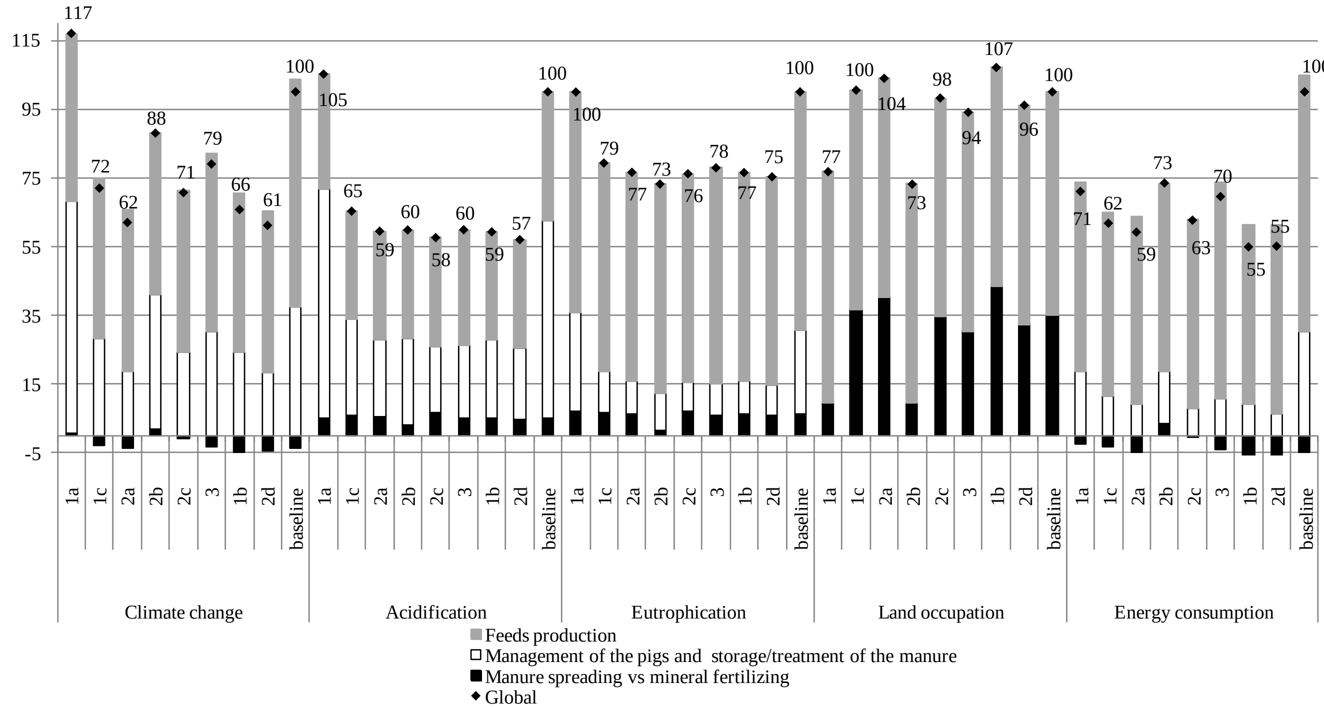

Figure 2. Relative result of LCA in % for the optimized systems compared to the baseline scenario with the importance of three main steps (1/ production and supply of the feeds, 2/ husbandry with the breeding of the pigs and manure management in the building and during the storage/treatment of the manure, 3/ organic fertilization compared to mineral fertilization).

4. Discussion

The result indicates the cumulative reduction of impacts which could be reached by the application of BATs in pig production at farm gate. The next step is to advise the farmers in order to encourage them to go from the current husbandries to the optimized ones. The adoption of BATs will depend on the information they will find. The benefit of BATs at the scale of the pig life cycle is useful and complementary to the efficiency at the application scale because it enables the relative interest of BATs to be measured.

Figure 3 gives the example of three BATs for the reduction of ammonia emissions in pig husbandries. The efficiency at application scale indicates that the pit cover is the most efficient with 70% of abatement versus respectively 50% and 40% with the bioscrubber and the V scraper (Table 3). The reduction rate obtained at life cycle scale shows that the bioscrubber is the BAT which can most reduce the acidification impact. This scale has the advantage of taking into consideration the relative importance of the emissions on which the BAT is applied. It makes it possible to compare different BATs used on different parts of the husbandry (i.e. building, storage …).

Even if the use of BATs indicates possible reduction of the environmental impacts for pig husbandries at LCA scale, the capacity of the current pig units to invest in these is limited because of their costs. The comparison between the three BATs could be completed by analyzing the cost of the reduction of 1 kg SO_2eq/kg of pig (Figure 3). This expression of the results points to the pit cover as being the best in terms of efficiency and the relative cost.

In the future, the cost of BATs could be a limit to their adoption. The bigger units should cope better because they are more likely to be trusted by the banks because of their size and their technical performances. The costs of BATs have been expressed for four types of husbandries: with less than 500 sows, with more than 500 sows, 20% of the best husbandries and 10% of the best husbandries (Table 5).

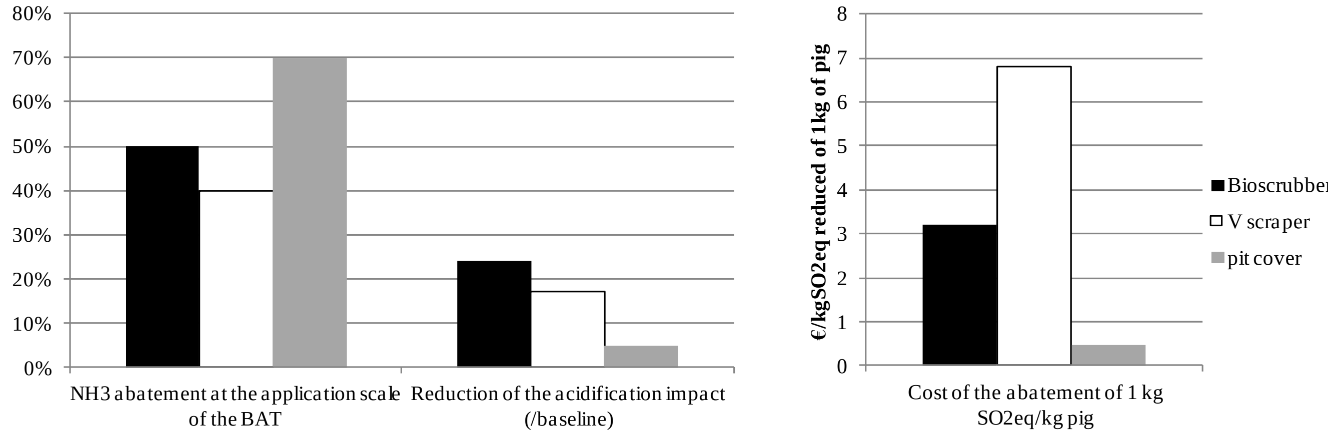

Figure 3. Relative interest for BAT – comparison for bioscrubber, V scrapper and pit cover of the relative interest considering efficiency at application scale (%), efficiency at life cycle scale for acidification (%), the cost of a reduction of 1 kg of SO_2eq per kilogram of pig (€/kg SO_2eq reduced).

For the husbandries with less than 500 sows (representative of current farms with buildings half depreciated), the average cost without BAT is 1.278 €/kg carcass, and goes from 1.359 to 1.438 €/kg carcass with the use of BATs. The BATs without any technical improvement cause an increase in the cost of 0.08 € - 0.15 €. As chosen for the optimized systems of this study, the husbandries of the future might have better technical performances but also increased costs due to necessary investments in modernizing the buildings. With a new building depreciated to 25%, the costs range from 1.300 to 1.453 €/kg carcass depending on the hypothesis made on technical performances. It should be higher than those of the best 10% to access a cost like the current one. This indicates that the implementation of these best practices in existing pig farms is hampered by the additional cost incurred, while the pig price paid to producers is determined in a very liberal and competitive European pig market.

Table 5. Economic assessment of the eight optimized pig systems

	Current pig systems with less than 500 sows*	Current pig systems with more than 500 sows**	20% best husbandries**	10% best husbandries**
Pig produced (/sow/year)	22.34	24.36	25.25	25.94
Weight of fattening pigs (kg)	116.0	116.0	116.7	117.0
Feed conversion ratio (kg /kg)	2.83	2.81	2.73	2.70
Price of fattening pig (€/ton)	184	178	183	183
Working time (h/sow/year)	20	15	15	15
Cost without BAT (€/kg carcass)	1.278	1.314		
Cost with 160€/sow of BAT (€/kg carcass)	1.359	1.384	1.323	1.300
Cost with 315 €/sow of BAT (€/kg carcass)	1.438	1.453	1.389	1.365

*buildings depreciated 50%; ** buildings depreciated 25%

5. Conclusion

This study sheds light on what could be the optimized pig systems for the future by taking into account a reduction of the environmental impacts. BATs have been applied on different parts of the life production of pig including crop production. Important reductions of impacts have been measured and indicate the level of global gain which could be achieved. Different options of BAT combinations could be used and all have results on an impact reduction. This allows the farmers to find the best solution for their system and its location.

The life cycle scale used for the assessment is interesting to measure the relative interest of BATs, and this kind of information is needed by the farmers if they decide to improve their system. The data concerning costs are also critical to the implementation in the field and the study underlines the economic difficulties of applying BATs in current French pig husbandries. The evolution will be correlated by the European pig market on which the price is defined by supply and demand. If all the countries do not decide to invest in BATs, those who do so will be penalized. If the solution is to absorb the additional costs, the improvement of technical performances should be higher than the 10% best current husbandries.

ABSTRACT

Sustainable nutrition can be defined as "the physical and economic access to sufficient, safe and nutritious food and water to fulfill dietary and cultural needs to enable an active and healthy lifestyle without compromising the ability of future generations to meet these needs". The combined assessment of the environmental performance (using Life Cycle Assessment) and nutritional performance (using the Nutrient Balance concept) of diets is explored in this paper as a method that can be used to inform strategy setting at Nestlé and to evaluate the progress made in this area. The results of the assessment of diets followed by families living in different countries are presented and discussed.

Keywords: diets, environmental impact, screening LCA, nutrient balance, sustainable nutrition.

1. Introduction

Taking the already established concept of food security as a departing point, the emerging notion of sustainable nutrition can be defined as the "physical and economic access to sufficient, safe and nutritious food and water to fulfill dietary and cultural needs to enable an active and healthy lifestyle without compromising the ability of future generations to meet these needs".

Life cycle assessment (LCA) researchers have already introduced elements of nutritional assessment in the LCA of food products and diets. These include the choice of an adequate functional unit (based on mass or nutritional composition (Kägi et al. 2012); based on protein content (Nijdam et al. 2012)); the comparison of environmental impacts of mainstream diets (omnivore, vegetarian, vegan diets (Baroni 2007; van Dooren et al 2014); or the evaluation of the environmental impacts of changes to healthier diets (Tukker et al. 2011).

Increasingly, research coming from public health and nutrition science is evaluating the link between nutrition and environment. For example, work has been carried out to formulate and recommend healthier, nutritious diets leading to reduced greenhouse gas emissions (Sáez-Almendros 2013; Vieux et al. 2013; Macdiarmid et al. 2011; Wilson et al 2013). The concept of nutrient density can challenge the assumption that excluding dairy products results in diets that meet both nutrient recommendations and result in reduced greenhouse gas emissions (Bruun Werner et al. 2014).

The complexity of food production systems and the potential number of ways of combining food products to achieve the required nutritional quality in a diet pose significant challenges: Is it possible to equate nutritious diets to environmentally sustainable diets (Macdiarmid 2013) (NORDEN 2014)? Do nutrition and environmental sustainability point to convergent or divergent goals (Garnett, 2014)?

This paper contributes to the debate in this field by exploring avenues to combine the nutrient balance and environmental impact assessment of diets. This method can be used by Nestlé at single product, brand or product portfolio perspective; it can also provide a holistic approach to product renovation and innovation.

2. Methods

2.1. Diets evaluated

Menzel and D'Aluisio (2005) inventoried the food supplies purchased in one typical week by 30 families living in 24 different countries. The dietary choices of five of these families were chosen for evaluation using LCA and new tools in nutrition science. It is clear that these are illustrative examples and cannot be taken as statistically reliable samples to represent the typical diets of their respective countries. In this work, as a first approach, it is assumed that all food purchased is consumed over one week in its entirety. Due to the type of data available, it is also assumed that the reported list of food items is not supplemented by additional food items, either already available at home or recently purchased. Table 1 summarizes the total amount of food purchased and total energy content, with the food supplies being further classified into eight categories.

Table 1. Summary of weekly, family food purchases evaluated in this study (Menzel and D'Aluisio 2005)

Labeling	Family A	Family B	Family C	Family D	Family E
Family size	4	4	5	5	4
Family residence	California, USA	North Carolina, USA	Texas, USA	Mexico	India
Total energy content (kcal)	61'306	90'900	110'968	134'694	87'417
Total amount of food purchased (kg)	42.371	78.022	65.814	114.618	51.765
Grains and starchy foods (kg)	6.531	4.522	7.840	15.575	15.358
Dairy products (kg)	4.718	5.383	11.921	14.609	10.388
Meat, fish and eggs (kg)	3.619	6.762	7.644	11.480	-
Fruits and vegetables (kg)	15.176	11.858	12.628	32.648	21.385
Condiments (kg)	0.994	1.925	4.753	2.954	2.156
Snacks and desserts (kg)	1.729	2.604	3.003	1.974	0.196
Prepared food (convenience food) (kg)	3.024	7.987	6.741	1.043	-
Beverages (kg)	6.580	36.981	11.284	34.335	2.282

2.2. Nutrient Balance Concept

The Nutrient Balance Concept (NBC) represents a new approach in nutrient profiling; it goes beyond individual foods and evaluates the nutritional values of multiple foods in meals and total diets. The NBC goes one step ahead of nutrient density by adding the new metric of nutrient balance (QB) to the qualifying (QI) and disqualifying (DI) indices (Fern et al. 2014).

The Qualifying Index (QI) is defined as the ratio of essential nutrients contained in 2000 kcal of a given food relative to the Dietary Reference Intakes (DRI) (USDA 2014) for those nutrients. In the absence of a DRI for a given nutrient, then Adequate Intake (AI) is used instead. The Disqualifying Index (DI) is defined as the ratio of public health sensitive nutrients contained in 2000 kcal of a given food, relative to the Maximal Reference Values (MRV) for those nutrients. The latter nutrients and their respective MRVs are: total fats (<35% of dietary energy); saturated fats (<10% of dietary energy); trans fatty acids (< 1% of dietary energy); cholesterol (<300 mg); and sodium (<2300 mg) (USDA 2010); total sugar (<25% of dietary energy) (Friday and Bowman 2006); alcohol (< 22g) (Foster and Marriott, 2006).

If the QI value is > 1, the food item is considered nutrient dense; if the QI value is < 1, the food item is considered energy dense. If the DI value is > 1, the food item is deemed "compromised" because it contains disqualifying nutrients in values higher than the MRV relative to the energy content of the food item.

Finally, the QB score is calculated as the average proportion of daily values for qualifying nutrients (QI) present in 2000 kcal of a given food. A QB score of 100% is achieved if every qualifying nutrient satisfies 100% of its daily requirement. If the QI for a given nutrient is > 1, then the value is truncated to 1 to avoid bias in the calculations. Table 2 summarizes the calculation of QI, DI, and QB.

The QI and DI values of meals /diets are calculated as the sum of the QI and DI values of the individual component food items, weighted by the contribution of the food items to the overall energy content of the meal /diet.

Table 2. Calculation of QI, QD and QB (Fern et al. 2014)

Equations	Description	Nutrients considered
(1) $QI = \frac{E_d}{E_p} \cdot \frac{\sum_{j=1}^{N_q} \frac{a_{q,j}}{r_{q,j}}}{N_q}$ (2) $DI = \frac{E_d}{E_p} \cdot \frac{\sum_{j=1}^{N_d} \frac{a_{d,j}}{r_{d,j}}}{N_d}$ (3) $QB\,(\%) = 100 \cdot \frac{\sum_{i=1}^{N_q} QI_i}{N_q}$	E_d = daily energy need (kcal) E_p = energy in the qtty. of food analyzed (kcal) $a_{q,j}$ = qtty. of qualifying nutrient (g) $a_{d,j}$ = qtty. of disqualifying nutrient (g) $r_{q,j}$ = DRI of qualifying nutrient (g/day) $r_{d,j}$ = MRV of disqualifying nutrient (g/day) N_q = Number of qualifying nutrients evaluated N_d = Number of disqualifying nutrients evaluated QI = Qualifying index DI = Disqualifying index QB = Qualifying nutrient balance score	**For QI**: folate; niacin; panthotenic acid; riboflavin; thiamin; vitamins A, B6, B12, C, D, E, K; Ca, Cu, F, Fe, Mg, Mn, K, P, Se, Zn; α-linolenic acid; linolenic acid; choline; dietary fiber; protein; water. **For DI**: total fat; saturated fat; cholesterol; trans fatty acids; total sugars; Na; alcohol.

To evaluate the dietary choices of the five example families, the recorded food items (covering the meals for a week) were located in the USDA food composition database (version SR26) (USDA 2013). This database provides the total amounts of the 28 qualifying nutrients and 7 disqualifying nutrients per food item. The DRI data were based on those published by the Institute of Medicine, National Academy of Sciences (USDA 2014). This allowed a comparison of the different results based on the existence of values for all included nutrients. For a more specific assessment, the use of country specific regulated DRI is advised. The MRVs for DI calculation were based on the Dietary Guidelines for Americans (USDA 2010).

2.3. Screening Life Cycle Assessment

The goal of the present screening LCA study was to understand the environmental impacts of real diets of families from varied backgrounds and residing in different locations. The results of this assessment, in combination with those of the nutrient balance concept (see section 2.2) are later used to evaluate the feasibility and implications of such a combined assessment approach.

The functional unit chosen for the assessments was expressed as the “food supplies purchased for consumption at home and to feed one family over the period of one week”. This functional unit was a minimum common characteristic among the 5 diets chosen, acknowledging the fact that the size of the families is not the same, nor the dietary and lifestyle requirements of the various family members. The food supplies consist of raw ingredients which are used to prepare meals at home as well as “convenience” food products which require minimal or no additional preparation.

The scope of the assessment covered the life cycle stages from “cradle to retail”, as shown in Figure 1. The agricultural production of food, the manufacture of ingredients, the manufacture of food products, the retail of the various food supplies and the transportation of materials from one step to the next were considered within the system boundaries. The inclusion of packaging as part of the scope of the assessment would entail taking a number of assumptions derived from the inventory of food supplies (packaging size; packaging materials; level of packaging: primary, secondary and/or tertiary). Packaging was excluded from this screening assessment because the gain in completeness is outweighed by the extensive data collection required and uncertainty introduced. The preparation, consumption and potential wastage of the food supplies along the supply chain and at home were excluded. This is because it is not known how the families combine and use the various food items to prepare meals at home. Accordingly, the end of life of food waste and packaging fall out of the scope of the study.

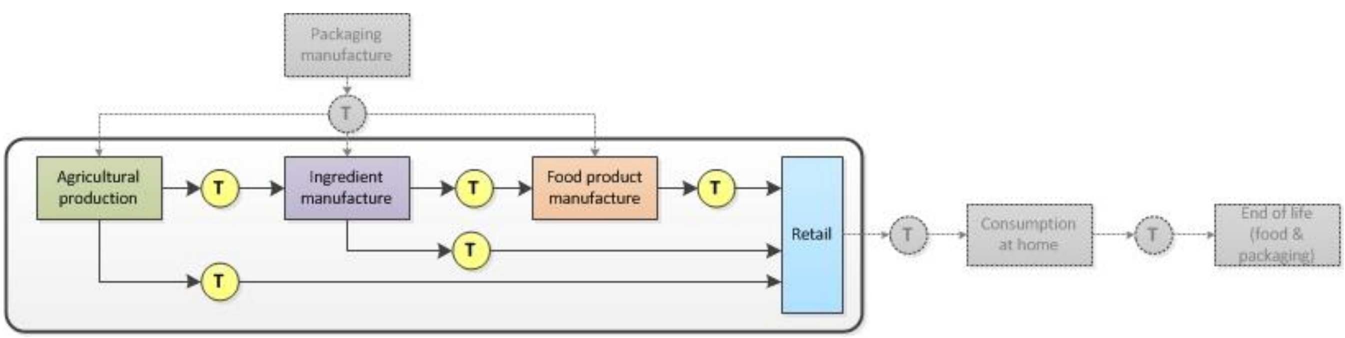

Figure 1. System boundaries considered in the assessment. T = transport.

It was assumed that the transport distance between stages was the same for all 5 case studies (farm to factory, factory to factory, factory to retailer, farm to retailer). Food supplies were considered as regionally produced. In the particular case of food supplies not typically produced in the country, then it was assumed these were imported, and the respective distance and means of transportation were included in the assessment.

Background data (transportation, energy, water supply) and agricultural production data of raw ingredients were taken from the Ecoinvent v.2.2 database (SCLCI 2009). Additional agricultural production data of raw ingredients was taken from Stoessel et al (2012) and the World Food LCA Database Project (Quantis 2014). Recipe composition, food manufacture and retail data were taken from internal Nestlé data repositories.

A screening LCA was performed for each food item reported in the list of purchases of the chosen families. For food items treated as raw ingredients, the scope of the assessment covered the agricultural production and retail; for ingredients and manufactured food items, the scope was extended to include the required intermediate manufacturing stages. Consideration was taken in the supply chain to include ambient or refrigerated transportation, depending on the requirements of each food item. The LCA of each family purchases was then consolidated adding the results of the individual food items.

The screening LCAs were performed using SimaPro 8 (Pré, 2013). Five environmental impacts (at inventory, midpoint and endpoint levels), relevant and adequate to food systems, were evaluated in this study: greenhouse gas emissions (IPCC 2007), freshwater consumption and land use at inventory level, abiotic resources depletion (CML 2014), and impacts on ecosphere / ecosystems quality (Impact 2002+ (Jolliet et al 2003)).

3. Results

3.1. Nutritional balance assessment results

Table 3 shows the relative contributions of the different food groups to the total energy content of the food purchases. It is evident that all families prefer some food groups that contribute the most to the energy content of the food they typically consume.

Table 3. Relative contribution of food groups to the total energy content of the evaluated weekly food purchases

Relative contribution (%)	Family A	Family B	Family C	Family D	Family E
Grains and starchy foods	29	6	18	28	51
Dairy	7	7	9	11	11
Meat, fish and eggs	14	9	12	9	0
Fruits and vegetables	15	15	8	13	22
Condiments	7	2	24	18	14
Snacks and desserts	10	3	10	6	1
Prepared foods	12	10	14	4	0
Beverages	6	48	5	10	1

Table 4 summarizes the results of the NBC analysis of the five family food purchases. The results clearly mirror the different choices the families make. The QB values in the gray fields are later used in the comparison with the environmental impact indicators.

Table 4. Summary of QI, DI, and QB values for the overall weekly, family food purchases and food groups

NBC element	Indices	Family A	Family B	Family C	Family D	Family E
Overall diet	QI	1.4	1.1	1.0	1.0	1.2
	DI	0.9	0.9	1.1	0.9	0.4
	QB	**56**	**40**	**28**	**36**	**68**
Grains and starchy foods	QI	1.4	1.3	1.7	1.0	1.0
	DI	0.5	0.5	0.3	0.3	0.3
	QB	52	52	56	53	40
Dairy	QI	1.3	1.2	1.3	1.1	0.8
	DI	1.3	1.4	1.2	1.3	1.2
	QB	40	40	40	40	28
Meat, fish and eggs	QI	1.1	1.4	1.4	2.4	-
	DI	1.6	1.8	2.1	1.9	-
	QB	40	44	48	52	-
Fruits and vegetables	QI	2.6	2.1	1.5	2.3	2.4
	DI	0.6	0.8	1.0	0.8	0.4
	QB	46	72	68	76	72
Condiments	QI	0.6	0.3	0.2	0.1	0.4
	DI	0.9	1.1	1.2	1.1	1.0
	QB	28	8	4	4	8
Snacks and desserts	QI	0.8	0.5	0.6	0.3	1.0
	DI	0.6	0.9	0.8	0.8	0.5
	QB	32	8	24	4	24
Prepared foods	QI	0.8	0.9	0.9	0.7	-
	DI	1.2	1.2	1.2	1.9	-
	QB	40	32	36	36	-
Beverages	QI	1.2	0.9	1.2	0.3	0.7
	DI	0.6	0.7	0.9	0.7	0.6
	QB	24	12	40	4	24

The overall results indicate that Family C achieved the lowest nutrient balance score (QB = 28) and Family E the highest score (QB = 68). None of the evaluated weekly purchases reached the maximum QB score (100), neither at food group level, nor at the overall level. This means that the recommended nutritional requirements were not met for the amount of energy content of the food purchased. For the various values of QI calculated, there is a range of QB values and vice-versa. The values of QB for the various groups of foods reflect the fact that qualifying nutrients are present in varying quantities. The overall QI values of all families are at or slightly above 1, indicating that the choices between energy-rich and nutrient-rich foods are on average evenly distributed. The DI values are also distributed slightly below or above a value of 1.0 for the DI. A comparatively small value for is observed in the case of Family E. The lacto-vegetarian diet followed by this family contributes to reduced values of fat and cholesterol, which are accounted for in the calculation of DI.

Figure 2 presents the overview of the nutritional qualities of the diets by positioning them in a 2-coordinate map according to their QI and DI values. The value of the calculated nutrient balance QB is also shown in the map. The use of QI and DI allows the mapping of meals/diets in relation to their components. The mapping reveals in which quadrant meals/diets fall, based on their relative quantities of nutrients and energy. Changes in the relative contributions of food items to meals/diets will result in shifts of the QI-DI position and, thereby, reveal the nutritional impact of dietary changes. As a consequence, the NBC tool allows the predictive modeling of dietary choices or choices motivated by non-nutritional needs.

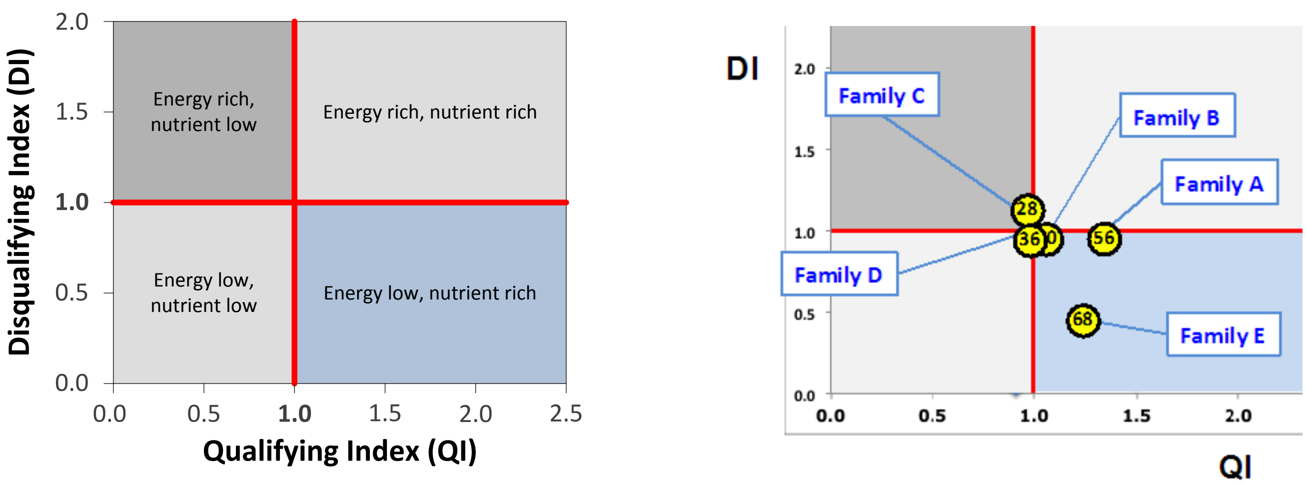

Figure 2. Comparison of the QI-DI positions and nutritional quality of the five weekly, family food purchases. The inserted numbers give the nutrient balance of each diet (QB).

3.2. Environmental impact assessment results

The results of the environmental impact assessment are summarized in Table 5. Figure 3 depicts the relative contribution to the overall environmental impacts of agriculture, transport, manufacture and retail. Figure 4, in turn, shows the relative contribution of the various food groups to the overall environmental impacts.

Greenhouse gas emissions are the lowest in the case of Family E, who follow a lacto-vegetarian diet (dairy products contribute to 31% of total GHG emissions). The high consumption of meat and dairy products for the Families B, C and D, in turn, contribute to around 50% of their GHG emissions.

The results seem to indicate another trend, where large consumption of fruit and vegetables is correlated with large freshwater consumption. This is the case for the Mexican family (Family D), where fruit and vegetables are consumed in large quantities, and account for 71% of the freshwater consumption. On the other hand, 62% of freshwater consumption for the Indian family (Family E) comes from grain consumption. It is necessary to acknowledge that to date water inputs have not been rigorously collected in the preparation of life cycle inventories from different sources. This might introduce a certain bias towards more recent datasets that do include exhaustive information on irrigation, as is the case for fruit and vegetables data used in this assessment (Stoessel et al 2012).

The results for abiotic resource depletion reflect the various levels of energy intensity required at the different stages in the food supply chain. For all cases, farm processes contribute to 70-75% of the results for this impact indicator. It has to be noted that packaging and preparation (which are excluded in the present assessments) can contribute strongly to this indicator, as experienced from previous assessments.

Table 5. Summary of environmental impact results for the weekly, family food purchases

Environmental impact	Family A	Family B	Family C	Family D	Family E
Greenhouse gas emissions [kg CO_2-eq/family*week]	83.65	178.03	136.48	140.61	50.96
Freshwater consumption [m^3/family*week]	3.17	6.10	8.89	10.77	5.37
Abiotic resource depletion [kg Sb-eq/family*week]	0.24	0.50	0.43	0.56	0.20
Land use [ha*year/family*week]	182.25	312.77	271.74	203.69	111.37
Ecosystems quality [PDF*m^2*year/family*week]	7.41	33.11	13.60	31.24	3.30

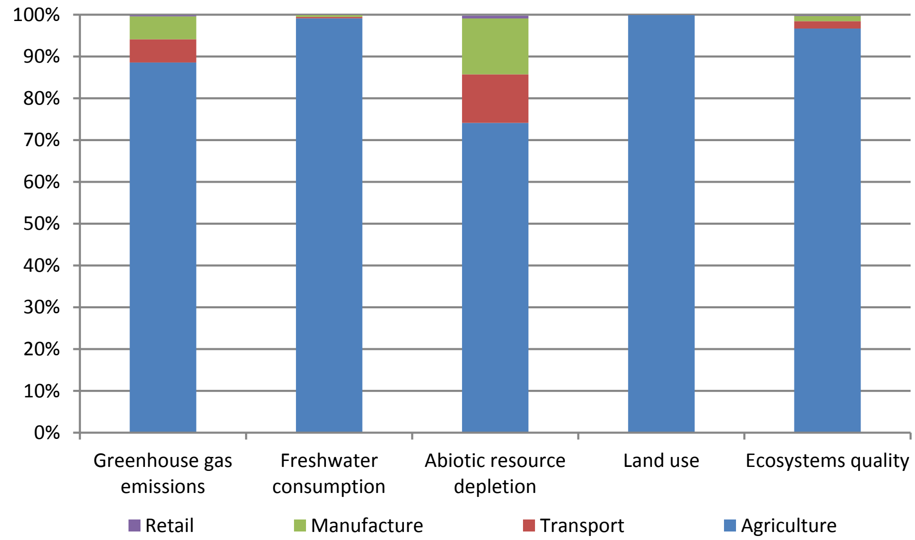

Figure 3. Relative contribution of the life cycle stages to the overall impacts. Average of the 5 assessments.

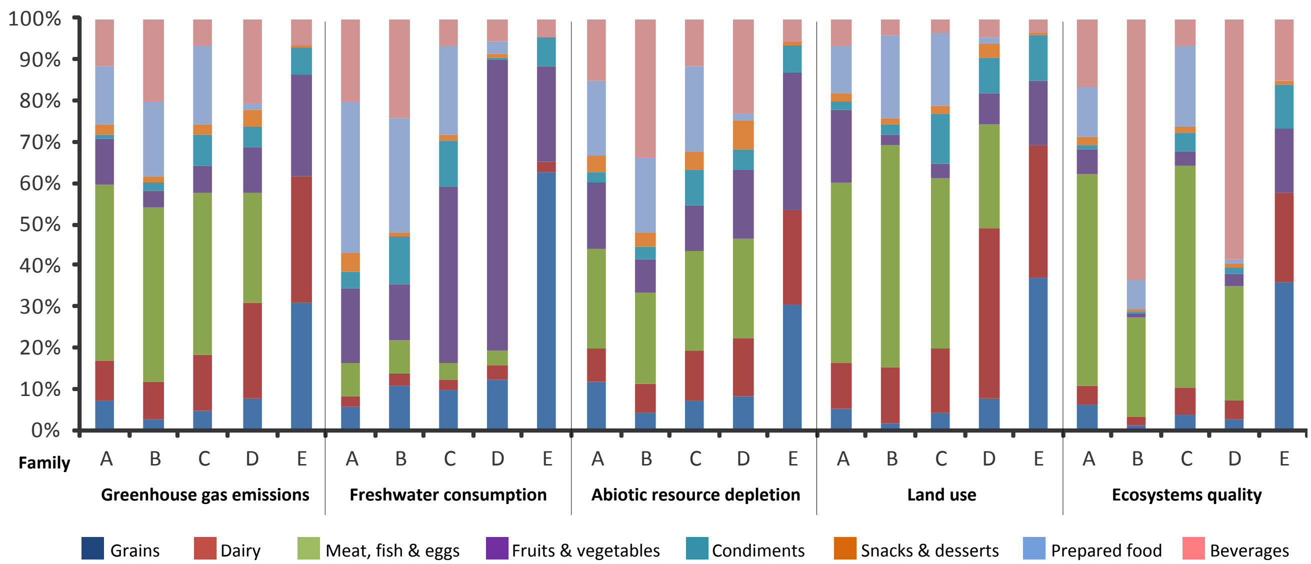

Figure 4. Relative contribution of the food groups to the overall environmental impacts.

Similarly to the trend observed for GHG emissions, land use is driven by the consumption of animal based products. 55% to 67% of the results of this impact are attributable to animal rearing and the cultivation of animal feed for the American families (Families A to C) and Family D. In the case of Family E, given the high proportion of plant-based foods consumed, the cultivation of grains, fruits and vegetables accounts for 53% of this impact. Ecosystems quality is a compound indicator taking into account eutrophication, acidification and ecotoxicity. In all cases, the agricultural activities are the largest contributor to this impact (around 90%).

From Figure 3, it can be seen that the largest contributor to the overall impacts is the agricultural phase. It is necessary to mention that this distribution is influenced by the share of food purchased as raw ingredients (fruit, vegetables, grains and meat) and used to prepare meals at home (23% to 44% of the food supplies). Transport is noticeable in the results for GHG emission and abiotic resource depletion, which is consistent with the use of fossil fuels to power different means of transportation. The contribution of the manufacturing step follows a similar pattern, which is governed by the use of electricity and fuels in the various operations of food processing.

3.3. Combined assessment: environmental impacts and nutrient balance

The results of the combined assessment of environmental impacts and nutrient balance are shown in Figure 5. The environmental impact results are weighted by the QB score of each of the weekly, family food purchases. Figure 5 presents the results normalized with regards to the maximum value for each environmental impact. Families A and E show consistently lower environmental impacts per unit of QB score compared to Families B, C and D. In turn, Families C and D alternatively show the maximum environmental impact per unit of QB score. This reflects not only the differences in dietary choices of the families but also highlights the fact that establishing a direct correlation between reduced environmental impact and high nutritional quality of a diet is not necessarily a straightforward task.

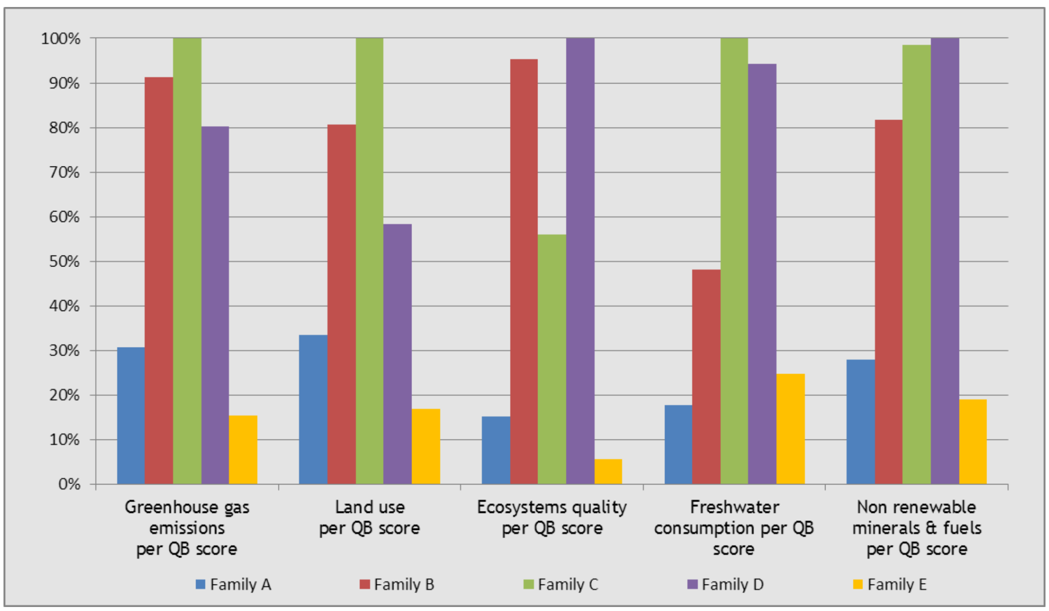

Figure 5. Environmental impact per QB score for each weekly, family food purchases and normalized to the maximum value.

4. Discussion

The presented analysis of the NBC mapping of five family food purchases is a contribution to gain in knowledge on the connection of environmental impact to the nutritional quality of a whole diet. The example of the five families shows that there can be a correlation between the choices leading to a nutritional quality increase and environmental impact reduction. This form of analysis stresses and illustrates the outcome of people's choices.

The USDA food composition database comprises around 8'200 food items covering nearly all food groups. It represents a large "basket" to choose from. However, given that not all the families chosen for the assessment reside in the United States, the food items are not necessarily comparable in all cases, and some were missing from the USDA database. In those cases, the closest match of a food item was substituted for the food item registered in the weekly shopping list. In other cases, the food item was reconstituted according to a matching recipe; then the ingredients where chosen from the USDA database. The "street food" items listed by Family E were not included in the assessment due to a lack of data describing these in more detail; moreover, this group of food items represents one out-of-home dinner at a restaurant (7% of the food expenditure for one week).

The use of a single food composition database and nutritional reference values makes the results comparable. The energy needs of the family members were calculated on the basis of gender, age, weight, heights and physical activity. However, the reference values were taken for an adult. Information for the specific allocation of food products to family members was not available. Moreover, the potential amount of food consumed by any one of the family members could not be taken into account. However, if reference values for families were established and validated, these could be used, resulting in a more representative description of the real situation.

The QB values calculated give an insight into the nutritional quality of food consumed by the families evaluated in this study. For example, Family C shows the strongest mismatch of the essential nutrients balance in their diet. The essential nutrients meet only 28% of the requirements calculated for the amount of energy contained in the food purchased. On the other hand, Family E shows the highest values (QB = 68), which indicates that in this case, the vegetable-rich diet appears to contribute to a more balanced nutrition. It is noteworthy to restate what was mentioned already in Table 2 when explaining the NBC methodology: QI, DI and QB are values calculated as arithmetic means. Therefore, relatively high and low values are likely to be canceled off as part of the calculations and it is not possible to pinpoint, using just the final scores, which nutrients are consumed adequately or not, although this data is generated as part of the model. Complementarity of food components achieve a better coverage of the essential nutrients and will result in a higher QB score.

Figure 4 clearly indicates that the environmental impact of dairy products should not be mixed up or aggregated with those of meat products. A comparison of the environmental indicators for Families A and E shows favorable outcome for Family E compared to Family A. This is due to Family E excluding meat but having a higher amount of dairy products in their diet. A similar conclusion was attained by Bruun Werner et al. (2014) when evaluating the significance of dairy products in realistic dietary choices in Denmark. If the optimization of a diet with regards to reduced GHG emissions implies the exclusion of dairy products, nutritional consequences may ensue. It might not come as a surprise that the improvement of a diet by increasing the energetic contribution of vegetables also leads to an improvement on the environmental indicators.

The results obtained in this study are not necessarily comparable to what is reported in published papers given that the nutrient balance concept is new. Whereas methods for nutritional profiling of diets are more prescriptive, the LCA methodology allows for flexibility depending on the goal and scope of the studies. A preliminary comparison could be done with regards to the GHG emissions associated with food consumption. In this study, GHG emissions range between 1.8 and 6.4 kg CO_2-eq per capita per day. At a national average diet level, reported values for GHG emissions are similar in magnitude: 7.1 kg CO_2-eq per capita per day for Europe (Tukker et al. 2011); 8.4 kg CO_2-eq per capita per day for the United States (Weber et al. 2008); or 4.1 kg CO_2-eq per capita per day for France (Vieux et al. 2013).

5. Conclusion

The FAO (Burlingame and Dernini 2010) sets a clear direction for the task ahead in the area of sustainable nutrition by affirming that sustainable diets are those "with low environmental impacts". The combined environmental impact and nutritional assessment of real diets provides a benchmark and an insightful starting point. This first attempt to assess the nutritional quality of whole meals and diets using the Nutrient Balance Concept has already produced new and unexpected insights. The use of country specific food composition databases and the specific daily reference intake tables of a studied country permit to target the analysis for decision on food production and food consumption taking personal choices of consumers into account.

Further work will focus on expanding the number of diets assessed and the scope of the LCAs (inclusion of packaging, food preparation and food waste); identifying patterns, hot-spots and trade-offs. This will lead to build the evidence base for recommendations and guide product development at Nestlé.

ABSTRACT

The general public is continuously concerned about effects from pesticide exposure via residues in food crops. However, impacts from pesticide exposure are mostly neglected in food product-related LCAs. Time-to-harvest and dissipation from crops mainly drive residue dynamics with dissipation as the most uncertain aspect in characterization modeling. We analyzed measured half-lives (n=4513) with 95% falling between 0.6 and 29 days. With ~500 pesticides authorized alone in the EU for several hundred crops, however, experimental studies only cover few possible pesticide-crop combinations. Therefore, we estimated dissipation from measured data and provide reference half-lives for 333 pesticides applied at 20°C under field conditions. Our framework allows for detailed explorations of dietary choices in LCA with respect to health impacts from pesticide exposure via crop consumption. The next step is to include pesticide exposure via crop consumption along with improved pesticide dissipation data into existing LCIA methodologies for consideration in future LCA studies.

Keywords: Pesticides, human exposure, crop consumption, dissipation half-lives, life cycle impact assessment

1. Introduction

A main concern of the general public in various regions including Europe and the U.S. is related to long-term or chronic effects from low-level exposures to pesticides (Pretty 2005; Slovic 2010). Human population-level exposure predominantly occurs from residues in food crops, supplemented by exposure from pesticide fractions lost from agricultural fields after application (European Commission 2006; McKinlay et al. 2008). However, in almost all existing food product-related life cycle assessment (LCA) studies human and ecosystem impacts from exposure to pesticides (or other potentially toxic chemicals) are not considered at all or considered negligible (Heller et al. 2013). This is partly due to the perceived high uncertainty associated with impacts from exposure to toxic chemicals (Finnveden et al. 2009). A framework to characterize human health impacts of individual pesticides applied to different agricultural food crop types grown in Europe has been recently published (Fantke et al. 2011, 2012a). This framework is based on a set of interconnected compartments, for which pesticide fate and residues are calculated by solving s flexible set of differential mass balance equations with assumed first order kinetics by means of matrix algebra. In this study, time between pesticide application and crop harvest along with pesticide dissipation half-lives in crops have been identified as key aspects driving residue dynamics, which is consistent with similar assessments focusing on crop residue dynamics (Juraske et al. 2009; Rein et al. 2011). Whereas the influence of time to harvest has been analyzed and parameterized for existing life cycle impact assessment (LCIA) models, pesticide dissipation in food crops remains one of the most uncertain aspects in characterizing human toxicological impacts of pesticides via food crop consumption (Juraske et al. 2008; Fantke et al. 2012b). In the present study, we aim at reducing uncertainty associated with pesticide dissipation in crops, thereby also facilitating a feasible starting point for including human health impacts from pesticide exposure via food crop consumption in future LCA studies.

2. Methods

We start from following the framework proposed by Fantke et al. (2012a) to calculate human health impact scores for pesticides applied to agricultural fields in Europe. This approach is based on estimated agricultural application data for the five most extensively used pesticides per crop and country in 2003 for 24 member states of the EU as of 2004 (EU24) from a collaboration report between Eurostat and the European Crop Protection Association (European Commission 2007). Health impact scores of pesticide i applied to crop c in a specific year, $IS_{i,c}$ (DALY/year), are calculated from the total mass applied in this specific year, $m_{i,c}$ ($kg_{applied}$/year), the pesticide residue fraction in crop harvest, $hF_{i,c}$ ($kg_{residue}/kg_{applied}$), the food processing factor, PF_c ($kg_{intake}/kg_{residue}$) accounting for reduction of residues in crop harvest due to e.g. washing or cooking, the dose-response slope factor, $ß_i$ (incidence risk/kg_{intake}), and the severity factor expressed in disability-adjusted life years as a composite measure for overall population health impacts, SF (DALY/incidence):

$$IS_{i,c} = m_{i,c} \times hF_{i,c} \times PF_c \times \beta_i \times SF \quad \text{Eq. 1}$$

Fantke et al. (2012a) reported an overall model output uncertainty range, i.e. a variance in health impact scores, associated with contributing input variables along the impact pathway (Eq. 1) between 4.75 and 838,505 DALY/year across EU24 in 2003. Main source of uncertainty in the mass balance resulting in residual fractions of pesticides in crop harvest is the first order rate coefficient representing dissipation from crops. Hence, we focus in this study to reduce uncertainty related to dissipation in crops. Uncertainty of any model input and output variable x can be characterized by its squared geometric standard deviation $GSD^2(x)$ and related probability of 95% = $\{x/ GSD^2(x) < x < x \times GSD^2(x)\}$. We use $GSD^2(x_k)$ for input variables $x_k \in \{m_{i,c}, hF_{i,c}, PF_c, ß_i, SF\}$ as provided by Fantke et al. (2012a) to obtain $GSD^2(IS_{i,c})$ of model output (health impact scores $IS_{i,c}$):

$$\mathrm{GSD}^2(IS_{i,c}) = \exp\left(\sqrt{\sum\nolimits_{k=1} (\ln[\mathrm{GSD}^2(x_k)])^2}\right) \quad \text{Eq. 2}$$

The uncertainty related to the calculation of pesticide residues in crop harvest is reported to be $GSD^2(hF_{i,c}) = 27$ and to correspond to a contribution of 29.6% to the output-related uncertainty of $GSD^2(IS_{i,c}) = 412.73$. To reduce $GSD^2(hF_{i,c})$ and thereby also $GSD^2(IS_{i,c})$, we systematically built an inventory database of existing experimental studies providing dissipation half-lives in agricultural food crops and other plants (Fantke and Juraske 2013). Measured dissipation half-lives from 811 scientific studies (>99% peer-reviewed) were available or calculated from concentration-time curves for 346 pesticides applied to 183 crops (n = 4513) with 95% of all half-lives falling between 0.6 and 29 days. However, with almost 500 pesticides authorized alone in the European Union for use on several hundred crops, analyzed experimental studies still cover only a small fraction of possible pesticide-crop combinations.

In response to this need, we developed models to estimate dissipation in crops based on the review from Fantke and Juraske (2013). We first characterized measured pesticide dissipation half-lives by describing their distribution and by determining the influence of temperature from a subset of 1030 data points with reported study condition average air temperatures. We then provided recommended geometric means of dissipation half-lives at 20°C and 95% confidence intervals for 333 reported pesticides, and used multiple imputations for substituting missing temperature data. Next, we proposed a regression-based model to predict dissipation half-lives for pesticides as a function of temperature, substance chemical class, selected substance properties and plant characteristics for all pesticides where reported data were not available. We finally evaluated model prediction performance using sums of squares of prediction residuals for excluded data. Results of these models for pesticide dissipation in crops were compared with previously used dissipation data in the assessment model framework proposed in Eq. 1 and compared in terms of model input and output uncertainty expressed in terms of GSD^2.

3. Results

Reference half-lives for 333 pesticides with reported temperatures applied at 20°C under field conditions range from 0.2 days for pyrethrins and 0.3 days for chlorsulfuron to 31 days for dalapon with 95% of all half-lives falling in the range between 1 and 18 days. Parameter estimates correct these half-lives for specific crops, temperatures, and study conditions. On average over all substances, temperature imputation only contributes with 5.1% to standard errors of half-lives. Standard errors of substance and plant parameter estimates approximately follow a decrease proportional to the inverse of the square root of the number of data points. With a minimum of 20 data points, we get a standard error of 0.08, implying a 95% confidence interval on geomean half-lives of a factor 1.5. For pesticides without reported data, we developed our final predictive model aims at estimating dissipation half-lives of pesticides as a function of their chemical class and properties. Substance class, plant species, cold storage conditions, temperature, substance molecular weight, octanol/water partition coefficient and saturation vapor pressure were taken into account as final predictor variables. All other tested substance properties (air/water and soil organic carbon/water partition coefficients, half-lives in air and soil) either did not significantly improve model accuracy or showed strong correlation with another variable. This model yields standard errors on the parameter estimates of 0.07 to 0.16 for substance classes and 0.06 to 0.15 for plant species. Implementing the new estimated dissipation half-lives into the model assessment framework proposed in Eq. 1 yields a reduced model input uncertainty in terms of a reduced $GSD^2(hF_{i,c}) = 12$, which corresponds to a reduction in variance of residues in crop harvest across pesticides and crops. Thereby, we reduced overall output-related uncertainty in terms of a reduced $GSD^2(IS_{i,c}) = 278.3$ and the contribution of residues in crop harvest (represented by $hF_{i,c}$) from initially 29.6% to now 19.5% (see Figure 1). With this, we reduced uncertainty in characterizing human exposure to pesticides via food crop consumption.

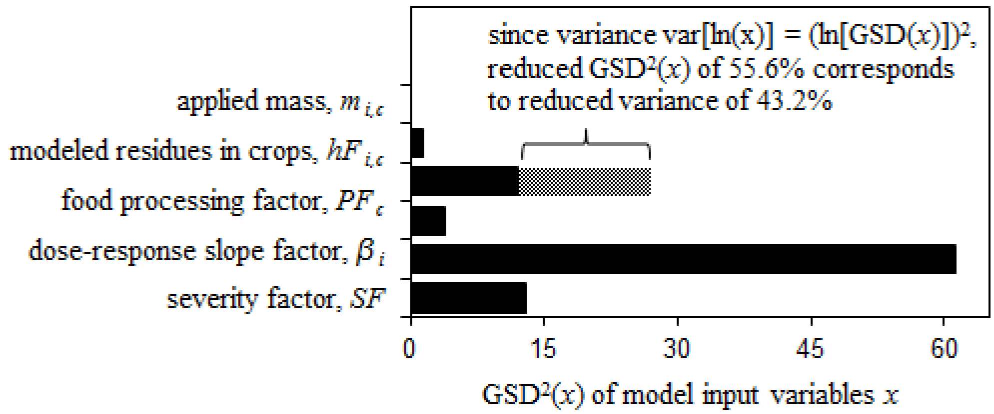

Figure 1. $GSD^2(x)$ of input variables along the pathway from pesticide application to severity of health impacts to obtain impact scores (DALY/year) due to the use of pesticides in EU24 in 2003.

Human health impact scores for use of pesticides in the EU24 countries in 2003 as applied in Fantke et al. (2012a) were re-calculated based on the newly obtained dissipation data. Overall, pesticides contributed annually to 1950 DALY/year in EU24 in 2003, to which only 13 substances applied to grapes/vines, fruit trees, and vegetables accounted for 90% of total annual health impacts. Impact scores thereby range from 0.34 DALY/year for sugar beet and 1.35 DALY/year for cereals to 724 DALY/year for grapes/vines and 1100 DALY/year for vegetables (Figure 2). The total burden per person in hours lost over lifetime was 1.5. Compared with figures for the burden from exposure to fine particulate matter in the air with 195 days or second-hand smoke in the air with 24 days (Hänninen et al. 2014), this figure is relatively low. However, uncertainties in our results – even though reduced for dissipation data in food crops – highlight the figure could be somewhat higher, ranking pesticides with other important environmental stressors in health impact terms when comparing with our upper end 95% confidence interval limit of 17.4 days burden per person over lifetime (see Figure 2).

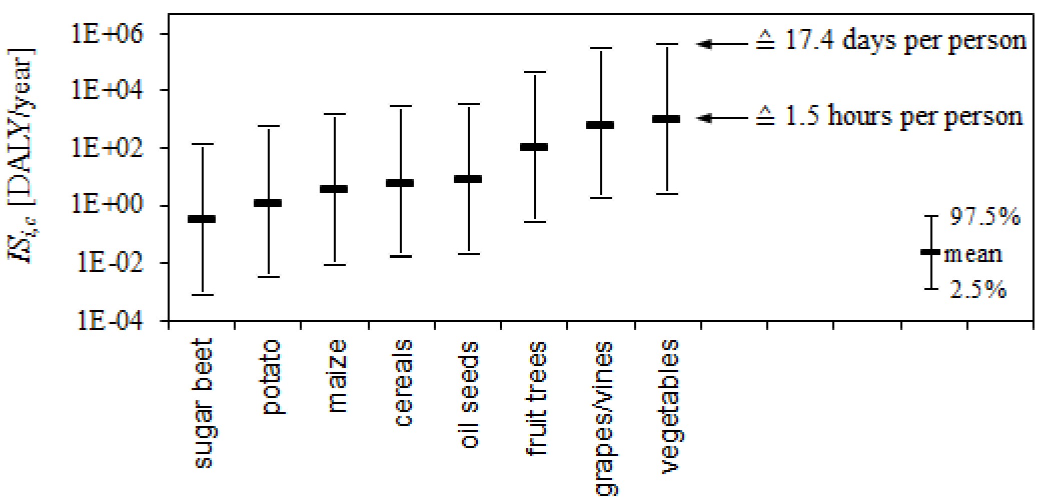

Figure 2. Mean and 95% confidence interval of impact scores (DALY/year) due to the five most extensively used pesticides on each crop class as well as sum over crops across EU24 in 2003.

4. Discussion

We developed a set of 333 comparative pesticide dissipation half-lives in food crops under reference conditions represented by an average plant, field conditions, and a temperature of 20°C (Fantke et al. 2014). These half-lives have been corrected to account for crop type, conditions, and temperature in the underlying experimental studies. This comprehensive approach, where we correct for measured temperature, reported crop species, and reported study conditions for predicting dissipation, and where we impute missing temperatures and finally study the variability of reported half-lives for each pesticide significantly reduces the uncertainty around each estimated dissipation half-life, thereby much better reflecting reference study conditions. Our additional predictive model is designed to estimate dissipation half-lives from properties of individual pesticides belonging to 14 substance classes, for which no half-lives representing reference conditions could be obtained in our study due to missing experimental data.

Considering the high variability between substances and crops, and data availability, our recommended reference half-lives along with the predictive model estimates constitute a first step towards reducing uncertainty in our assessment framework with respect to pesticide degradation in food crops. However, we acknowledge that for LCA studies, the underlying data also need to be available across pesticides and crops. Therefore, additional research is required to systematically assess the relationship between overall pesticide dissipation and degradation in crops, since typically degradation is considered as separate process in LCIA models, to further understand the influence and importance of degradation in crops as one of the main drivers of subsequent human exposure and related health impacts to be included in future LCA studies. Furthermore, reporting guidelines for measuring dissipation from food crops need to be improved with respect to providing sufficient information on environmental study conditions (e.g. reporting temperature, humidity, soil type) and residues in crops (providing enough data points to account for measurement variability and to effectively perform curve fitting for estimating dissipation kinetics). This will further increase LCIA input data quality when using experimentally-derived half-lives.

5. Conclusion

Our pesticide- and crop-specific assessment framework allows for detailed explorations of dietary choices in a LCA context with respect to human health impacts from pesticide exposure via food crop consumption. Furthermore, we reduce uncertainty related to one of the key drivers of pesticide residue dynamics in food crops in support of improving the reliability of impact assessment results. The next step is to include human exposure via crop consumption along with improved pesticide dissipation data into existing LCIA methodologies for consideration in future LCA studies. We further acknowledge that impacts from pesticides in LCAs are often dominated by impacts on biodiversity (Geiger et al. 2010) and on groundwater (Arias-Estévez et al. 2008). Hence, we emphasize the need to include pesticides into food-related LCA studies and recommend covering all relevant impact categories related to pesticides including human toxicity, ecosystem toxicity and groundwater contamination to provide an improved basis for LCA-based decision support.

ABSTRACT

Cashew (*Anacardium occidentale*) is a native Brazilian perennial tree that is also present on 30 other tropical countries and produces three worldwide-commercialized food products: cashew nuts, apple, and gum. This study assesses the life cycle environmental impacts of Brazilian dwarf cashew considering the management and crop functions. From the joint analysis of both functional units, we conclude that the best option to improve the environmental performance of Brazilian cashew production is to adopt the reference system with modifications regarding fertilization and land use change. From this case study, we highlight the benefits of considering both functional units and all production stages in the study of perennial crops.

Keywords: cashew nut, cashew apple, cashew gum, dwarf cashew, *Anacardium occidentale*

1. Introduction

Cashew orchards are of great importance for the social economy of many developing regions of the world (Azam-Ali and Judge 2004, Hall et al 2007), since this plant grows in harsh semi-arid climatic and soil conditions and generate income to many small farmers. Cashew producers may benefit from the commercialization of cashew nuts (CN), cashew apple (CA) and gum (CG) from the cashew tree in the international market. The renewal of orchards after 20 years of production also generates wood (CW) that is usually used by potteries as a renewable fuel.

World demand for cashew nuts has increased at a rate of about 4% annually from 2007 to 2011 (FAO 2013, INC 2013). This demand was mostly (79%) attended in 2011 by small farmers located in Vietnam, Nigeria, India, Ivory Coast and Brazil. In 2011, the United States, the United Kingdom, Germany and The Netherlands imported 76% of the cashew nut produced in tropical developing regions.

Cashew agriculture research in Brazil and in other countries has focused in developing high productive cashew clones and production systems. As this goal has been achieved in Brazil, research starts to focus on the evaluation of the environmental sustainability of cashew production systems. The knowledge about the environmental hotspots in cashew production may shed light on the identification of improvement options that will contribute to the environmental sustainability of producing regions. Besides, consumers and companies all over the world utilize cashew nuts in nature or as ingredient in diverse food (e.g. snacks, sauces, protein concentrates), making the cashew nut life cycle assessment of interest for many production chains.

This study assesses the life cycle environmental impacts of Brazilian dwarf cashew (Anacardium *occidentale*). We consider two agriculture functions: land management (agriculture system level) and production (product level). The study considering the land management function evaluates the environmental impacts of two production systems and the study focused on production, the impacts caused by cashew products (CN, CA, CG and CW).

2. Methods

We followed ISO 14040 directives to perform a life cycle assessment (LCA) for quantifying the environmental impacts of Brazilian dwarf cashew systems and products (CN, CA, CG and CW).

2.1. Scope and functional unit

The scope of this study is cradle to cashew farm exit-gate, considering the production of inputs (diesel, fertilizers and pesticides), transport of inputs to the cashew farm, and cultivation of dwarf cashew trees. Two functional units are used: one ha with 208 trees for the study of the cropping system; and one kg for the analysis of cashew products (CN, CA, CG and CW). The inventory data for the study of cropping systems covers the production of dwarf cashew cultivated during 20 years. Cultivation is organized by production stage: nursery, establishment (includes land preparation and planting during the first year), low production (4 years) and full production (years 6 to 20).

2.2. Inventory data

Two production systems for dwarf cashew are considered: the reference system (REF-farm) developed along 20 years of research, and the low input system (LI-farm) as practiced by a sample of farms.

Input data for the reference system come from reports of experiments and interviews with researchers on the subject of dwarf cashew production systems. Experiments started in 1980 at the Embrapa Tropical Agroindustry Experimental farm, located at Pacajus, Ceará State, Brazil. Their results are summarized by Crisóstomo et al (2007), Cardoso et al (2013), Crisóstomo (2013), Cavalcanti Junior (2013), Mesquita and Sobrinho (2013), Miranda (2013), Serrano and Oliveira (2013), and Vidal Neto et al (2013).

Input data for the low input system is derived from interviews applied to a sample of ten cashew farmers and two rural extension managers in 2013, located in six municipalities of the Ceará State, Brazil. The Ceará State holds 57% of the cashew production area (IBGE, 2013). The interviewed farmers and extensionists provided the average amount of input and production obtained for CN and CA during production stages, considering the last three years.

Inventory data for the cradle to gate production and transport of inputs used on cashew orchards (manure, mineral fertilizers, diesel, pesticides and plastics) were obtained from the *ecoinvent* 3.0 database (Weidema et al 2013).

2.3. Description of dwarf cashew production

Dwarf cashew production in the REF and LI farms encompass the following stages:

Nursery: Cashew seedlings are produced by grafting in nursery farms. The nursery involves three steps that take 120 to 150 days. First, dwarf seeds are sown on compost substrates that are deposited in small polypropylene tubes (diameter of 6 cm and height of 20). After 60 days of sowing, the germinated plants are grafted on rootstocks of the scion obtained from dwarf clone gardens. The grafted plants stay during 30 to 40 days in a greenhouse. After this time, seedlings are acclimatized in open fields for 30 to 50 days when they are apt to be planted in cashew orchards. Irrigation of the seedlings occurs every day of the production cycle and foliar fertilization, four times per cycle. We considered that 60,000 seedlings of grafted cashew are produced per year in 5.6 ha, with 60% of seeds producing viable seedlings; 20x6x4m grille of high density polyethylene are used to cover the shaded greenhouse (50%), lasting for 5 years; and that the polypropylene tubes last for 10 years.

Establishment (year 1): Land conversion, plowing and harrowing are performed before seedlings transplantation to orchards. The transplantation occurs in the raining season (January to April). Grafted cashew seedlings are planted into pits of 40x40x40cm on sandy soils with the pits spaced 8x6m (208 plants.ha^{-1}). Calcareous dolomite is applied at the bottom of the pits that are then filled with a mixture of surface soil, micronutrients, bovine manure and simple superphosphate at the REF-farm or only with soil poultry or bovine manure at LI-farms. Post-planting fertilization at REF-farm is based on nitrogen and potassium fertilization and at LI-farm on nitrogen from manure. Manual pruning is practiced in order to take out stems, which emerge from the rootstock, and flowers, in order to foster plant growth. In this first year, at the REF-farm, localized irrigation at the pits occurs four times per month during the dry season (from May to December).

Low production (year 2 to 6): Dwarf cashew plants grow until the sixth year after planting when they achieve growth stability. During each production year, the tree has a low and an intense vegetative growth: low in the raining season (January to April) and an intense growth in the dry season (May to December). During the intense growth period, the leaves fall, and flowering and fructification occur. Cashew orchards are rain fed from the second year onwards. Fertilization aiming plant growth occurs along the raining season (January to April). REF-farm uses manure and mineral (NPK) fertilizers and LI-farm, only manure. Manual pruning is practiced after harvest (December to January) and aims to reduce branches interlacing. This increases illumination in the canopy, and prevents pest and disease dissemination among branches. The REF-farm applies herbicides or mechanical weeding below the tree canopy to prevent competition among cashew and other plants (weeds). The LI-farms use manual weeding only before harvest. Both the REF-farm and LI-farms mow between lines of cashew trees to facilitate harvesting and promote soil covering with green manure (mulch). Insecticides, fungicides and herbicides are used only at REF-farm and follow the integrated pest and disease management plan. As many as 97 species of insects and 10 types of fungus may attack cashew orchards in Brazil. The calculus of the amount of pesticide used, however, consider only those pests and diseases that have caused most damage to orchards and that have registered pesticides for this culture. The production of CN (fruit) and CA (pseudo fruit) starts on the second year, and the CG, on the sixth year. CG is produced with the monthly application of growth hormone on lateral cuts made at the tree trunk.

Full production (year 7 to 20): The adult dwarf cashew tree may be 4 m high with a canopy diameter of 6 to 8 m and roots that may achieve 12 m (Crisóstimo et al 2007). CN (kernel and shell) average weigh ranges from 7 to 12 g, and CA, from 80 to 160g. During the full production period, fertilization aiming the CN production of 1,200 kg.ha^{-1}.year^{-1}, CA of 2,160 kg.ha^{-1}.year^{-1} and CG of 90 kg.ha^{-1}.year^{-1} is applied at the REF-farm. LI-farm relies only on composted manure and may produce 600 kg.ha^{-1}.year^{-1} of CN and 1,080 kg.ha^{-1}.year^{-1} of CA. Annual mowing, weeding and pruning are performed as in the low production years. At the end of the 20th year, new cashew trees replace old ones and the CW is commercialized at the local market.

2.4. Calculation of emissions

The calculus of greenhouse gas emissions (CO_2, CH_4 and N_2O) from agriculture fields for both production systems follows IPCC (2006). The following airborne emissions are estimated according to the methods described by Nemecek and Schnetzer (2012): ammonia (NH_3) and nitrogen oxides (NO_x) to air; nitrate (NO_3) and phosphorous compounds as phosphate (PO_4) and phosphorous (P) to water; pesticides and heavy metals (Cadmium (Cd), copper (Cu), zinc (Zn), lead (Pb), nickel (Ni) and chrome (Cr)) to soil. All pesticides applied for crop production were assumed to end up as emissions to, and remain as pollutants in the soil. The further fate of the substances is taken into account in the impact methods for human toxicity. We assumed that no leaching of soluble phosphate (PO_4) to ground water occurred because of the high aluminum and iron oxides content usually found in the type of soils where cashew orchards are located (Crisóstomo et al 2007) in Brazil. These oxides adsorb phosphate molecules in soil particles impeding leachate.

The humidity, carbon and nitrogen content of dwarf cashew tree are measured according to Silva et al (2009) from samples of roots, trunk, leaves and steams of a ten years old Clone BRS 226 tree. Samples were collected at Embrapa Pacajus Experimental Station, Ceará, Brazil.

2.5. Allocation procedure

No allocation is needed for the functional unit of one ha with 208 trees. Allocation is necessary, however, for the functional unit of one kg cashew nut products due to the multiple cashew products harvested from a dwarf cashew tree (CN, CA, CG and CW). We applied allocation according to mass and economic criteria to illustrate sensitivity of results for the allocation principle used. Allocation considers the production weight of cashew products over 20 years. The replacement of the cashew orchard allows the commercialization of CW at the end of the 20th year. CG may start to be extracted from dwarf cashew by commercial farms in the sixth year of plant growth. CG market value is assumed the same as the acacia gum that is a similar product and has long been commercialized in the world market. The allocation factors for each farm system and product is presented in Table 1.

Table 1. Allocation factors

		REF-farm			LI-farm		
Product	**Price (US$/kg)**	**Production in 20 years (kg/ha)**	**Economic allocation**	**Mass allocation**	**Production in 20 years (kg/ha)**	**Economic allocation**	**Mass allocation**
CN	0.8	17,330.00	44%	15%	6,432.50	51%	8%
CA	0.4	31,194.00	39%	27%	11,578.50	46%	14%
CG	4.0	1,260.00	16%	1%			
CW	0.004	67,392.00	1%	58%	67,392.00	3%	79%
Total		117,176.00	100%	100%	85,403.00	100%	100%

2.6. Impact assessment

We applied the Recipe model (Goedkoop et al 2009) focusing on the midpoint environmental impact categories natural land transformation, climate change, acidification, eutrophication and human toxicity. The reasoning behind this selection is that these categories are important to the study of fruit products, according to Michalopoulos and Christodoulopoulou 2012). Furthermore, the emissions calculated for cashew production in this study may directly cause these impacts.

The reference situation for land transformation is the change from Caatinga (Brazilian savannah) forest to dwarf cashew orchards.

The method Monte Carlo for uncertainty analysis is applied to the study results. We assume log normal distributions for probability functions and run the model for 1,000 cycles. The Pedigree matrix in SimaPro is used to determine the deviations of each variable (Goedkoop et al., 2008).

3. Results

3.1. Inventory of inputs from primary data per ha

The full and low production stages require most of the inputs per hectare of cashew cultivated in both production systems, i.e. REF-farm and LI-farms (Table 2). In these stages, macronutrients and pesticides are more intensively applied than in the earlier stages. Nursery requires in general the smallest amounts of inputs, although the establishment year requires most of the water and all the micronutrients (boron, copper, manganese, molybdenum, zinc and iron).

The majority of dwarf cashew orchards are located on deep, well-drained, sandy loam soil of low natural fertility, usually Quartzarenic Neosols (Quartz Sands), Latosols and Argisols (Podzolics) (Crisóstomo et al 2007). Fertilization is required in these soils to promote plant growth and improve yield. Potassium and phosphorous are essential during growth (low production) stage for root development. Nitrogen increases the flowering period and the yields of CN, CA and CG (Crisóstomo 2013, Lima 2014). The LI-farms apply per ha less fertilizer than the REF-farm in all production stages.

Pesticides are required to control the population of pests and diseases when infestation levels are above the rates determined by the integrated management plan (Cardoso et al 2013, Mesquista et al 2013). These pests and diseases attack seedlings and cashew trees during inflorescence, reducing nut and apple yields. Only the REF-farm controls infestations of pests and diseases. In this farm, deltamethrin (insecticide) is used to control infestations of drills (*Anthistarcha binocularis Meyrick*) and thrips (*Selenothrips rubrocinctus Giard*), and copper oxychlorate (fungicide), to combat Anthracnose (*Colletotrichum gloeosporioides (Penz) Pez. & Sacc)*. Glyphosate (herbicide) is applied to control weeds, especially *Senna obtusifolia, Alternanthera sp., Panicum maximum, Cenchrus echinatus*, *Eleusine indica, Setaria geniculate, Ipomoea sp., Sida cordifolia, and Solanum sp.*

The low fertilization and no control of pests and diseases in LI-farms result in CN and CA yields that per ha are 63% lower than in REF-farm. CG is a new product from cashew orchards and is not yet produced by most of the commercial farms in Brazil. Nonetheless, Lima (2014) reports that cashew orchards with reduced fertilization rates (150 g.plant^{-1} of N, 300 g.plant^{-1} of P_2O_5 and 90 g.plant^{-1} of K_2O) produce 7% less CG yield per ha than orchards subjected to fertilization as adopted in the REF-farm.

Lime and gypsum are applied to cashew orchard soils, both in the REF and LI-system, because of their high acidity and aluminum saturation percentage (above 40%) (Crisóstomo 2013). Gypsum is incorporated in deep soil layers to reduce aluminum saturation before seedling transplantation at the REF-farm, while lime is applied on all production stages to correct soil pH in both farm systems.

The best climate conditions for dwarf cashew production occur when temperature ranges from 22 to 32^{o}C along the year, relative humidity, from 70% to 85%, and annual precipitation, from 800 to 1,500 mm, distributed over 5 to 7 months per year (Serrano and Oliveira, 2013). The presence of this climate condition allows cashew cultivation in semi-arid regions without irrigation, such as the Brazilian Northeast. Nonetheless, during nursery and the first establishment year, continuous water supply through irrigation is necessary and used by REF and LI-farms. Irrigation is necessary because of the small size of the rooting system that is not able yet to extract water from deep soil layers.

3.2. Impacts per ha of dwarf cashew considering the land management function

The production system adopted by LI-farms cause significant less environmental impacts per ha than the system used by the REF-farm, for all but the land use impact category (Table 3). This result is expected since the LI-farms use less input and generate less emission than the REF-farm. However, both systems may require land transformation for the same area.

The main sources of environmental impacts at the REF-farm and LI-farm are:

Land use and climate change: Carbon stock losses during land transformation and nitrous oxide emissions from nitrogen fertilizers used in cashew orchards emit most of the greenhouse gases causing climate change.

Human toxicity: Fertilizers are contaminated by heavy metals and these are released to soil (e.g. Cd when single superphosphate is applied to agriculture soil). Pesticides applied in cashew orchards are also released to soil. These emissions may degrade human health. This occurs in the REF-farm that uses mineral fertilizers and pesticides. In LI-farms, upstream processes related to the poultry manure production chain emit most of toxic substances.

Terrestrial acidification: The use of mineral nitrogen fertilizers at the REF-farm emits most of the NH_3 and NO_x that cause terrestrial acidification. For the LI-farms, NH_3 emitted in the production of composted poultry manure is the main cause of acidification.

Marine and freshwater eutrophication: The production and use of mineral and organic fertilizers on both REF and LI farms emit most of the nitrogen and phosphorous compounds with potential to cause marine and freshwater eutrophication.

Table 3. Environmental impacts per ha in REF and LI farms, for 20 years

Impact category	REF-farm	Li-farm	Uncertainty (LI-farm >= REF-farm), Confidence interval of 95%
Climate change (kg CO_2 eq.ha^{-1})	176,556.95	117,300.62	1%
Human toxicity (kg 1,4-DB eq.ha^{-1})	36,890.62	768.44	0%
Terrestrial acidification (kg SO_2 eq.ha^{-1})	1,426.53	43.40	0%
Freshwater eutrophication (kg P eq.ha^{-1})	20.22	2.72	0%
Marine eutrophication (kg N eq.ha^{-1})	258.68	142.15	0%
Natural land transformation (m^2.ha^{-1})	19,984.02	19,972.88	51%

3.3. Impacts per kg of cashew products considering the crop production function

Mass as well as economic allocation is used to calculate the environmental impact per kg cashew product (see section 2.5 and Table 1 for mass and economic values). The type of allocation criteria affects the magnitude of cashew products impacts (Table 3). CG is the most sensible product to the choice of allocation criteria due to its relative high economic value. The impact values for CG may increase at least fifteen times when moving from mass to economic allocation.

Table 4. Impacts per kg of CN, CA, CG and CW, considering economic and mass allocation

Cashew Product	System	Allocation procedure	Climate change (kg CO2 eq.kg^{-1})	Terrestrial acidification (kg SO2 eq.kg^{-1})	Freshwater eutrophication (kg P eq.kg^{-1})	Marine eutrophication (kg N eq.kg^{-1})	Human toxicity (kg 1,4-DB eq.kg^{-1})	Land transf. (m2.kg^{-1})
CN	REF-farm	Economic	4.46	0.04	0.0005	0.01	0.93	0.51
		Mass	1.51	0.01	0.0002	0.002	0.315	0.17
	LI-farm	Economic	9.34	0.003	0.0002	0.01	0.06	1.59
		Mass	1.37	0.001	0.00003	0.002	0.009	0.23
CA	REF-farm	Economic	2.23	0.02	0.0003	0.003	0.47	0.25
		Mass	1.51	0.01	0.0002	0.002	0.31	0.17
	LI-farm	Economic	4.67	0.002	0.0001	0.006	0.03	0.80
		Mass	1.37	0.001	0.00003	0.002	0.009	0.23
CG	REF-farm	Economic	22.31	0.18	0.0026	0.033	4.66	2.53
		Mass	1.51	0.01	0.0002	0.002	0.31	0.17
	LI-farm	Economic						
		Mass						
CW	REF-farm	Economic	0.02	0.0002	0.000003	0.00003	0.005	0.003
		Mass	1.51	0.01	0.0002	0.002	0.31	0.17
	LI-farm	Economic	0.05	0.00002	0.000001	0.0001	0.0003	0.01
		Mass	1.37	0.0005	0.00003	0.002	0.009	0.23

Economic allocation assigns higher impacts for CN, CA and CG in both farm systems since these products have higher market values. Since CG is not yet widely commercialized by LI-farms, no impacts are assigned to this product for this system.

Moreover, mass allocation highlights the participation of CW in impact values, in both farm systems. The lower CN and CA yields obtained in LI-farms explain the higher allocation value assigned for CW.

The combined analysis of allocation criteria and production systems shows that the environmental performance of products cultivated in different production systems change according to the allocation criteria adopted.

If the choice is for economic allocation, CN, CA and CW cause less impact on land use, marine eutrophication and climate change when produced in the REF-farm. If mass allocation is used, these products cause similar impacts for these impact categories. The high yields obtained in the REF-farm are not enough to reduce the impacts of cashew products on the other impact categories (freshwater eutrophication, human toxicity and acidification) to values lower to the ones obtained in the LI-farm.

4. Discussion

In this study, cashew production was evaluated at the per ha (land management) and per kg product (production) levels. The land management study compared two production systems: one resulting from consistent field research (REF-farm system) and the other based on common practice at small and medium sized farms (LI-farm). The comparison of these systems showed that LI-farms perform better in terms of environmental impacts per ha.

However, these farms maintained the same low fertilization rates in all production stages, and hardly controlled pests and diseases, leading to low emissions and impacts but also low yields. These low yields of CA and CN and no production of CG may result in higher impact per kg of product for LI-farms than for ref-farms, according to the allocation procedure chosen. The low yields from the LI-farms also mean low incomes for the small farmers, reducing their capacity to invest in better management practices. The interviews with the LI-farmers also highlighted the reduced access to technical assistance and little knowledge of updated cashew production systems. Considering these aspects, the argument for refraining from the LI-farm system becomes stronger. A better option may be to keep the high yields of the REF-farm system and try to reduce its environmental impacts per ha.

Three main activities considerably affect the environmental performance of the REF-farm system: land use transformation, mineral fertilization and pesticide applications. The best choice for reducing impacts on land use, and as a consequence on climate change and biodiversity, is to establish dwarf cashew orchards in already deforested areas currently set aside or used to produce annual crops. Conversion of Caatinga (Savana) vegetation to dwarf cashew orchards results in losses of carbon stocked on biomass and soil and also cause biodiversity loss in the already much disturbed Caatinga biome. Regarding fertilization options, organic instead of mineral fertilization is preferred from the perspective of impacts per ha. The use of mineral fertilizers in the REF-farm is responsible for the major impacts on human toxicity, acidification and eutrophication. The amount of pesticides can be decreased with the use of intercrop systems that increase biodiversity in cashew orchards (Xavier et al 2013).

The intercrop of cashew trees with leguminous and grass species may decrease the need for mineral fertilization and reduce the level of pest and diseases in orchards. Some small cashew farmers in the Brazilian Northeast already adopt this practice to increase their sources of income, cultivating cashew in association with beans and corn during the raining season, but medium and large farms hardly adopt this practice. Previous research showed that the cultivation of *Canavalia ensiformes* (type of bean) between lines of dwarf cashew trees during the raining season leveled CN yield to 1,179 $kg.ha^{-1}$ already in the fourth low production year (Oliveira et al 2000). This yield is 108.7% higher than the one obtained in the experimental parcel with no consociation. The association of legumes with cashew also reduces weed development and the need for the use of herbicides, besides increasing soil carbon stock, organic matter and nutrient content (Xavier et al 2013). However, further research is still necessary for determining the amount of mineral fertilizers that can be substituted by green fertilization with leguminous species adapted for the semi-arid environmental conditions.

The impact per kg product level was evaluated by means of a sensitivity analysis with both economic and mass criteria to allocate impacts over the multiple product outputs of the cashew orchards. Although both allocation procedures can be adopted to calculate the impacts of cashew products, results considerably change with the choice made. Economic allocation increases the impacts of CN, CA and CG and decreases the impact of CW in all categories. It also leads to the conclusion that products from the REF-farm may cause lower impacts than when cultivated in LI-farms, according to the analyzed impact category. On the other hand, mass allocation does not differentiate products from both production systems, for half of the analyzed impacts categories.

CG is presently starting to be extracted from dwarf cashew by commercial farms and the assumptions made in this study for the evaluation as CG using mass allocation represents a near future situation for Brazilian cashew farms. Nonetheless, CG real price is not settled yet in the local or international markets. The value used for CG was assumed the same as the acacia gum, although this situation is not yet at stake now since CG is starting to be commercialized. The acceptance of this new product by the food industry is not yet clear and it may take years for CG to become a real substitute product for the acacia gum. Nevertheless, CG is expected to be commercialized in few years, and the study results are therewith representing a future situation.

The prices for CN and CA are volatile ranging from $ 0.4 to 0.8 per kg of CN and from $ 0.2 to 0.4 per kg of CA, respectively, in the last five years. We therefore recommend the use of mass allocation for the evaluation of cashew products. This is also in accordance with ISO 14040 that recommends allocation on physical relationships over allocation based on other relationships.

5. Conclusion

Cashew production in small and medium farms in Brazil use a low input system with reduced environmental impacts per ha. These farms, however, also have low yields and profits. Many years of experimental research developed a reference production system with increased yields of nuts and apples as well as gums extracted from the trees trunk. This reference system relies on fertilization with specific rates for each production stage, and on the integrated management of pests and diseases. The higher yields per ha result in the reference system having similar or lower impacts per kg of product than the low input systems, for half of the impact categories.

The impacts caused by Brazilian cashew orchards and products change according to the choice of functional unit (i.e. per ha or per kg product) and allocation procedure adopted (i.e. mass or economic allocation). When the land management function is applied (one ha of cultivated orchard), the low input production system is preferable, but if the production function is chosen the results per kg of product produced in each system are not conclusive.

From the joint analysis of both functional units, we conclude that the best option to improve the environmental performance of Brazilian cashew production is to adopt the REF-farm system with modifications. That is, this system provides higher yields and income for the cashew farmers and may cause less impact if orchards are installed in agricultural or degraded areas and intercrop practices are adopted.

Keywords: comparative LCA, emissions reporting, urban agriculture, land use change, fresh vegetable production

ABSTRACT

Local policy makers typically do not have useful, quantitative metrics to compare environmental costs and benefits of urban vegetable production versus the large-scale commercial production in the typical grocery store supply chain. While urban agriculture has been championed as a way to address social issues such as food access and nutrition, we know relatively little about net environmental benefits, if any. The study combines a comparative life cycle assessment of vegetables with effects of direct and indirect land use change resulting from the urban vegetable production. This paper presents a methodology and selected results of scenarios of land use change due to urban vegetable production address resource use, greenhouse gas emissions, employment, and soil organic carbon. Surprisingly, urban vegetable production is not categorically favorable for each metric; several key parameters can shift the balance in favor or out of favor for either growing format, and these parameters are distinctly bottom-up.

1. Introduction

The popularity of urban vegetable production on a small-scale is, in part, explained by the way people feel about the food system, and is a response of sorts – a response to the existing dominance of large-scale production formats. Much of what we know about the supposed benefits of small-scale production, then, is relative to large-scale production. Typically, the belief is that small-scale is better than large-scale. However, a quantitative comparison of these two formats using a life cycle approach that could corroborate these beliefs has not been done on a scale that is relevant. Further, to have relevance with a number of municipal climate and sustainability action plans, a life cycle assessment would have to be fairly specific to that locale.

Food life cycle assessment (LCA) studies commonly draw from any one or more of the intermediate sources, from raw data to proprietary software tools, as depicted in Figure 1. Pathways of agricultural production emissions reporting can include measured, estimated, and modeled data and each use can support far-reaching and impactful policy decisions on the part of government and industry (Grubb 1995; Lynch et al. 2011; Smith et al. 2008; Zborel et al. 2012). This study carefully chooses appropriate data sources that match the level of variability and scale of the components of the vegetable production system where national or regional data may be used otherwise. In doing so, methodological accuracy is increased and uncertainty is reduced, although a component of this study relies on data collected in a case study whose sample size is small. This paper presents selected data, methodology, and findings from a more comprehensive study (Fisher 2014).

While some LCAs are conducted with interest in greenhouse gas accounting, this study contributes additional valuable environmental metrics such as resource use (for water, energy, fuel), ecotoxicity, and human health impacts. Additional impact metrics such as soil organic carbon (SOC) levels, indicating soil health and supporting ecosystem services, land use change, and employment provide a larger picture of sustainability. SOC is interesting for carbon sequestration and indicates if soil is being improved or depleted. Second, the labor indicator is used because there is a stark and measurable difference between the labor inputs of large-scale and small-scale growing. This can be seen as an opportunity for local employment, but a risk for corporate efficiency.

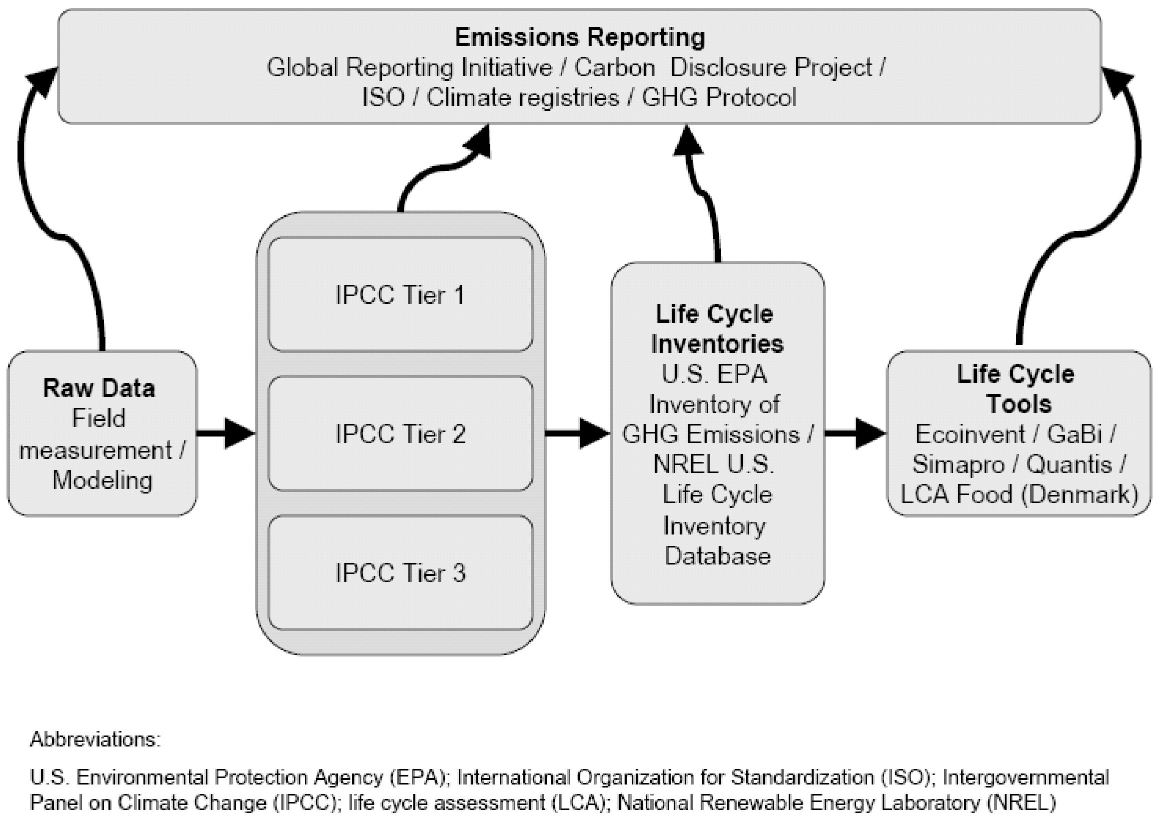

Figure 1. Data Sources and Emissions Reporting.

2. Methods

Formally speaking, this study is an attributional LCA with a component of consequential LCA using direct and indirect land use scenarios (decisions). Although mostly a process-based LCA, a few flows have been characterized by economic input-output and databases that represent regions and nations. For this component, the LCA study could be characterized as hybrid. The LCA follows the well-recognized International Standards Organisation (ISO) Series 14000 standards.

2.1. Scope and System Components

A group of four vegetables was chosen based on their contribution, by calorie, of the average American diet of fresh vegetables. These are potato 53 percent; onion 12 percent; carrot 7 percent; and tomato 6 percent. These comprise approximately 78 percent of the fresh vegetable consumption of the average American (USDA 2009). These are found readily in any supermarket, and are all grown in the Denver metropolitan area by operators of neighborhood supported agriculture (NSA), community supported agriculture (CSA), and individuals. The LCA was conducted on these four vegetables, from field to consumer, in each of nine locations where they are grown. The small-scale urban production occurred entirely in Denver, Colorado. The large-scale commercial production occurred in eight different locations (Comazzi 2012), as shown on Figure 2. The functional unit was set to 1 pound of fresh vegetable (potato, onion, carrot, tomato) to the consumer.

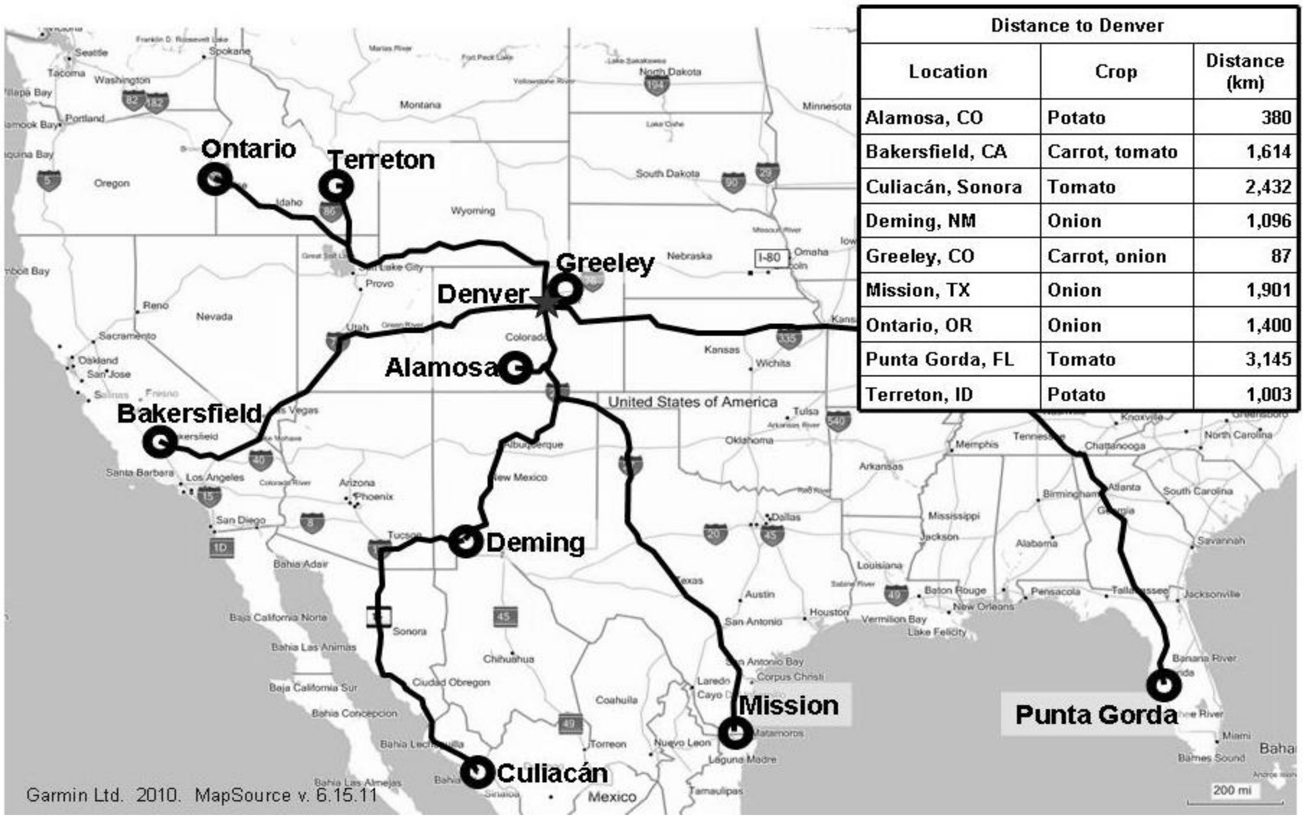

Figure 2. Regional sources of supermarket produce for Denver, Colorado.

2.2. Inventory

Life cycle inventory materials and flows were derived from published sources, such as agricultural extension services farm enterprise budgets, phone interviews with extension agents, and direct measurement (in the case of four growing operations in Denver, Colorado). Most of the inventory involved materials that were assumed to have properties that do not vary with location (e.g., fuel, plastics, fertilizer, etc.). However, a key contribution of this study is recognizing that the plant/soil ecosystem is influenced greatly by site-specific factors. For this reason, the inventory, components supporting ecosystem services (e.g., SOC, N-fixation), and impacts for soil and agricultural production were characterized using the Denitrification-Decomposition (DNDC) model (Li 2000). The inventory list and data sources are presented in Table 1 and Figure 3, respectively.

Table 1. Life cycle inventory materials.

Category	Specific Material	Region	Unit
Fossil Fuel	Diesel, gasoline (well to pump – WTP)	U.S.	L
Electricity	Electricity (Scope 1,2)	eGrid region	kWh
Soil	Bagged potting soil – organic	U.S.	kg
Fertilizer	N, P, K, Zn, Mn, Mg, Cu, gypsum, sulfur, lime	U.S.	kg
Plastics (virgin resins)	HDPE, LDPE, PP, PS, PET	U.S.	kg
Paper	Cardboard	U.S.	kg
Chemicals	Herbicide, pesticide, fungicide	U.S.	kg
Water	Raw irrigation water	Site-specific	L
Water	Potable irrigation water	Denver, CO	L
Transport	Refrigerated tractor / 17-ton trailer	Varies	km
Transport	Light pickup truck	Denver, CO	km
Web Hosting	20 Mb site, 1 yr.	U.S.	year

A key parameter directly tied to the functional unit is yield. Typical yields for the four vegetables under both growing formats, used as the basis of the functional unit, are presented in Table 2. Because the sample size was low for the urban case studies, it was recognized that yield values from direct measurements during only one growing season should be modified based on expert interviews and a sense of what is typical.

Table 2. Estimated yields

Crop	Estimated Typical Yield – Commercial	Estimated Typical Yield – Urban
Potato	1.15 (lbs/ft^2)	0.88 (lbs/ft^2)
Carrot	2.02 (lbs/ft^2)	0.94 (lbs/ft^2)
Onion	0.60 (lbs/ft^2)	0.74 (lbs/ft^2)
Tomato	0.60 (lbs/ft^2)	0.77 (lbs/ft^2)
Notes: Commercial yields adapted and summarized from enterprise budgets published by land grant university cooperative extension services in respective crop regions. Urban yields estimated from expert interview and direct measurement from the case studies.		

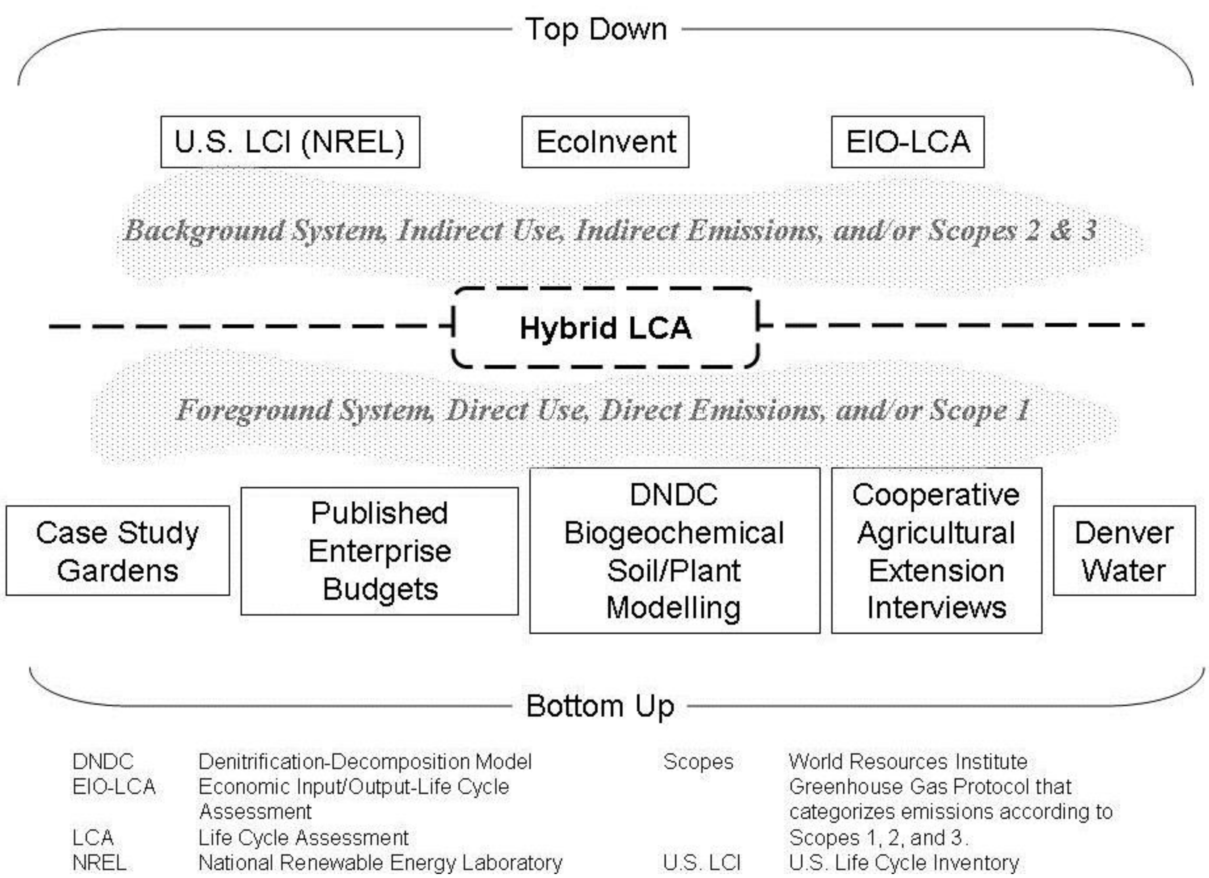

Figure 3. LCA Data Sources.

2.3. Land Use Change

It is asserted that land area used for vegetable production in one location is put into service or out of service based on the incidence of vegetable production in another location, normalized by respective yields. In this way, the product (vegetable) retains an embedded transboundary supply chain accounting element, even though vegetables are grown or consumed in only one location. A number of researchers have characterized SOC and agricultural emissions for various long-term land uses and as it relates to land use change (Kim 2009; Pouyat et al. 2007). This study expands the inventory and life cycle impact categories more comprehensively and sets urban gardening as a type of land use that displaces existing land uses. Conversion to urban garden involves displacement from one of three land uses, namely:

1. Large-scale commercial farmland – each new instance of urban gardening is assumed to displace an equal amount of commercial farmland, adjusted for differences in land productivity related to the functional unit.
2. Neglected and degraded urban areas – in the existing urban setting, a new urban garden can purpose these unused areas that typically have the poorest soil health and lowest SOC levels.
3. Residential turf grass – in the existing urban setting, the demand for space for an urban garden may force conversion from turf grass.

These land uses and scenarios are shown on Figure 4. Although common land uses exist in the urban setting, they are assumed to be similar in the degree of dense plant matter, cultivation, and richly-maintained soil that urban vegetable gardening has.

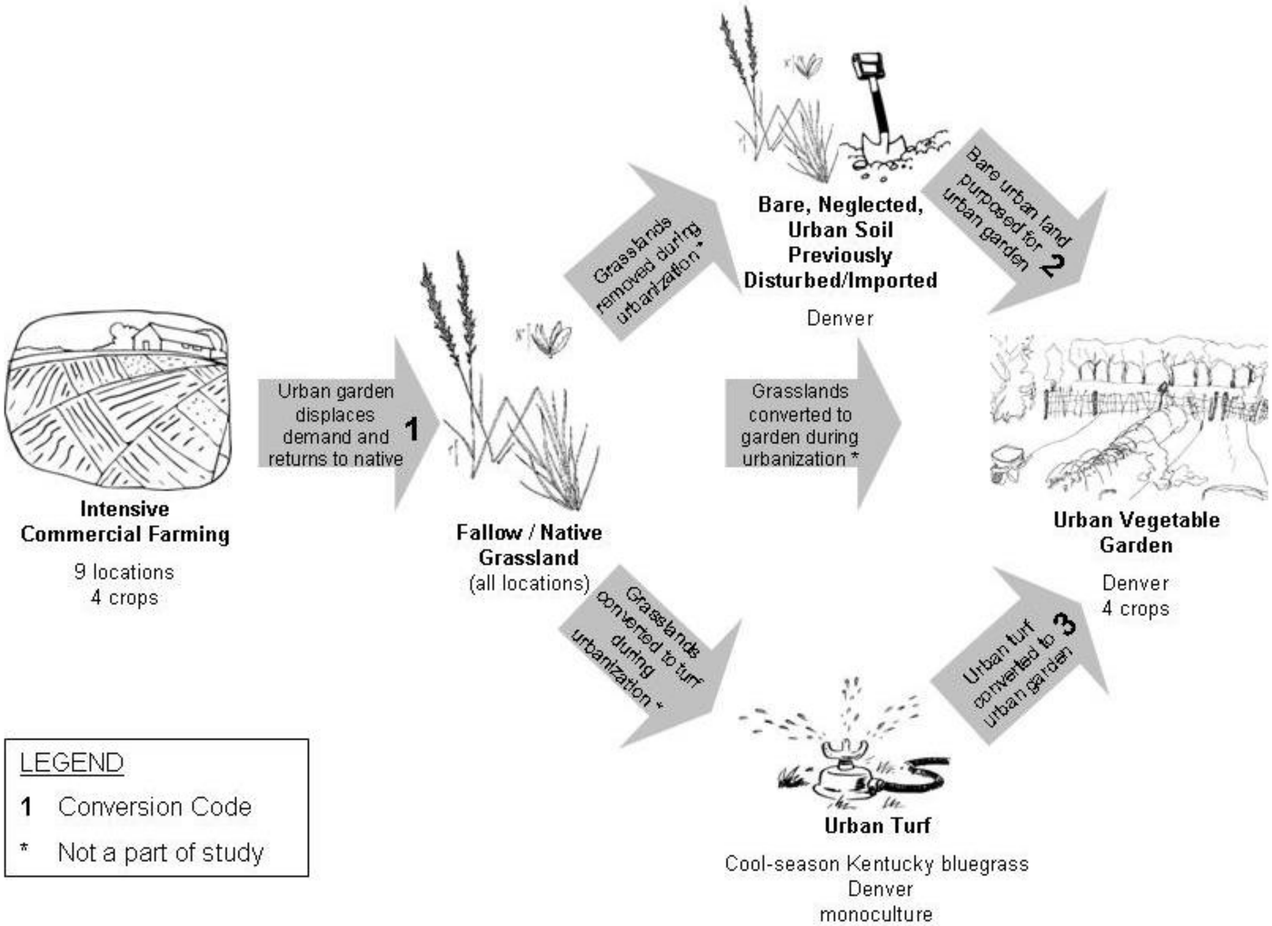

Figure 4. Land Use Change and Conversion Scenarios.

The array and variety of vegetable and production formats combined with land use scenarios results in 19 unique vegetable-land use combinations. In each scenario, a given land use is modeled for 30 years and paired with a subsequent land use for another 30 years. The 30-year time frame was chosen because this amount of time is sufficient to achieve relatively steady-state values for the parameters of interest (SOC, CH_4, CO_2, N_2O emissions), and is a time frame used for environmental analysis. Following the order shown on Figure 4, net changes in impact categories from commercial to urban formats are reported by first calculating the net impacts from two conversions to urban production in the urban setting (from turf production or no production). This is then compared to the net changes in impact categories when commercial production land is put out of production.

3. Results

Life cycle impact categories included direct resource use, upstream resource use, midpoint environmental impacts, labor value, and labor hours. Midpoint impacts were chosen for the life cycle impacts assessment

(LCIA). Examples of midpoint impacts are global warming potential, resource depletion potential, or 50% lethal concentration. Impact methodologies include the Intergovernmental Panel on Climate Change (IPCC) 100-yr global warming potential (IPCC 2007) and the U.S. Environmental Protection Agency Tool for the Reduction and Assessment of Chemical and Other Environmental Impacts (TRACI) which utilizes "the amount of the chemical emission or resource used and the estimated potency of the stressor" (Bare 2011).

The study found that displacement of two previous urban land uses (vacant/degraded and ornamental turf grass) by instances of urban vegetable production had beneficial environmental impacts in terms of greenhouse gas emissions, water use, and soil organic carbon. Displacement of vegetable production on commercial farmland by urban vegetable production also had significant benefits. Most notably, and the basis for application of a social LCA impact methodology, is value of labor in both wages and level of effort. As expected, there is a stark and measurable difference between the labor inputs of large-scale and small-scale production of any kind. This can be seen as an opportunity for local employment, but a risk for corporate efficiency. The data exemplify the significant influence of mechanization and economies of scale for industrial processes. Surprisingly however, urban vegetable production is not categorically favorable for each metric; several key parameters can shift the balance in favor or out of favor for either growing format, and these parameters are distinctly bottom-up. Selected results from the inventory impact assessment are presented in Table 3 and on Figures 5 and 6. Impacts and inventories are not presented for every crop-location combination for brevity.

4. Discussion

The study found that, for some location-crop combinations, smaller resource use and fewer emissions result from urban vegetable production compared to commercial farmland. Displacement of ornamental turf grass in an urban setting by instances of urban gardening had the most beneficial environmental and social impact even when using treated, potable water. Displacement of commercial farm land use by urban garden land use also had significant benefits. Impacts for each crop and conversion scenario were segregated into direct production impacts (direct applied water and energy), indirect production impacts (upstream impacts of products used in on-farm production), and post-production impacts (wholesale packaging and transport to the consumer). For brevity, only two categories (energy inventory and CO_2e impacts) are presented as examples (Figures 5 and 6). In the figures, the stacked categories are direct emissions from production, indirect emissions from production, and post-production emissions. The graphs are arranged by impact and show all crops individually, and the land use change conversion scenarios associated with them. Land use change is presented on a separate y-axis (right hand). The large differences associated with tomato, for example, are owed to the use of lighting to start plants from seed before transplanting, as is common practice for small-scale urban tomato production.

5. Conclusion

Generally, hybrid LCAs are saddled with significant limitations in terms of reconciling scales, data sources, and tracking variability and uncertainty. No quantitative error or distributions were possible due to this approach. The study could have benefitted from a larger sample size of instances of urban production, spanning several years of growing seasons. Because yields affect all impacts linearly, variations in yield can strongly influence whether one growing format is more environmentally friendly than others. Data collection could have been more vigilant and more commitment and communication between the author and growers would have benefitted the amount and accuracy of the primary, case-study data.

These data could allow state and local policy makers to claim, in some instances, that benefits of urban agricultural production outweigh costs. It is clear that multiple independent variables influence impacts; this study offers a first quantitative look at parameters, local practices and conditions that could be further encouraged or modified to improve metrics. The inconsistent relative contributions of different life cycle phases to overall metrics for each crop-location combination were particularly interesting. Another strength of the study is a point of comparison with other LCAs of specialty crop production and market gardening (although few in the literature), shedding light on the importance (or not) of local practices and conditions and potential pitfalls of the adoption of relatively few LCAs applied regionally or nationally. These results can also be used in the larger life cycle assessment and land use analysis of urban areas that recognize many transboundary urban infrastructure contributions, appropriate scales, and their corresponding data sets.

How to use LCA in a company context – the case of a dairy cooperative

Anna Flysjö[1,*], Anna-Karin Modin-Edman[2]

ABSTRACT

The present paper uses the dairy cooperative Arla Foods as an example how life cycle assessment (LCA) can be used within a company. The total carbon footprint for Arla Foods, from cow to consumer, is estimated at almost 18 million tonnes CO_2e, where primary production represents about 80% of the emissions. Arla Foods has defined environmental goals for all stages of the life cycle. The goal for greenhouse gas (GHG) emissions is to reduce emissions with 30% per kg milk at farm level (between 1990 and 2020) and with 25% for processing, transports and packaging (between 2005 and 2020). Another goal is to help consumers to reduce their food waste with 50%. In order to follow up and reach the goals, different tools have been developed to support the environmental work. Some of the challenges faced during the process, especially at farm level, are also discussed.

Keywords: dairy, life cycle assessment, carbon footprint, greenhouse gas emissions, emission reduction

1. Introduction

During recent years there has been a change in the focus of the environmental work among companies. From being a matter of complying with environmental legislations at site level, many companies now also have strategies and targets to reduce the environmental impacts at other parts of the value chain. Life cycle assessment (LCA) is a useful tool to understand the magnitude of environmental impacts at different stages of the life cycle and how these can be reduced. Life cycle thinking is also important to be able to track net-improvements and to avoid (or minimize) shift-of-burden problems, where solutions to one problem becomes the cause of another. The present paper uses the dairy cooperative Arla Foods as an example how LCA can be used within a company context to reduce environmental impact and to become more sustainable. Arla Foods is one of the largest dairy companies owned by about 12000 farmers in seven different countries (Sweden, Denmark, UK, Germany, the Netherlands, Belgium and Luxemburg) and with a global milk intake of almost 13 million tonnes milk.

Arla Foods has worked with reducing the environmental impacts for several decades. Initially the focus was on issues within Arla Foods' own operation, e.g. waste water, emissions to air, noise and odor at site level, followed by reductions in energy and water use as well as logistic planning to reduce fuel consumption. Around year 2000, the focus expanded to include packaging and externally managed transports. In 2008, the concept *'Closer to Nature'* was launched by Arla Foods with environment and climate concerns as an essential element. One of the goals was to reduce greenhouse gas emissions with 25% within the areas processing, transport and packaging between 2005 and 2020. Some years later, in 2011, a new environmental strategy for 2020 was presented, in which Arla Foods promised to take responsibility for the full value chain – 'from cow to consumer'. It was stated that Arla Foods would promote sustainable dairy farming and that specific targets should be developed. At processing level it was decided that 50% of all energy use should be renewable and that there should be zero waste (i.e. all waste should be reused or recycled). Specific goals were defined also at the last stage of the value chain, at consumer level and for waste management, where food waste at consumer level should be halved and all packaging should be 100% recyclable. After a couple of years a dairy farming sustainability strategy was adopted focusing on the areas animals, climate, resources and nature. A climate target was defined at farm level, where greenhouse gas (GHG) emissions should be reduced with 30% per kg of milk between 1990 and 2020. Figure 1 illustrates how the environmental work at Arla Foods has evolved and how Arla Foods has developed specific environmental targets, starting with its own operations (processing, transport and packaging) to finally include the whole value chain. The cradle to gate carbon footprint (CF) for Arla Foods has been calculated previously, but no study of Arla Foods' total CF from cow to consumer has yet been conducted.

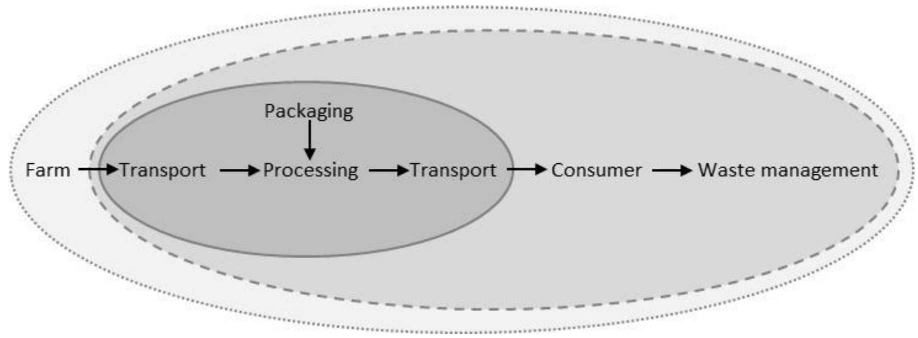

Figure 1. Illustration of how Arla Foods has worked with defining environmental targets within different areas over time, starting with processing, transport and packaging (solid line), then including also consumer and waste management (stippled line) and finally also including farm level (dotted line).

Arla Foods has also established goals on other parameters besides contribution to global warming (such as animal welfare, water and energy). However, the present paper focuses primarily on GHG emissions since this is the area which has gained most attention and where several methodological challenges have been identified.

The overall purpose of the present paper is to show how LCA can be used within a company context in order to reduce environmental impacts. More specifically the total CF for Arla Foods, from cow to consumer, is estimated, as well as the CF for some specific dairy products. In addition some of the main challenges and difficulties faced during the process are discussed. Finally some aspects of Arla Foods future work on sustainability are addressed.

2. Methods

LCA has been the methodological approach for the whole environmental work of Arla Foods, both when setting targets based on the strategies and when defining actions to fulfill the targets as well as following up on targets. The applied methodology related to the different stages of the life cycle is described in the following.

2.1. Farm level

Pre-farm gate emissions constitute the largest share of the environmental burdens in the value chain of dairy products. Raw milk production typically constitutes 80-90% of the CF of milk at the point of distribution to retail (Gerber et al., 2010). It is therefore pivotal to include farm level when promoting a more sustainable dairy production. One critical aspect for the CF result of milk at farm level is which LCA methodology is used: attributional LCA (ALCA) or consequential LCA (CLCA) (Thomassen et al., 2008). The two methodologies obviously answers different questions, where ALCA has a 'what is' focus while CLCA has a 'what if' focus. Some standards leave room for interpretation and leave it up to the practitioner to define the 'rules' for ALCA and CLCA (e.g. ISO 14040 and ISO 14044 (ISO 2006a,b)). Other standards/guidelines give clear guidelines when ALCA and CLCA should be used and how e.g. co-product handling should be conducted in the different cases (e.g. ILCD by the European Commission, Joint Research Institute and Institute for Environment and Sustainability (2010)). There are also some standards/guidelines that specifically recommend a certain LCA method (e.g. PAS2050 (BSI, 2011)). As farm level results in the largest share of GHG emissions of milk, Arla Foods decided to develop a tool that could handle several LCA methodologies in order to answer different questions to assure that reductions are achieved no matter what methodology is used. It resulted in a tool that has a 'switch' that makes it possible to generate results according to CLCA, ALCA (using only economic allocation), PAS2050 (Carbon Trust, 2010) and IDF (IDF, 2010) respectively, using the same input data (Dalgaard et al., 2014).

However, it is not feasible to report and communicate results from four different methodologies. Arla Foods has therefore decided to follow the methodology from the International Dairy Federation (IDF, 2010), developed by the global dairy industry, to report and deliver on the goal of reducing GHG emission. Since there is no agreed method on how to deal with emissions from land use change (LUC) Arla Foods do not include LUC emissions as default.

In the calculations of the total CF of Arla Foods in the present paper, the average CF of milk at the farm gate is estimated to be one kg CO_2e per kg milk, as no more detailed and uniformly calculated CF data are available in all countries where Arla Foods has production. This estimate is based on reviewing literature (Flysjö et al., 2011a; Hagemann et al., 2011; Kristensen et al., 2011; Williams et al., 2006) and comparing with the CF for milk in Sweden and Denmark in 1990 and 2005, and in Germany and UK in 1990 (Figure 3) (Dalgaard and Schmidt, 2012; De Rosa et al., 2013; Schmidt and Dalgaard, 2012), and is considered realistic and even somewhat conservative. As described above, emissions associated with LUC is not shown in the results in the present paper, however, the tool developed for calculating the CF of milk at farm level has a 'switch' to include missions from LUC using different methods. The different features of the CF tool are further addressed in the discussion.

2.2. Processing, transport and packaging

Arla Foods is collecting data on a yearly basis for all energy use for and waste from processing, transports (own operations as well as externally managed) and packaging. The data is used to follow up on reduction goals and is used in the present study to calculate the total CF of Arla Foods. Dairy products such as cheese, butter, milk powder and whey are also purchased together with 'other' raw materials and ingredients such as jam, sugar, salt and vegetable oil. To estimate the CF for purchased dairy products the method presented in Flysjö *et al.* (2014) is used, and data for other raw materials and ingredients are obtained from Davis et al (2011), Ecoinvent (2010), Schmidt (2007) and SIK (2009).

In the present study, the CF for some general dairy products is presented; whole milk (3% fat), yoghurt (3% fat), butter blend (with 60% fat of which 63% butter fat and 37% vegetable oil) and yellow cheese (17% fat). The packaging for the different products are one liter paper carton with plastic cap for milk and yoghurt, 250 gram tub for butter blend and plastic foil for cheese (packaging size of 800 gram). One of the most critical decisions for the CF of dairy products is co-product handling. To calculate the CF for the products mentioned above the method in Flysjö et al. (2014) is used, where allocation of raw milk is done based on the value of the different milk solids (fat, protein and lactose) in the final products.

2.3. Consumer level

To analyze the CF of the whole value chain of Arla Foods, the consumer stage also needs to be accounted for. In the present paper data for GHG emissions from retail, home transport and storage in refrigerator at consumer have been added to the total emissions of Arla Foods. Data for the latter part of the life cycle is taken from Flysjö (2011) and Flysjö (2012). Another aspect that can impact the CF value is food waste, especially at consumer level. This is also analyzed and estimated numbers on food waste at consumer used in the present study are 4% for milk, 10% for yoghurt, 3% for cheese (Berlin et al., 2008) and 5% for butter blend (Flysjö, 2011).

3. Results

The total CF – from cow to consumer – of Arla Foods in 2013 is estimated to almost18 million tonnes CO_2e (Figure 2). Milk and raw materials stand for the largest share of the CF (about 80%), while processing, transport and packaging stand for about the same amount of emissions as consumer stage. Emissions associated with raw milk production represent the largest share (almost 90%) of the first bar in Figure 2, whereas purchased dairy products stand for about 10% and other raw materials and ingredients stand for less than 2%. The largest share of direct emissions at consumer stage is from home transport (about 70%). Food waste is not shown in Figure 2 as these emissions are related to up-stream activities. Overall, however, food waste is likely to represent the largest environmental impact at the consumer stage.

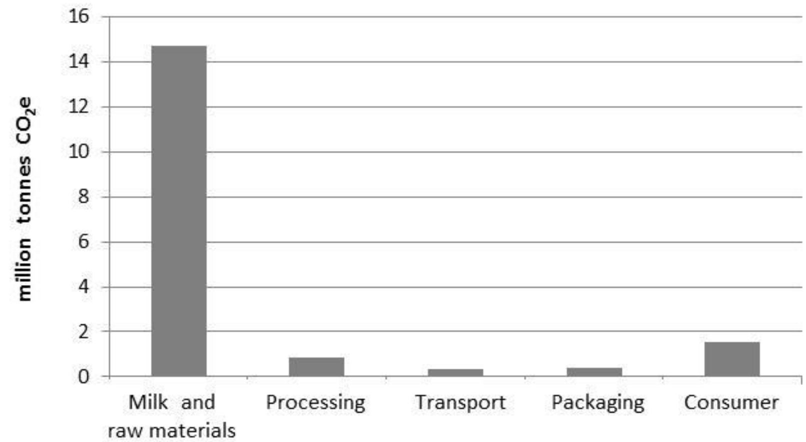

Figure 2. Total CF of Arla Foods production, from cow to consumer.

The CF per kg of fat and protein corrected milk (FPCM) at farm gate was about 1.25-1.3 kg CO2e in Sweden, Denmark, Germany and UK in 1990 (using the IDF methodology and excluding emissions from LUC) (Dalgaard and Schmidt, 2012; De Rosa et al., 2013; Schmidt and Dalgaard, 2012). In 2005 the CF per kg FPCM was reduced by 15% and 22% for Sweden and Denmark, respectively. No CF results have been estimated for Germany and UK for 2005. The stippled line in Figure 3 shows the reduction goal of -30% emissions per kg milk in 2020, compared to 1990.

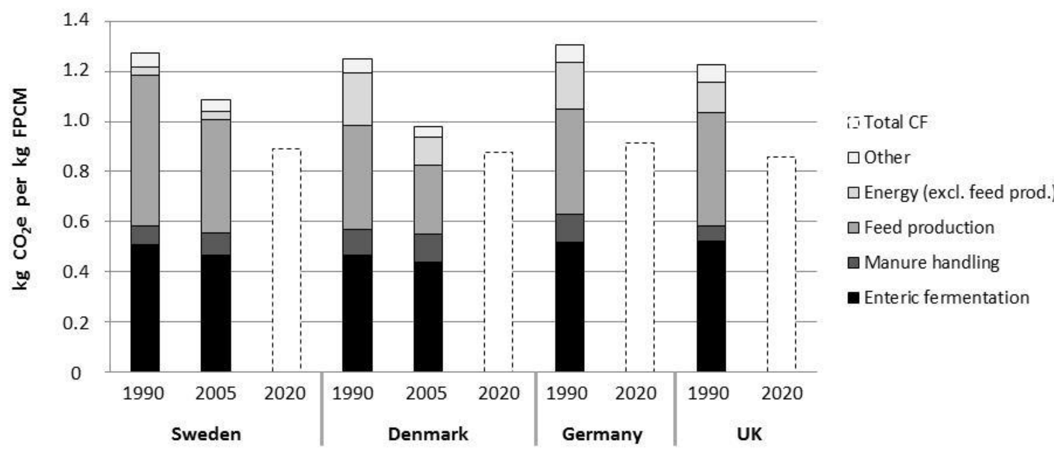

Figure 3. The carbon footprint of fat and protein corrected milk (FPCM) at farm gate in Sweden, Denmark, Germany and UK in 1990 and 2005 (latter only for Sweden and Denmark). Stippled line shows 30% lower CF compared to 1990, which is Arla Foods target at farm level.

Figure 4 shows the total reductions for Arla Foods in GHG emissions for processing, transport and packaging from 2005 to 2013. Most reductions have been achieved for processing and packaging (about -15%, respectively), while transport is about same in 2013 as in 2005. There are uncertainties in the numbers, as Arla Foods has been through a number of mergers and acquisitions since 2005 and reporting might not be the same in other companies.

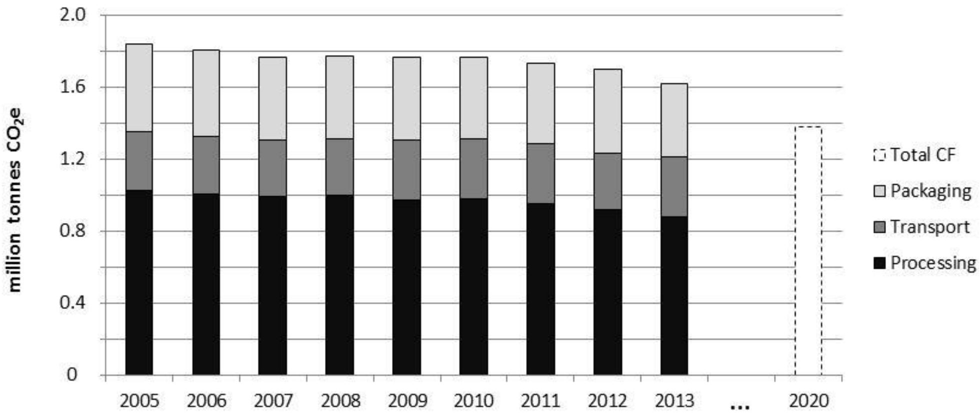

Figure 4. Arla Foods' total reduction in greenhouse gas emissions from processing, transport and packaging from 2005 to 2013. The stippled line shows the goal of -25% emissions in 2020.

Figure 5 shows the relative distribution of GHG emissions between the different life cycle stages for milk, yoghurt, low fat butter blend and yellow cheese, both including and excluding waste at consumer level. The estimated CF for each product including waste at consumer is 1.4 kg CO_2e per kg milk, 1.6 kg CO_2e per kg yoghurt, 7.1 kg CO_2e per kg butter blend and 8.8 kg CO_2e per kg cheese. Retail and consumer level emissions constitute a relatively larger share of the CF for milk and yoghurt, as these products has a lower CF per kg product compared to butter blend and cheese.

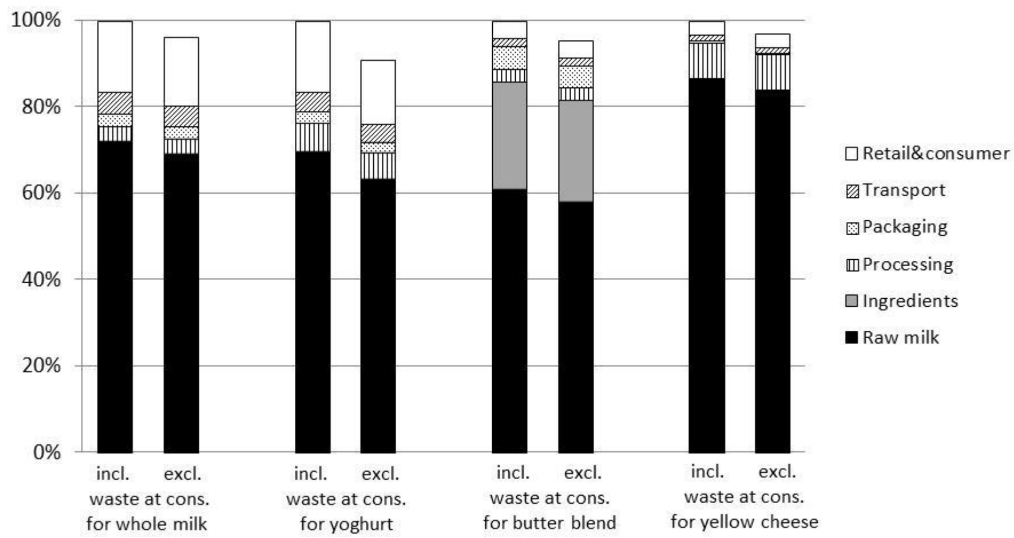

Figure 5. Relative distribution of the carbon footprint between life cycle stages for the different dairy products; milk, yoghurt, butter blend, and yellow cheese, including and excluding waste at consumer level. Ingredients in butter blend is vegetable oil.

4. Discussion

Having a life cycle perspective is important to achieve efficient environmental improvements and to ensure net benefits throughout the value chain. Initially, focus was put on Arla Foods' own operations, but today the whole value chain is included. Figure 6 shows the relative environmental impact of the different life cycle stages and illustrates the possibility Arla Foods has to influence the different life cycle stages. Farm level is obviously the life cycle stage which stands for the largest share of emissions for dairy products, followed by the consumer stage (Figure 2). Thus, from a life cycle perspective, farm level and consumer level would be the two life cycle stages to focus to reduce emissions most efficiently. However, these two life cycle stages are also the ones most challenging to influence. Some of the challenges related to the LCA methodology and data gathering are discussed below. One of the critical aspects is to find a model that captures enough detail and relevant aspects of GHG emissions at farm level to ensure that the goals are reached, i.e. that actual reductions are achieved.

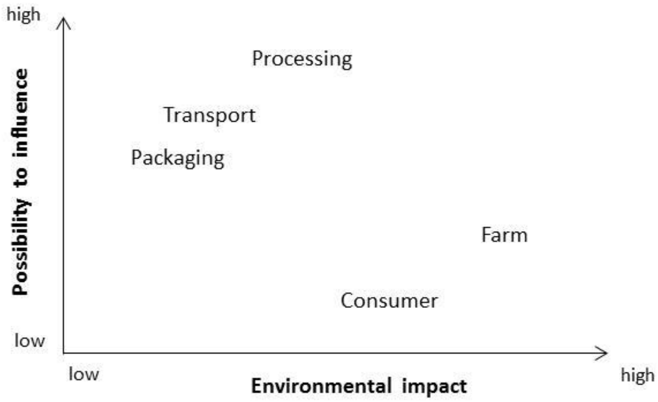

Figure 6. Illustration of which life cycle stages have the largest emissions and where Arla Foods has the largest influence.

4.1. Farm level

One of the main differences between primary production and the rest of the value chain is that methane (CH_4) and nitrous oxide (N_2O) constitute the largest part (70-80%) of the GHG emissions, while for processing, transport, packaging and consumer level it is carbon dioxide (CO_2) from combustion of fossil fuel that is the main contributor to the CF. There is a relatively large certainty in the CO_2 emissions from combustion of fossil fuel and a reduction in these emissions is thereby relatively certain. When it comes to emissions of CH_4 and N_2O on the other hand, there is a larger inherent uncertainty in these emissions (Flysjö et al., 2011b). The main share of the CH_4 is from enteric fermentation when the cow is digesting the feed and is a naturally process for ruminants in order to make use of grass and other feed sources inedible for humans. The largest share of N_2O emissions is from nitrogen turnover (from synthetic fertilizers, manure/excreta and crop residues) in agricultural soils used for feed production and is also a natural and inherent variable process. Hence, there will always be CH_4 and N_2O emissions from milk production due to the characteristic of milk and agricultural production. Also, the CF of milk at farm level is related with a relatively large uncertainty, which obviously makes it more difficult to estimate total emissions and to follow up on reduction measures. In some cases reduction measures can be known (e.g. drainage of soils), but not captured in the models/calculations and thereby not part of the reported emission reductions as it is not possible to quantify them. Another challenge is the representativeness. Arla Foods has over 12000 dairy farms in seven different countries delivering milk, and it is not realistic to collect data from all these farms. The ease at which a CF for an individual farm can be calculated is very much related to data availability and differs between countries. In Denmark farmers report more data to statistics compared to e.g. Sweden and Germany. Hence, in Denmark it would be easier to calculate the CF for a larger number of farms compared to the other two countries. However, Arla Foods want to have a similar approach in all countries and plan to calculate the CF for about 200 farms yearly in Sweden, Denmark, UK and Germany, respectively (Germany also include the farmers in the Netherlands, Belgium and Luxembourg). The number of CF assessments at farms is assumed to be more than enough to be representative according to the Carbon Trust (2010). Today about 1500 CF assessments have taken place together with almost 300 farm workshops that Arla Foods has arranged with focus on sustainable dairy farming in Sweden, Denmark and UK. However, it needs to be evaluated whether it is possible to use these ‘bottom-up’ CF numbers to follow up on the overall reduction goal, where the baseline for 1990 was calculated ‘top-down’ using national statistics. It is important to keep in mind that CF numbers should not be compared unless they are estimated in a comparable way (Henriksson, 2014). At the moment different support is also provided from authorities in the different countries regarding calculating CF at farm level and extension services coupled to these calculations. It is important to make use of national initiatives, but risks introducing differences in methodology. The feature with the Arla tool was to use the same tool, but with country specific background data, to calculate the CF for milk for different countries. However, due to data availability and data transfer this is not up and running for the moment. Another feature with the Arla tool was to be able to use the same input data and generate results according to different LCA methodologies. Being able to present CF results using different methodologies can be useful in some situations. While the IDF methodology is chosen for reporting and in communication with farms, the CLCA approach can be useful on a policy level and to understand e.g. the link between milk and meat production and what effect milk production has on other systems. Having the different methodologies in the tool can also be used to assure that improvements are taking place. This was shown when calculating the CF for milk in Sweden and Denmark in 1990 and 2005, where there had been a reduction in emissions between the years no matter which LCA methodology was used (results not shown).

4.2. Processing, transport and packaging

For the next part of the value chain, on the other hand, it is much easier to ensure that reductions are achieved, since a reduction in e.g. fuel oil results in lowered emissions. On-site energy use is also within the direct control of Arla Foods and it is thereby easier to implement actions to ensure reductions. The same also goes for own operation transports. In many cases, however, infrastructure can be limiting and it can thereby be difficult to e.g. increase the use of renewable energy sources. For the externally managed transport it is important to work with suppliers and request transports with lower emissions. When it comes to packaging there are several aspects to consider. Different materials have different environmental impact, so the choice of the material is obviously important. The packaging should preferably also be possible to recycle, why also the end-of-life needs to be considered. Again, a limiting factor can be infrastructure, such as waste management systems in the country where the products are sold, since not all countries have a recycling system for waste. To put focus on the environmental impact of packaging, Arla Foods has developed a tool to analyze the CF of different packaging solutions (materials, end-of-life solutions etc). This allows incorporating environmental thinking already in the design of the packaging. The function of the packaging is another aspect that needs to be considered. The trend today is that there are more single households, more advanced packaging (e.g. milk cartons with plastic cap, sliced cheese in plastic pack) and more 'on the go' meals (one portions with plastic spoon etc). All this results in more packaging per kg of product, but at the same time such packaging can contribute to less food waste. So in total there might be a net benefit considering the whole life cycle of the packaging (including the product).

Arla Foods are reporting its total GHG emissions according to the greenhouse gas protocol (World Business Council and World Resource Institute for Sustainable Development) and the goal on reducing the GHG emissions is established according to that. The 25% reduction is in absolute numbers, i.e. not per kg of product. However, if the company is expanding through mergers or acquisitions the baseline needs to be recalculated, but any organic growth is not accounted for. Since the reduction goal does not account for the amount of products produced, it would also be desirable to calculate the CF per product or product group, to also capture the efficiency of production. Today Arla Foods has developed a method to calculate the CF of dairy products (Flysjö et al., 2014) and has assessed the CF for a number of dairy products (Flysjö, 2012). The next step is to implement the model on site level to follow improvements on product level. This would for example account for reductions in product losses which currently are not reflected in the reporting according to the GHG protocol.

4.3. Consumer level

Home transport showed to be the activity leading to the main share of direct emissions at consumer stage (Figure 2). This estimate is obviously related with rather high uncertainty, and little information is found on consumer travels associated with food purchasing. Sonesson et al. (2005) suggests 28-63 km per week and household to be a reasonable assumption for food purchases in Sweden. The present study uses the lower value when estimating Arla Foods total CF.

Another aspect, probably even more important to focus on at consumer level, is food waste. Even though the emissions associated with food waste occurs up-stream of the value chain (e.g. at farm level, processing, transport), the consumer has the possibility to reduce the amount of food waste and therewith reduce the amount of food that is produced for no reason. A study initiated by the Food and Agricultural Organization of the United Nation (FAO) estimated that 7% of dairy products are wasted at consumer level in Europe and in US the number is about twice as high (Gustavsson et al., 2011). Sonesson et al. (2005) found even larger waste numbers for dairy. Assuming the food waste of dairy products to be 7% it would equal a CF on 1.3 million tonnes CO_2e, and if the waste would be 15% it would be about 2.7 million tonnes CO_2e, for Arla Foods total production.

Arla Foods has a goal on reducing food waste at consumer with 50% by 2020 and are analyzing ways to help and inspire consumer to avoid wastage of food. Among other things an 'empty your fridge' app for smart phones is developed (for the Danish market), with recipes to help consumers make use of left overs. Packaging design is another way to reduce food waste and is one aspect Arla Foods is working with. A study analyzing the CF of butter showed that 37% of the butter in mini-tubs was wasted (Flysjö 2011). Arla Foods has now redesigned the packaging which now consists of 8 gram butter instead of 10 gram. There has not yet been any study to follow up the results, but less butter in mini tubs are likely to be wasted.

4.4. From minimizing negative impact to maximizing positive impact

During the last decades, the environmental work of Arla Foods has shifted from focusing on single impacts (e.g. emissions and resources) at only part of the value chain where Arla Foods has direct influence (e.g. processing), to include several impact categories to better capture the whole concept of sustainability (e.g. GHG emissions, resources, animal welfare, biodiversity) for the entire value chain from cow to consumer (Figure 7). Hence, the scope has broadened both regarding focus areas/impact categories as well as stakeholders/value chain.

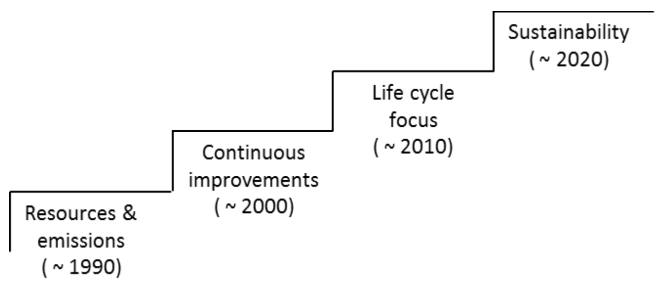

Figure 7. The development of focus areas for Arla Foods' environmental work (inspired by Nielsen and Remmen, 2005).

One recent example is that in order to further improve the sustainability of the production, Arla Foods has decided to purchase RTRS certified soy (for all soy fed to the dairy cows delivering milk to Arla), certified palm oil (used in dairy products) and certified cacao (used in dairy products). There is also some other 'sustainability' projects on e.g. tree planting in Mozambique and Uganda.

As a cooperative, Arla Foods has a close dialogue with the dairy farms. This creates a unique possibility to work together to improve and reduce GHG emissions at farm level and promote a more sustainable dairy production. At the same time, however, it can be challenging as the farmers are the owners of Arla Foods and it is therefore not possible to simply define targets and put demands at farm level without their accept. In order to influence farmers a combination of awareness raising and motivation has to be adopted. Similarly, in order to achieve the goals related to consumer food waste, focus needs to be on motivating consumers to make more sustainable choices in addition to offering them e.g. packaging sizes that will enable them to avoid throwing valuable food away. Arla Foods has a long tradition of communicating closely with the consumers, through recipes, home pages, social media and apps for smart phones. The "empty the fridge" app for smart phones, mentioned earlier, is one concrete example on this. Other activities are advices on how to store food, recommendations on portion sizes and advices for "food planning".

The focus of Arla Foods so far is mainly on minimizing the negative environmental impact – the footprint. However, it is also important to focus on maximizing the positive impact – the handprint. Handprints can be generated by reducing the footprint, helping someone else reducing their footprint or taking other generative action (e.g. tree planting) (G Norris, Harvard School of Public Health, Boston, Massachusetts, USA, personal communication). By broadened the scope to include e.g. consumer stage, Arla Foods is trying to inspire others to reduce their footprint. Actively engaging with consumers and other stakeholders, and creating a dialog on sustainability, is more about generating a positive impact and creating a handprint than just reducing the footprint.

Thus, shifting from only focusing on minimizing the environmental impact to maximizing the positive impact is important for a sustainable development.

5. Conclusion

During the last decades, the environmental work of Arla Foods has grown in scope and includes now the full value chain. The broadened scope has also resulted in more challenges. LCA is a valuable tool to report and focus the environmental work. The total CF of Arla Foods from cow to consumer is estimated at almost 18 million tonnes CO_2e. About 80% of the emissions occur at primary production while consumer stage represents about 10% of the CF. Environmental goals are defined for all stages of the life cycle, including consumer level. Between 1990 and 2005 GHG emissions at farm level have been reduced with about 15-20% in Sweden and Denmark. The average reduction in GHG emissions for processing, transport and packaging is 12% between 2005 and 2013. One of the goals at Arla Foods is to help consumers to reduce food waste with 50%. If this goal is achieved it would save about 0.6 million tonnes CO_2e of Arla Foods CF (assuming that 7% of all dairy products are wasted, as estimated for Europe).

ABSTRACT

Life Cycle Assessment (LCA) and approaches based thereon, e.g., Eco-Efficiency Analysis and SEEBALANCE, have proven useful tools for a quantitative sustainability assessment along value chains and across industry sectors. In order to holistically assess sustainability in agriculture, AgBalance™ combines LCA with environmental, economic and social impact indicators, generalized to varying spatial scales. The methodology comprises up to 70 sustainability indicators, which are grouped into the three dimensions "environment", "society" and "economy". Sensitivity and scenario analyses can be employed to study the robustness of the model results, and to investigate trade-offs or the response to external influences. In order to better translate findings from the socio-economic LCA studies to continuous improvement on farm, web-based crop management applications are developed. They interactively conduct scenario analysis for a set of sustainability indicators that were shown to be the most relevant ones in an AgBalance case study. This new strategy is designated "AgBalance Farm".

Keywords: Socio-economic LCA, agriculture, AgBalance, continuous improvement, AgBalance Farm

1. Introduction

1.1. Sustainability in the Food Chain

A focus on sustainability in the food value chain has become a basic prerequisite for suppliers and consumers. There is no other industry where so many product and production characteristics are marketed as "sustainable" as in food production (Frank et al. 2013). If sustainability is manifested and proven with different methods, varies widely in the different value chains of the food sector. Sustainability is mainly driven by the farming activities of the farmers who continuously implement new practices and improvements, in a challenging environment of weather, market needs and consumer expectations. Numerous existing sustainability programs often have their roots in Corporate Social Responsibility (CSR) activities, which are not integrated into the core business of the company (Porter and Kramer 2011). However, more and more companies recognize that these types of initiatives not only represent an investment in their brand and reputation, but they can also help to effectively resolve of one of their primary problem areas: supply chain security. Lawrence and Burch (2007) report that food producers and supermarkets increasingly rely on cooperation with suppliers and long term contacts for a secure supply of high quality products, particularly in product categories with high potential for differentiation. These contacts may include multiple layers of the value chain concerned, as they strive for considerably closer cooperation with the producers (Nestlé 2013).

1.2. Sustainability Assessment in BASF

Against this background, there is a demand to be able to map the whole food value chain with respect to the contribution of each stage to the sustainability footprint of the entire chain. BASF comprises one of the few companies being active on all different stages of the food value chain, starting from seed provision, plant protection and fertilizer additive manufacturing, provision of food ingredients, packaging and many more. Therefore, BASF has pioneered an array of LCA tools to capture the impacts on the various levels of the value chain. Tools such as Eco-Efficiency Analysis (Saling et al. 2002) and SEEBALANCE (Kölsch et al. 2008) are used by BASF and its customers to assist strategic decision-making, facilitate the identification of product and process improvements, enhance product differentiation as well as to support the dialogue with opinion makers, NGOs and politicians. Both Eco-Efficiency Analysis and SEEBALANCE analysis are comparative methods; the advantages and disadvantages of several alternatives are assessed according to a predefined customer benefit with a holistic approach. The analysis uses a Life Cycle Assessment approach with the whole life cycle of a product – from cradle to grave – being considered. Next to the environmental impact, which is assessed based on ISO14040, ISO14044 and ISO 14045 norms, all economic factors are taken into account. The SEEBALANCE also considers social impacts of products and processes (Uhlman & Saling, 2010).

Both Eco-Efficiency-Analysis and SEEBALANCE have been employed in the food and feed value chains in order to assess the key drivers of sustainability in various production systems. It has been shown in various case studies that agriculture can have a large share of the entire sustainability profile of food and feed value chains. At the same time, logistics, transport, processing and, not least, consumption can play a substantial role as well. In 2012, for example, BASF analyzed the CO_2 balance for veal and beef products with the client Westfleisch, supporting them in improving the sustainability of their meat production along the whole value chain (Westfleisch 2010.).

Feed ingredients for a more sustainable aquaculture of salmon have been identified through Eco-efficiency Analysis in the collaboration with Biomar A/S (Saling et al. 2007). Three ways to produce astaxanthin as an ingredient of salmon diets were compared: chemical synthesis, fermentation and production via fermentation of algae. In this case study, the astaxanthin derived from chemical synthesis was the most eco-efficient product (Saling et al. 2007). Other examples comprise the production of beef with Cattlemen's Beef Board and National Cattlemen's Beef Association (NCBA 2014). The Eco-Efficiency Analysis portfolio shows that the present-day U.S. beef value chain is more sustainable than in 2005. While there was detected a 6 percent increase in the price of beef between 2005 and 2011, there was a simultaneous decrease in the overall environmental and social impacts from the U.S. beef value chain of approximately 7 percent.

Case studies were also performed on food packaging. In collaboration with the German dairy company Müllermilch, for instance, plastic cups made of polymers turned out to be the more sustainable option compared to returnable glass containers and composite cartons (BASF 2003). In a similar approach, various bottling alternatives for carbonated mineral water were compared. The customer benefit involved consumption of 1000 l mineral water at a distance of 300 km from the bottling plant. The disposable 'Office Line', a novel packaging method for office use, option outperformed the disposable PET or carton as well as the reusable glass bottle due to the favorable environmental footprint (Gerolsteiner 2005). The main sources of impacts are the material production, the cleaning steps and the recycling options for the different alternatives. Transportation plays a minor role. The relation of volume and packaging material and the reuse-cycles is very important for the position in the sustainability portfolio. The limitation of Eco-efficiency and SEEBALANCE to cover the agricultural production level is the lack of specific indicators, among others capturing the impacts on biodiversity, soil health and the agri-sociological context of production. For this reason, BASF has developed AgBalance™: a holistic method for assessing sustainability in agriculture and identifying key drivers for improvement.

2. AgBalance – Life-Cycle Assessment in Agriculture

AgBalance comprises a multi-criteria life cycle based approach in combination with a defined aggregation and summary of single results into a single sustainability score (Frank et al. 2012). AgBalance™ delivers results that enable farmers, the food industry, politicians and society to objectively evaluate processes in terms of their sustainability profile. In doing so, a vast amount of information on individual factors can be ascertained in addition to overall statements on the sustainability of agricultural practices (e. g. ploughing). AgBalance was finalized in mid of 2011. In September 2011, the methodology was given independent assurance by the global expert agencies TÜV SÜD, DNV Business Assurance and NSF International. AgBalance™ can be used to map an individual farm or the whole agricultural sector in one region, for example. The focus can either be on the agricultural production system alone or on the processes that have established themselves downstream in the value chain, such as logistics or processing.

A case study with the holding company SLC Agricola in Brazil involved an internal benchmarking of two large farms, each with over 10,000 hectares, to identify the central sustainability drivers for their crop rotation consisting of soya, maize and cotton and to derive follow-up opportunities for their continuous improvement. An average cultivated hectare for each of the two farms, Panorama (Bahia state) and Planalto (Mato Grosso do Sul state) were compared on the basis of the operation data from the 2009/2010 season. The indicators from all three sustainability dimensions – environment, economy and society – were investigated using a holistic approach over a section of the life-cycle that starts with the raw materials used in the production (the "cradle" of the process, for example phosphorus extraction or oil production) and ends with the delivery of the harvested goods at the nearest port. The analysis revealed that the Planalto farm is substantially more sustainable than the Panorama farm (Fig 1), which is largely due to better results in the economy and environment dimensions.

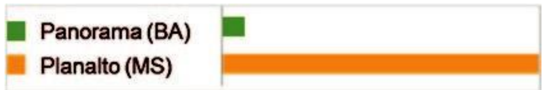

Figure.1. Relative sustainability index of the two farms Panorama and Planalto. Planalto achieved a 40% better result

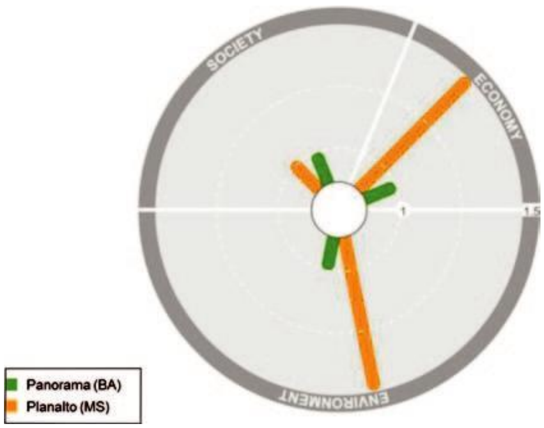

Figure 2. Representation of the sustainability index in terms of the three dimensions of sustainability. The length of the bar indicates higher sustainability. Each time the worse alternative is normalised to the value 1

Whereas the result in the social indicators did not exhibit significant differences (Fig. 2), the most important drivers in terms of economy turned out to be an improved cost situation and an increased profit of the Planalto farm. In terms of the environment, the key drivers turned out to be a predicted imbalance for nitrogen and above all, phosphorous in the soil as well the pesticide regime. According to initial calculations, the optimization of the fertilization regime in Panorama could lead to savings of almost 15 million kWh of energy (this corresponds to the energy use of roughly 2,000 households in Brazil) in addition to substantial cost savings. The CO2 equivalents saved using AgBalance™ amount to almost 8,000 tons per year. These results, together with the additional findings on pesticides, can serve as the starting point for a continuous improvement program at SLC Agricola. With its knowledge base, BASF supports a suitable product portfolio throughout the whole life-cycle and works towards creating common solutions towards greater sustainability.

Measuring sustainability can be a central key to steady improvements towards sustainable agriculture. It is therefore an essential requirement that it succeeds in translating results from complicated life-cycle analyses into farmers' everyday reality and to derive specific recommendations for action. However, agricultural production globally is strongly dependent upon smallholder farming, which is not easily accessible by complex and expert-based LCA approaches. Novel IT solutions are required in order to make use of LCA-based knowledge for a more sustainable crop management on-farm. This is the basic idea of the concept "AgBalance Farm".

3. AgBalance Farm - From LCA to Farm Management

Global food security and sustainability stands and falls with the adoption of sustainable crop management practices by millions of smallholders in developing countries. As outlined above, Life Cycle Assessment has proved capable to reveal the key drivers of sustainable agriculture and thus to serve as a guardrail for improvement strategies (Frank et al. 2012). However, the translation of the results of LCA studies into on-farm decision support has mostly failed. Here, we present a strategy designated "AgBalance Farm" that uses key learnings of Socio-Economic LCA studies for the development web-based crop management support applications for farmers. This strategy is based upon BASF's experience with the Eco-efficiency Analysis manager as outlined in Saling (2013). India is the fifth largest producer of soybean in the world but soybean yields currently reach only half the global average of 2.4mt/ha. Lack of knowledge about good farming practices comprises the key reasons for the low productivity. Through the training program 'Samruddhi' (Sanskrit for 'prosperity'), farmers are educated not only on the timely usage of crop protection inputs, but also about correct fertilization, seed rate and spacing to enable higher yields (GIZ 2013). A group of self-reliant farmers, the so-called 'Margdarshaks', are trained by BASF's technical advisors and are entrusted to promote 'Samruddhi' in their village and to help other these farmers to adopt the best practices. While the contribution of Samruddhi to the profitability of the Indian soybean farmers had been shown (PWC 2013), its contribution to the sustainability of the production was largely unknown (Voeste 2012). Against this background, a holistic socio-economic life cycle assessment using AgBalance™ methodology was conducted. As a test case, soybean production under 'Samruddhi' and 'non-Samruddhi' in the state of Madhya Pradesh were compared. The AgBalance™ revealed that the 'Samruddhi' production practice outperfomed 'non-Samruddhi' in all three dimensions of sustainability. In the economic dimension, a better cost position (fixed & variable) and higher profits per ton of soybean resulted in a better score. In the social dimension, a stronger emphasis on professional training favoured the 'Samruddhi' practice. In the environmental dimension, the better performance of the 'Samruddhi' practice in some LCA impact categories was accompanied by the inferior scores in categories such as soil health, biodiversity potential and emissions. As the key driver for this, the fertilizer regime of 'Samruddhi' was identified (PWC 2013). Based upon this AgBalance™ study, 12 sustainability indicators with a big impact on the study result were selected. Through regression analysis of data sets of approx. 100 individual farmers, mathematical functions describing the interdependencies between the respective indicators were derived, e.g. between yield and nutrient management. A web-based application was generated that can be used e.g. by 'Margdarshaks' to help soybean farmers in their villages optimizing their production protocol towards higher yield, profitability and sustainability. It basically conducts scenario analysis interactively, as demonstrated for the concept of the Eco-efficiency Analysis manager. With this "AgBalance Farm" strategy, we aim to effectively use the potential of socio-economic LCA to support crop management decisions of individual farmers.

4. Summary

Sustainability is becoming increasingly important as a key factor for growth and value creation. Customers along supply chains want more sustainable products and system solutions. There is a need to integrate sustainability much more closely into businesses and decision-making processes. To manage this in an effective way and to support decision-making processes, a sustainability evaluation toolbox is needed which can be applied to assess products and processes in a holistic manner. Both detailed in-depth results of individual impact indicators, as well as aggregated results and a single sustainability evaluation score are output of the sustainability Evaluation methods. Different types of footprinting in combination with other information can support decision-making efficiently. The communication of the results is a key aspect of this type of studies, especially in the food supply chains, where also end consumers are involved. Holistic, LCA-based and scientific sound methods to measure sustainability are key success factors for the realization of more sustainable production systems. Nutrition of human beings will be one of the key challenges of the future and can only be realized in a more sustainable manner. BASF cooperates with all players and producers in the supply chain, from basic production and farming via processing, packaging, transportation and preparation of foodstuffs.

The link between LCA and CSR with espresso coffee as an example

ABSTRACT

Corporate Social Responsibility (CSR) and a 360 degree approach to sustainable development including environmental, social and economic aspects are of growing interest. Lavazza is engaging its efforts to ensure an integrated approach aimed at providing a holistic perspective of sustainable development. Lavazza's efforts in ecodesign and LCA activities began in 2009 as part of the company's wider CSR programme. Gradually LCA and CSR have been linked in order to create an integrated approach. Whilst LCA adopts a product perspective, at the same time it contributes to the overall CSR strategy. The coordinated work between departments, within Headquarters, promotes an integrated approach to CSR, which includes the different technical corporate aspects, where LCA is one of the specific tools available fostering continuously improved environmental management. Other examples of tools are PackageExpert, which allows the performance of simplified LCA by packaging designers and the communication of results to managers, and a CSR tool that collects CSR data, partially originating from LCA activities, and enables the calculation of requested indicators. This approach is not only useful to enhance information exchange within the company, but is also a *conditio sine qua non* of an integrated CSR strategy.

Keywords: LCA, CSR, espresso coffee, sustainability, integrated approach.

1. Introduction

Sustainable development and minimization of environmental impacts within the coffee supply chain, the second most valuable commodity worldwide, are of growing interest. This trend is also visible by the increased application of current (ISO 14040:2006; ISO 14044:2006; ISO 14064-1:2012) and new environmental management standards (ISO 14067:2013; ISO 14046:2013) which focus both on product and corporate perspectives. Lavazza's innovative approach consists in ensuring that Life Cycle Assessment (LCA) is not only used as a technical tool but is part of the overall Corporate Social Responsibility (CSR) and that the two are used complementarily for environmental management.

Lavazza's corporate sustainability strategy identifies four key areas: product sustainability, production processes, human resources valorization and the interaction with stakeholders along the value chain.

Lavazza has been active on ecodesign and LCA activities since 2009; efforts to draft the first sustainability report, according to Global Reporting Initiative (GRI) standards, are ongoing (Lavazza 2014). Furthermore, Lavazza participates in a project of the Italian Ministry for the Environment, Land and Sea aimed at measuring, reducing and eventually compensating CO_2 emissions of two main coffee products: espresso coffee capsules and moka coffee (Italian Ministry for the Environment, Land and Sea 2014). At the sector level through the SAI platform, Product Category Rules (PCR) have been defined for Carbon Footprint (International EPD® System 2014).

Lavazza developed its strategies on environmental management and sustainable development, both at policy and at product level, by using LCA and CSR as two complementary approaches with different perspectives. The corporate perspective initially concentrated within the company's boundaries (gate to gate), is projected to expand those boundaries to external stakeholders such as suppliers, clients and consumers (simplified cradle to gate for all products). The product perspective looks at a particular section of the company's supply chain, analyzing the life cycle stages of a single product (detailed cradle to grave).

Although some studies have identified weaknesses of the LCA technique, its overall evaluation is nevertheless positive (Matuszak-Flejszman 2007; Lewandowska 2011). In detail, LCA has the advantage of providing an holistic perspective which is not limited to the boundaries of the organization (design, development, production processes, energy resources consumption and waste management), but also analyses the effects of environmental policies and practices of manufacturers and suppliers, extraction, transformation and distribution of raw materials, finished products distribution, use and waste management. From this point of view, a distinction between direct and indirect environmental aspects is important. Direct environmental aspects are associated with activities, products and services over that the organization has direct control. Indirect aspects concern the potential activities over which the company has no direct control but could be expected to influence.

The LCA approach measures ecological impacts, related to both direct and indirect environmental aspects. Espresso coffee is a complex food system with a multiple-actor supply chain which involves coffee plantations worldwide, green coffee traders and exporters, packaging suppliers, the coffee manufacturer, the distribution chain, consumers, clients and finally waste disposal management.

Although the involvement of all stakeholders might initially be more cumbersome, a holistic approach will transform barriers into mutual opportunities and thus strengthen market of all stakeholders on environmental management (Furfori et al., 2012).

LCA and CSR both contribute to the continuous improvement process aimed at the minimization of environmental, social and economic impact of the company's operations. LCA methodology follows a bottom-up approach, providing ecodesign feedback to R&D and pointing out possible improvement options (e.g. for green coffee cultivation and packaging) that can be implemented by the environmental product strategy. In this way, LCA has started at R&D (bottom-up) and is now contributing to core values of the company. On the other hand, CSR follows a top-down approach, starting at the management level and embedding LCA in the corporate strategy. This double strategy allows the company to have a complete perception of its environmental performances, both at corporate and product level.

The link and information exchange between LCA (product) and CSR (corporate) are crucial and specific tools, and have been developed to facilitate the interaction between the two levels. Examples of such tools are PackageExpert, which allows the performance of simplified LCA by packaging designers and the communication of results, and a CSR tool that collects CSR data, partially originating from LCA activities, and enables the calculation of the requested indicators and graphics.

The link between LCA and CSR will be illustrated with espresso coffee as an example, showing results from the tools applied. This link is not only useful to enhance information exchange between product and corporate perspective, above all it allows alignment between the CSR strategy with the product sustainability strategy.

2. Methods

2.1. LCA of espresso coffee capsule and moka coffee

LCA is a tool which allows to assess the potential environmental impact of a product, process or service along its entire life cycle (Guinée, 2002). In collaboration with the Italian Ministry for the Environment, Land and Sea LCA has been also applied to espresso coffee (Italian Ministry for the Environment, Land and Sea 2014).

The objective of Lavazza is to combine various LCAs that are interconnected in the coffee supply chain, in order to enhance ecodesign and communication and to reduce the environmental impact related to a cup of coffee.

The functional unit is defined as one cup of espresso coffee (30 cc.), prepared with an espresso machine using capsules. In case of moka coffee the functional unit is identical, but applied to moka coffee. The espresso machine is assumed to prepare 5000 cups of coffee during its lifetime. The system boundaries of espresso coffee include green coffee cultivation, processing and transport to Italy, coffee roasting, grinding and packaging, distribution, use phase (preparation of one cup of espresso with an espresso machine) and the end of life of coffee, packaging and the espresso machine. The system boundaries of moka coffee are identical, except for the production plant which is located in Torino and the preparation of the moka coffee which takes place with an electric moka machine.

In order to facilitate the elaboration of the complex life cycle of espresso coffee (containing more than 350 process units), the LCA has been divided into four sub LCAs as represented in Figure 1: LCA of coffee, LCA of manufacturing, LCA of packaging and LCA of the espresso or moka machine. Primary data are obtained from green coffee plantations and packaging suppliers using personalized questionnaires. To conduct LCA of agricultural products is a very complex task taking into account the data acquisition, modeling and compilation but it is a fundamental step for understanding the potential environmental impacts and then establishing the basis for product ecolabelling. Different agricultural practices produce different environmental performances. The amount of chemicals is directly related to cultivation practices such as tillage rotation, density of plants, etc. The goal of the LCA study on green coffee was to establish a good correlation of the agricultural practices and potential en-

vironmental impacts of coffee, increasing the internal knowledge on environmental sustainable aspects related to the raw material.
Future updates of this research will collect a large and representative number of primary data from the biggest suppliers (in this study, the primary data come from Brazil, India, Vietnam) and show the evolution of the natural resources management as land use, new agricultural practices, lower fertilizer and chemical use.

Also inventory data of Lavazza's production plants and the use phase of the espresso or moka machine are based on primary data and direct measurements. Secondary data are obtained from scientific literature, particularly for the green coffee cultivation phase (Coltro et. al., 2006) and the Ecoinvent database v2.2. Greenhouse gas emissions and other impact categories are quantified using IPCC 2007 (IPCC, 2007) and ReCiPe (Goedkoop et. al., 2008). The LCA has been conducted in line with ISO 14040/14044 (ISO, 2006), using SimaPro software (PRé, 2013).

At the product level LCA is used for ecodesign, hot spot analysis and environmental communication; whilst at the corporate level, LCA is used both strategically, to align CSR with product sustainability, and operationally, to provide a scientific basis for environmental data collection in a life cycle perspective, feeding tools such as the PackageExpert and the CSR tool.

2.2. PackageExpert

PackageExpert is a simplified ecodesign tool, which allows corporate packaging designers to develop simplified screening LCAs of different packaging solutions, enabling comparative analysis. By inserting packaging input data, such as, components' materials and weights, typology of transport, manufacturing processes and end of life options (ISPRA, 2012), PackageExpert calculates the Carbon Footprint and the Cumulative Energy Demand of the selected packaging solution.

The link between PackageExpert and the product level consists in its use by packaging designers working on ecodesign. On the other hand, the tool is regularly updated and based on scientific LCA knowledge. The link with the corporate level is the possibility to apply PackageExpert to all packaging solutions performed in a company's production plant, providing aggregated data to the CSR tool.

2.3. CSR tool

The CSR tool is a simplified tool with a corporate approach, which allows the collection of LCA data related to the entire supply chain of all products manufactured in a certain production plant. By inputting aggregated input data, such as total amount of green coffee transported to the plant, typology of transport, total amount of coffee manufactured, total distribution and waste treatment, the CSR tool calculates the Carbon Footprint and the Cumulative Energy Demand of the entire supply chain of all products manufactured in the production plant.

The link between CSR and the product level consists in including ecodesign activities in a corporate strategy: this way, LCA is embedded in a context and becomes a core tool for environmental management. Operationally, LCA provides useful information that needs to be collected for the implementation of a CSR strategy. The link between the CSR tool and the corporate level speaks for itself: the collection of environmental, economic and social data, and their aggregation in key indicators requires a dedicated tool. The CSR tool focuses on the environmental dimension, combining and aggregating LCA data with material flows and production volumes in order to obtain relevant key environmental performance indicators.

3. Results

3.1. LCA of espresso coffee capsule and moka coffee

Greenhouse gas emissions and other impact categories are quantified using IPCC (IPCC, 2007) and ReCiPe (Goedkoop et. al., 2008), as illustrated in Figure 2. The results express the relative contribution of each life cycle stage to the total impact of one cup of espresso coffee.

The results show that the most significant impacts are generated during the upstream processes (55%-82%), a small part is caused by the core processes of the coffee manufacturer (4% - 14%), while a significant remaining part is generated during the downstream processes (16%-42%). The environmental hot spots are the green coffee cultivation (32%-70%), coffee consumption (17%-28%) and packaging (3%-19%). Overall, the LCA results appear to be consistent with other studies published on coffee (e.g. Humbert et al., 2009; TCHIBO, 2008).

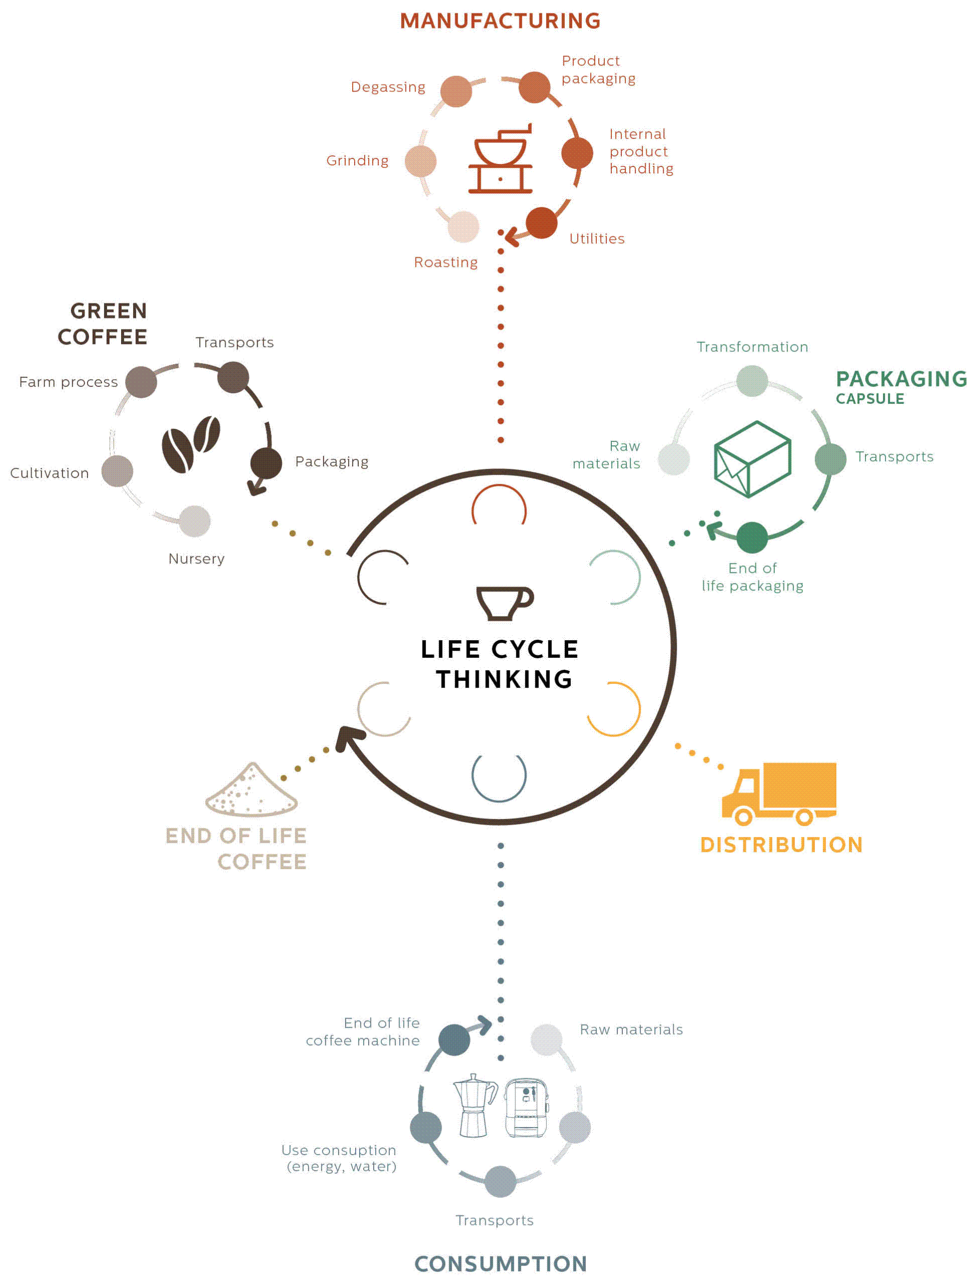

Figure 1. Combined espresso coffee LCAs .

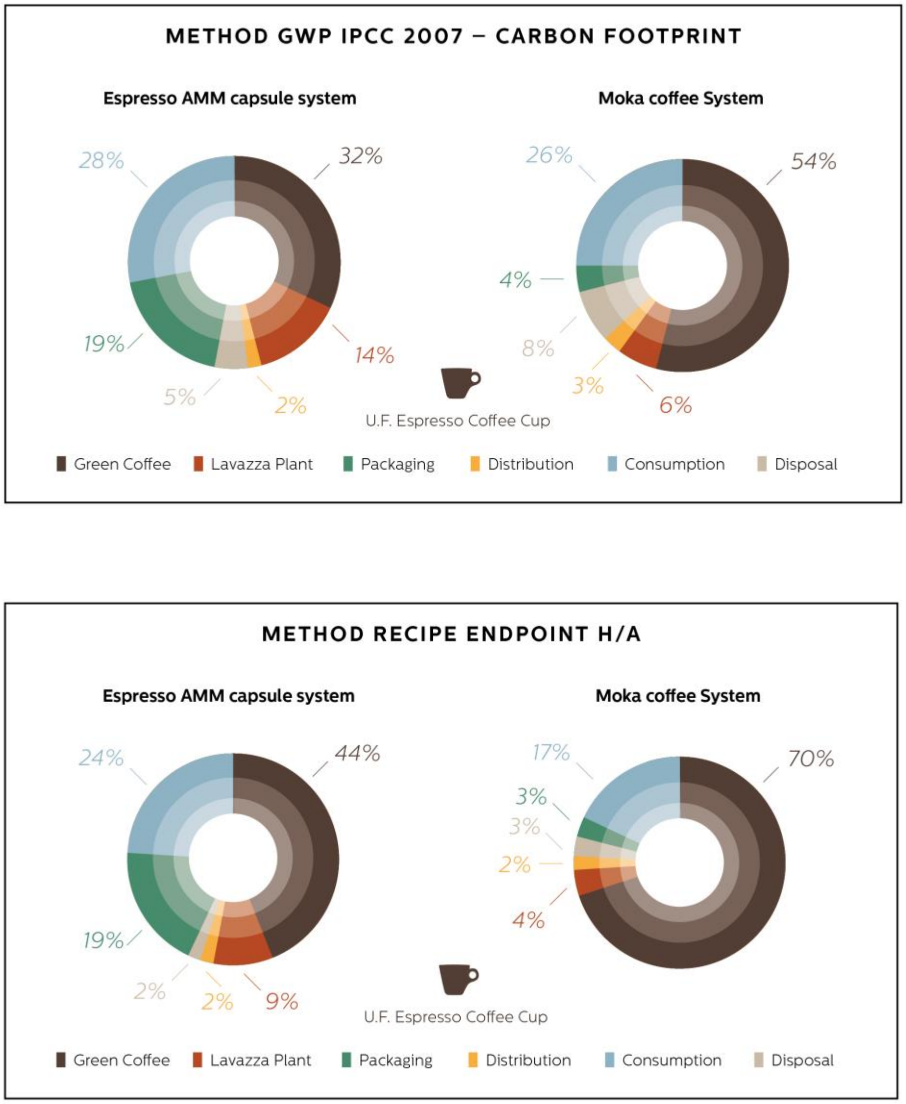

Figure 2. LCA results of one cup of espresso coffee, according to IPCC and ReCiPe.

3.2. PackageExpert

An example of the results of PackageExpert is shown in Table 1, illustrating the environmental indicators of the life cycle of a single packaging solution. Since PackageExpert is a simplified tool, it is feasible to apply the tool to all packaging solutions performed in a company's production plant. This allows to calculate not only the impact of single packaging can be evaluated (product level), but also the environmental contribution of all packaging solutions within a given production plant (corporate level).

3.3. CSR tool

The CSR tool enables aggregation of LCA data into environmental performance indicators at the corporate level. Figure 3 shows the results of the CSR tool applied to the entire supply chain of the Torino production plant, expressed in CO_2 eq. (Carbon Footprint) and MJ (CED) per life cycle stage. The CSR tool can be applied to each location and comprises besides the gate to gate analysis (processing at plant) as well as upstream (green coffee) and downstream processes (distribution, end of life). In a simplified way, based on aggregated LCA data, material flows and production volumes, the CSR tool evaluates the life cycle stages (excluding the use phase) of all main products manufactured at the production plant. In other words, it represents an aggregation of many product levels into the corporate level.

Table 1. Example of results of PackageExpert for a single packaging solution.

Packaging Life cycle	**Carbon Footprint (IPCC) [g CO_{2eq}]**	**Cumulative Energy Demand [MJ]**
Raw materials	48,5	1,291
Raw materials transport	0,8	0,014
Processing	6,5	0,131
Packaging Transport	0,5	0,009
End of life	8,0	0,008
Total	**64,3**	**1,453**

Table 2. Example of results of PackageExpert for multiple packaging solutions performed at the corporate level.

Packaging	**Amount (pieces)**	**[g CO_{2eq}]for 1 piece**	**[tCO_{2eq}] tot.**	**[MJ] for 1 piece**	**[GJ] tot.**
Packaging 1	1.000.000	115	115	2,85	2.850
Packaging 2	2.000.000	100	200	2,50	5.000
Packaging 3	1.000.000	200	200	5,00	5.000
Etc.					
Corporate			**515**		**12.850**

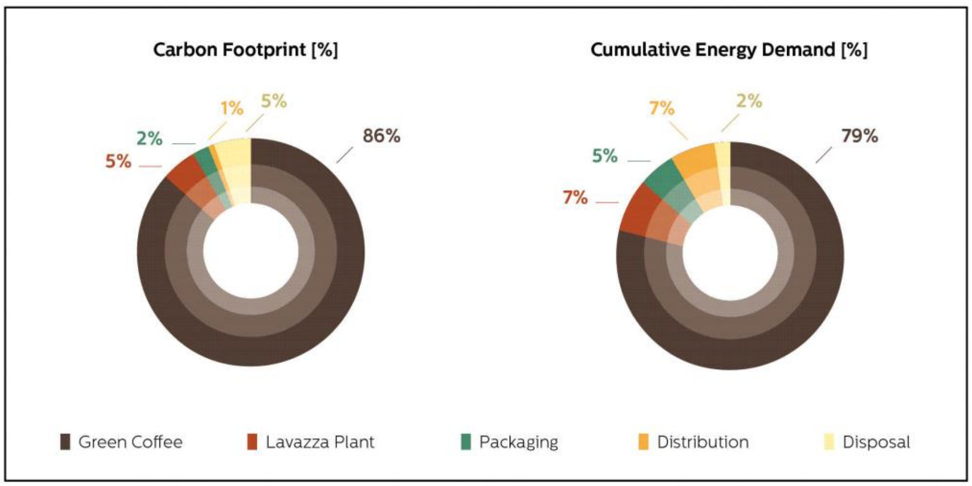

Figure 3. Results of the CSR tool for the entire supply chain of all products of the Torino production plant.

4. Discussion

LCA studies on coffee show that environmental hot spots are in particular green coffee cultivation, preparation of coffee during the use phase and packaging. In relation to the above, coffee processing (core) only generates a limited environmental impact. This emphasizes the need to view the environmental performance of coffee in a life cycle perspective (upstream and downstream).

In Lavazza, LCA was at first used in the R&D department (bottom-up) while the next step required embedding of LCA in the corporate strategy. This was achieved through CSR (top-down) thus allowing the company to have a complete perception of its environmental performances, both at product and corporate levels.

Information exchange between LCA (product) and CSR (corporate) with crucial and specific tools was developed to facilitate the interaction between the two levels. Examples of such tools are PackageExpert, which allows the performance of simplified LCA by packaging designers and the communication of results to managers, and a CSR tool that collects CSR data, partially originating from LCA activities.

Initial experiences with the different tools indicate that the tools are well interlinked, and provide added value both at the strategic and the operational levels. LCA is used strategically to align CSR with product sustainability, and, operationally, to provide a scientific basis for environmental data collection in a life cycle perspective, feeding tools like PackageExpert and the CSR tool. Besides single packaging solutions, PackageExpert can be applied to all packaging solutions of a company's production plant, providing aggregated data to the CSR tool. On the other hand, CSR takes care of embedding LCA and ecodesign activities in the corporate strategy.

The integrated LCA and CSR approach, in the context of being used for identification and assessment of environmental aspects in the corporate strategy, has advantages but also its limitations (Figure 4, SWOT). The main weaknesses, from the point of view of the considered application, includes higher time consumption and the complexity of the assessment. On the other hand, LCA enables a number of possibilities like capturing of indirect aspects, obtaining quantitative results, fostering a holistic approach through the cooperation of all stakeholders.

Figure 4. Advantages and limitations of LCA with regard to using in CSR strategy.

5. Conclusion

In conclusion, whilst an integrated LCA and CSR approach can seem more time consuming and complex to manage in terms of costs as well as unification of data, at the same time it provides a distinct advantage in terms of holistic approach, data collection, optimization and verification as well as methodology. Further, it provides an unique opportunity to achieve maximum alignment of product and corporate strategies as well as an effective stakeholder engagement.

Future work on the integrated LCA and CSR approach will focus on the improvement of the interaction between the two concepts, both at the strategic and the operational level, enhancing the information exchange between tools and systems. The obtained experience will be used to further implement this integrated approach to the entire organization of Lavazza, both at all production facilities and along the entire coffee supply chain.

ABSTRACT

Allocation of the environmental burdens to the co-products generated in the meat processing sector is a methodological issue. A study was undertaken on six animal species (beef, veal, lamb, kid goat, pork, broiler) to identify the co-products generated at slaughtering and cutting stages. The status (waste or co-product) and destination of each co-product were defined. Their masses as well as their physical composition (dry matter, protein, fat and energy contents) were quantified. A sensitivity analysis was performed on seven kinds of allocation rules in order to propose the most appropriate for the meat sector: mass, dry matter content, energy, protein, fat content, a combination of the fat and protein contents, and the economic value. This led us to propose the allocation on the basis of dry matter, which corresponds to the content in fat and protein, and consequently is appropriate to reflect all the co-products functions.

Keywords: animal co-products, meat processing, allocation, life cycle assessment

1. Introduction

The environmental impact assessment of the food products through Life Cycle Assessment is a matter under development and some methodological issues are still discussed. The allocation of burdens between the various co-products of the animal after slaughtering (edible products, bone, offal not intended for human consumption, skins, etc.) is a tricky point. These products may represent until 60 % of the animal live weight and are raw materials for several economic sectors downstream (gelatine, leather, pet food, fertilization, etc.).

International guidelines and standards can help to handle this question. ISO (2006) suggests that allocation should be avoided as far as the system allows it, by (1) subdivision of the multifunctional process in sub-processes, or (2) system expansion to include the functions of the co-products. Then when allocation can’t be avoided, an allocation rule based on (4) physical causality linked to the function of the co-products must be preferred to (5) other relationships, such as economic value; (6) several of these options can be mixed. PAS 2050 (2008) follows partly the ISO standard but recommends economic allocation as the third step, if sub-division and system expansion are not feasible. The recent draft guidelines provided by the LEAP initiative, in particular on animal feed (LEAP 2014), suggest the same hierarchy as ISO and introduce a new notion: co-products are waste, residues (marginal price) or “real” co-products. Those standards recommend doing a sensitivity analysis if several allocation procedures are applicable. Most of the LCA studies identified use economic allocation (Bengtsson et al. 2012, Joseph and Nithya 2009, Notarnicola et al. 2011), at least between groups of meat co-products having the same type of usages and market. One limit of the economic allocation is that the market value of some Animal By-Products (APB) does not reflect their subsequent usage. As a consequence of animal crises in the two last decades, the ABP market prices drastically collapsed, while they still are used. Other authors also explored other possibilities. Katajajuuri et al (2008) applied an allocation on the meat-mass of the chicken co-products; Schmidt et al. (2010) for meat, and Clarke (2012) for leather prefer system expansion if possible; Bier et al. (2012) in a study on blood conclude that both allocate on mass and consider blood as waste are appropriate. The dairy industry is probably the food sector in which the issue of allocation has been studied the most. The International Dairy Federation (IDF 2010) recommends allocating raw milk and transportation on the basis of the milk solids of the final products and to allocate other inputs and emissions using a physico-chemical allocation matrix (proposed by Feitz et al. 2007). At French level, in the perspective of environmental labeling, the dairy sector has proposed to use a physical allocation based on the content of dry matter (milk solids) of the products (CNIEL and Quantis, 2012).

Then, a study was undertaken to analyze the issue of allocation for meat co-products considering six animal species: beef, veal, lamb, kid goat, pork and broiler. It aimed to better define meat co-products, explore several allocation procedures and provide recommendations for the meat sector.

2. Materials and methods

2.1. Scope of the study

The study concerns slaughtering and cutting stages in the meat processing sector, considering six animal species: beef, veal, lamb, kid goat, pork and broiler.

2.2. Status and composition of the meat co-products

The co-products generated are Edible co-products and Animal By-Product (ABP) among which ABP of C1, C2 and C3 categories are distinguished referring to the European regulation on waste (CE/1069/2009). These ABP are components presenting sanitary risks relating to conventional agents (C2) and to bovine spongiform encephalopathy (C1), proteins (PAP) C3 and fat C3, bones C3 processed in gelatine, raw fat processed into fat and “cretons”, raw skins used in tannery and organic matter used for land-spreading, composting or biogas production.

Each material was also defined as a co-product or a waste, following the recommendations of the European directive on waste (CE/98/2008). Following this regulation, ABP do not have to be considered as waste if they follow the four following criteria: (1) the later use is certain, (2) the by-product can be used without any specific treatment different from usual industrial practices, (3) the by-product is part of the production process, (4) the later use is legal.

Table 1. Co-products from the meat industry and their destination

Co-products	Destination	Direct or after process usage	Status
Meat, offal, blood, fat, rind	Food industry	Human Food	Products
SRM, sanitary seizures, residues from the first waste water treatment	Processing of ABP C1-C2 in MBM and Fat	Cement works (MBM C1), fertilizing (MBM C2), Biodiesel (Fat C1-C2)	Waste
Other meat, offal, blood, fat, rind	Processing of ABP C3 in PAP C3 and Fat C3	Pet Food, Animal Food	Products
Bones, tendons	Processing of bones C3 in gelatine	Edible gelatine; fertilizing meal	Products
Tallow, grease	Processing of raw fat C3 in fat and “cretons”	Lipochemistry, oleochemistry, fertilizers, pet food, animal food	Products
Hide, masks	Tannery	Clothes, shoes, furniture	Products
Digestive tract content, manure, residues from the first waste water treatment	Land spreading, composting, biogas	Organic matter use	Waste

SRM: Sanitary Risk Materials; MBM: Meat and Bone Meal

2.3. Allocation procedures explored and corresponding data collection

Seven kinds of allocation rules were tested, after excluding waste components. Six rules are related to physical causalities: mass, dry matter mass, energy, protein, fat content, a combination of the fat and protein contents. They were chosen to their relevance with the different functions of the meat co-products (providing feed protein, fat and energy). The last rule is the economic allocation.

To describe the slaughtering and cutting processes and the composition of the co-products obtained at each stage, a survey has been performed on 16 French plants. Additional data from literature were used to complete the data set. For each of the seven destinations identified, the mass of co-products (Table 2) as well as their physical composition (dry matter, protein, fat and energy contents) and price were quantified.

System expansion was also explored. The aim was to define a substitution scenario for each co-product and each destination. It was not always possible to define clear and objective hypothesis, as shown in Table 3, and to collect corresponding LCA data. In consequence, this way of handling co-products is not presented in this paper.

Table 2. Part of the animal live-weight (in %) to the different co-products destinations for 6 animal species (primary data from 16 processing plants in France)

Destination	Culled cow	Veal	Lamb	Kid goat	Pork	Broiler
Food industry	45%	56%	44%	44%	70%	43%
Processing of ABP C1-C2 in MBM and Fat	10%	9%	2%	2%	5%	6%
Processing of ABP C3 in PAP C3 and Fat C3	7%	6%	13%	13%	5%	51%
Processing of bones C3 in gelatine	8%	6%	3%	3%	9%	0%
Processing of raw fat C3 in fat and “cretons”	13%	6%	6%	6%	4%	0%
Tannery	6%	7%	14%	14%	0%	0%
Land spreading, composting, biogas	10%	9%	17%	17%	7%	0%
Losses	1%	1%	1%	1%	1%	0%
TOTAL	**100%**	**100%**	**100%**	**100%**	**100%**	**100%**

Table 3. Substitution scenarios for each destination of meat co-product

Destination	Final use	Function indicator	Substitution scenario
Food industry			
Processing of ABP C1-C2 in MBM and Fat	Heat	Lower calorific value	French mix heat
Processing of ABP C3 in PAP C3 and Fat C3	Mainly pet food and animal food	fat and protein content	Other sources of fat and protein; animal or plant origin
Processing of bones C3 in gelatine	Human and animal food Fertilizer industry	Gelatine power N, P	Vegetal gelatine (algae?) Mineral fertilizer
Processing of raw fat C3 in fat and “cretons”	Human and animal food Lipochemistry	Fat content	Plant oil
Tannery	Clothes, shoes, furniture	Area (m²)	Cotton? Synthetic fabrics ?
Land spreading, composting, biogas	Land spreading, composting, biogas	N, P	Mineral fertilizer

3. Results

Figure 1 presents a selection of the allocation factors obtained with the different allocation rules, those for pork and beef (culled cows and young bulls).

For pork, from about 80% to 100% of the environmental impacts are allocated to co-products intended to human food. The impacts results of those co-products won’t vary so much through the allocation procedures tested. This is related to the fact that most of co-products are used for human food industry.

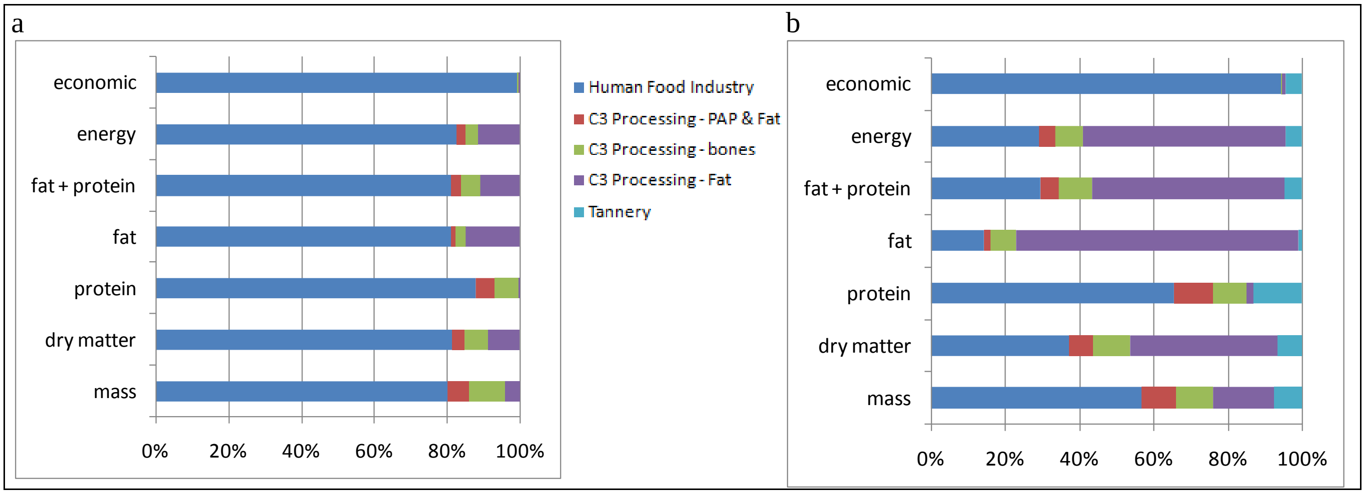

Figure 1: Distribution keys between pork (a) and beef (b) co-products (excluding wastes) according to different allocation rules

Cattle provide a wider range of different kind of co-products. For a given co-product destination, the distribution factors vary a lot from one allocation rule to another. The LCA impact results will be very sensitive to the allocation chosen. About 55% of the co-products (in mass) are valued in the food industry, while hide, bones, fat and other co-products represent a non negligible part. Economic allocation attributes almost 95% of the upstream impact to the human food industry destination and the rest to the hide. None impact is attributed to other co-products despite their downstream use. Fat and protein allocations give very contrasting allocation factors. Energy, fat + protein and dry matter procedures give almost the same allocation factors, as they all represent the interest of main of the co-products and their function in providing protein and fat.

Other species present in-between results, underlining the specificities of each of them: comparing to beef, veal factors are lower for most of the co-products, due to higher carcass yield; the relative part of tannery and C3 – PAP & Fat is higher for lamb, according to the low carcass yield and the grease component for this type of animal; for kid goats, sold as entire carcass, there are less co-products at plant gate, so a higher part is attributed to Human food industry destination; for broiler, every physical allocation procedures give about half of the impacts to human food and half to pet food (PAP & Fat).

4. Discussion

The choice of an allocation procedure should first intend to be meaningful for all co-products regarding their function. In the meat sector, most of the co-products generated are used for their physicochemical characteristics: for their content in protein (human food, pet-food) and/or in fat (gelatine, fats). That pleads for the choice of a physical allocation. A recommendation for the meat sector should be relevant for all animal species. In that way, the allocation on the dry matter content has the following advantages: this criterion combines all of the physico-chemical characteristics of interest (in particular lipids and proteins); it is relevant for the different uses and markets (food, chemistry, leather and for all animal co-products, irrespectively of their destination; it provides stable figures, few dependant of the economical context.

This approach seems appropriate for most of the European countries. Nevertheless, it is now necessary to make sure it could suit in other contexts, where animal by-products could have different status, usages and markets.

System expansion is also probably still a relevant area for future studies even if including functions of the meat co-products has limits.

5. Conclusion

The recommendation of our study is to use an allocation based on the respective dry matter content of each co-product which is relevant to consider all the functions of the co-products in their different uses and markets. It also has the advantage to be in accordance with the dairy sector. Indeed, the same approach shall be probably preferred for all animal productions from the livestock sector.

Anyway, none of the allocation procedures is perfect and these results underline the fact that a sensitivity analysis should be performed if it can have a great incidence on the impact results, such as carbon footprint. This study provides both primary data on meat processing and helpful figures for sensitivity analysis in LCA in the meat sector.

Further works, such as the actual ACYVIA program in France, would be helpful to go ahead with the allocation issue: dividing in sub processes and perhaps proposing physico-chemical allocation matrix (Feitz et al. 2007) to reflect the underlying relation between resources/impacts and the co-products. This subject should be further explored in the framework of the future Product Environment Footprint European Pilot.

ABSTRACT

A new biophysical procedure to handle co-products in LCAs of livestock systems, combining subdivision of the system and allocation, has been developed. Systems were divided into animal classes, defined as dedicated to specific physiological functions (e.g. growth) and so to specific products (e.g. animals for meat). When allocation is needed, the environmental burdens of the animal class were attributed to the co-products pro rata the feed energy required to produce them (biophysical causality). This has been applied on cattle, sheep, goat, pig, poultry, rabbit and fish production systems. On the example of some dairy and pig systems, it is shown that the attribution of the burdens to the different co-products of a system changes from one impact category to another. Indeed some resource consumption or emissions are specific to an animal class and then, to a product. A sensitivity analysis, considering five other allocation procedures, allows considering their respective advantages and limits.

Keywords: life cycle assessment, allocation, livestock products, sensitivity analysis

1. Introduction

Life Cycle Assessment (LCA) results depend greatly on methodological choices. One of the most important and much debated choices concerns the allocation of the environmental flows among the co-products. At the moment, the LCA practice is not harmonized regarding the allocation of impacts to the outputs of livestock production systems. However, the question of allocation has been extensively studied, especially concerning milk production.

For dairy systems, in particular since the publication of the IDF standard (IDF 2010), most recent publications use allocation ratios based on feed-energy (Flysjö et al. 2011; Dollé and Gac 2012; Thoma et al. 2013) or feed energy and protein requirements (Cederberg and Mattsson 2000; Basset-Mens et al. 2009; O'Brien et al. 2012) needed to produce milk and animals (live weight). Depending on the authors, this procedure is called biological, physical or biophysical causality allocation. The principle is always to consider the strong causal relationship between physiological requirements, especially for growth and lactation, and the feed use for the production of live-weight and milk. From an author to another, some differences appear in the way it is applied: while IDF (2010) and Thoma et al. (2013) only consider growth and lactation needs and propose a meat/milk ratio, Dollé and Gac (2012) include five requirements, i.e. maintenance, activity, growth, lactation and gestation. Those authors highlighted that choices regarding which physiological requirements are considered could lead to significant differences of allocation ratios for a French dairy system, with 82% of impacts attributed to milk applying the IDF method, to 73% when the five types of requirements are considered. For suckler-beef production systems, it seems that only Nguyen et al. (2012) applied an allocation procedure (comparing allocation on live weight mass, protein mass and economic value through a sensitivity analysis), while other studies did not allocate impacts to the different types of animal produced. Most studies report impacts for an average live-weight, mixing cull cows, young bulls and finishing heifers, even weaners, without considering they provide different qualities of meat and that some of those animals will be slaughtered directly while others will be finished. Looking at the current literature, the situation is the same for other species, such as pork and poultry.

Nevertheless, biophysical allocation seems also relevant for other livestock production systems, especially for beef systems, because it allows having the same approach for dairy and suckler beef systems that both provide beef. When considering the allocation of impacts to the different co-products, the appropriate approach is to refer to the ISO 14044 (2006) hierarchy. First, ISO 14044 suggests that allocation should be avoided as far as the system allows it, by subdivision of the multifunctional process in sub-processes, so that inputs and outputs can be assigned to specific products. When subdivision is not possible, an allocation rule based on physical causality must be preferred to other relationships, such as economic value.

The AGRIBALYSE program has provided a public database of Life Cycle Inventories (LCIs) of French agricultural products at the farm gate (Colomb et al. 2014) according to a common methodology (Koch and Salou, 2014). The reports and summary factsheets of the AGRIBALYSE program are available on line (www.ademe.fr/agribalyse-en), while the full database is available free of charge on demand to ADEME (agribalyse@ademe.fr). Concerning animal production, AGRIBALYSE produced: (1) LCIs for animal systems that provide several co-products (e.g.: milk / cull cow / calf) and (2) LCIs of systems that provide both agricultural products (e.g.: cull sow) and living animals used as inputs in other systems (e.g.: cattle weaners, piglets for fattening units). One of the objectives of the project was to harmonize methodological choices as much as possible between all animal species. In fact, concerning allocation, the aim was to apply the same approach for cattle, sheep, goat, pig, poultry, rabbit and fish production systems.

The purpose of the paper is to present how co-products were handled in the AGRIBALYSE program, outlining amongst others the specific data collection procedure. First, we divided the processes and then we applied a biophysical allocation. Our results were compared to LCA results calculated according to other allocation methods in a sensitivity analysis. The paper focuses on the example of milk / live animals in bovine production but also provides highlights for other systems when relevant.

2. Methods

2.1. The handling of co-products in the AGRIBALYSE program

The biophysical allocation method is based on the causal relationship between feed requirements and the different products of a system: production of milk (or egg, living animal's muscles, wool) and its energy content, are driven by the energy required to support the function of lactation (respectively pregnancy, growth and wool production). Six main functions are identified: maintenance, activity, growth, pregnancy, lactation / egg production, production of wool. These functions are directly related to animal products. In current livestock production systems, most of the time, animal life stages correspond directly to different functions and so, to the corresponding products. Indeed, in all species, females become mature and productive once they have finished the main part of their growth and are then dedicated to the production of milk, calves, piglets, lambs or eggs.

This led us to consider that some life stages of an animal can be attributed to a co-product. Then, life-stages are considered as sub-processes of the whole livestock farming system. In accordance with ISO (2006), allocation can then be avoided by dividing the animal life cycle in several stages that we call "animal classes" corresponding to a characteristic physiological stage (calf to weanling, heifers, milking cows, finishing cows). Inputs and outputs were then assessed for each animal class. The output product of an animal class is a living animal that enters the following animal class, or a sold product (e.g. heifers for replacement in another herd). Figure 1 illustrates this principle for a dairy herd, making the assumption that the growth of the milk cows can be neglected.

Data were collected through a specific tool which allowed splitting information between animal classes (calf, heifers, cows…). Some data were directly available at the animal class level (feed, manure), others were available at the herd or farm scales (energy consumption). These data were attributed to animal classes using technical references (e.g. pro rata for the livestock units). When an animal class yielded a single product, allocation was not needed. When allocation was required (e.g. for the stage "milking cow": milk / calf), this was done pro rata for the estimated metabolic energy required for the various physiological functions of the animal and to produce each co-product. All requirements for the different functions were considered and not only those directly linked to a function yielding a product. Then, for the milking cows, part of the maintenance and activity functions was allocated to milk, while the other part was allocated to the calf.

The procedure developed to handle co-products in livestock systems is then a combination of division of the system and allocation.

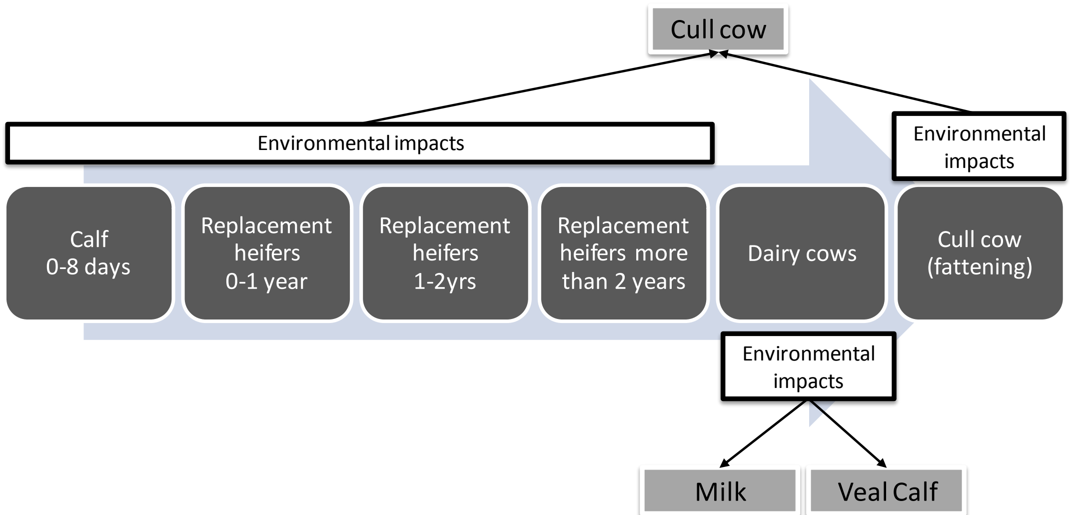

Figure 1. Allocation of inputs and impacts to co-products using a "bio-physical" representation of a dairy herd (blue: animal classes allocated to the cull cow; green: animal class allocated to milk and calves).

Table 1 provides an extract of how animal classes and their estimated requirements for the different functions were attributed to the different co-products. The energy requirements were calculated using equations from NRC (1996, 2001) for cattle in accordance with IPCC (2006) for enteric methane assessment, and national models for pork and poultry (Sauvant et al. 2004). All details are available in Koch and Salou (2014).

Table 1. Animal classes, output products and physiological functions, for allocating environmental impacts depending on the energy required for these functions.

Systems	Animal class	Output products	Physiological functions						Comments / Formulae
			Maintenance	Activity	Growth	Lactation / Egg	Gestation	Wool	
Dairy systems	Calf 0-8 days	Veal calf	X	X	X				
	Rplt Heifer 0-1yr	Cull cow	X	X	X				
	Rplt Heifer 1-2 yr	Cull cow	X	X	X				
	Rplt Heifer +2 yr	Cull cow	X	X	X				
	Milking cow	Milk	X	X		X			$Lactation + (Maintenance + Activity) * \left(1 - \frac{Gestation}{Lactation}\right)$
		Veal calf at birth	X	X			X		$Gestation + (Maintenance + Activity) * \left(\frac{Gestation}{Lactation}\right)$
	Finishing cow	Cull cow	X	X	X

	Layers	Egg	X	X		X			

2.2. Sensitivity analysis

A sensitivity analysis comparing the proposed biophysical method with other methods for co-products handling was carried out on one of the five dairy systems assessed in the program (lowland, maize + grass) to analyze the consequences in terms of allocation factors and climate change impact values obtained. Six allocation methods were tested.

System expansion is the first step suggested by ISO (2006). It was performed considering that the meat from dairy cull cows and from dairy calves replace the average meat produced by the suckler and finishing beef systems analyzed in the AGRIBALYSE program (a mix of suckler cows, heifer and young bulls: 16.23 kg CO_2 eq./kg LW).

Economic allocation was done using data from the case study which provided the price of milk and animals sold for the year 2008 (Réseaux d'Elevage, 2009).

For the protein allocation, protein production by milk and animals were derived from the production of the farm and the average amount of protein in milk (33.2 g/liter) and the amount of protein per kg of live weight (150 g/kg) (CORPEN 1999).

The IDF allocation factor was calculated following the equation provided (IDF 2010):

$$R = 1 - 5.7717 * (\text{meat} / \text{milk}) \quad \text{Eq. 1}$$

The biophysical allocation method proposed by Dollé and Gac (2012) for dairy herds helps to consider the five functions in a simple way: all the functions of milking cows are allocated to milk, except pregnancy dedicated to the sold veal calves and all the functions of replacement heifers are allocated to the cull cow (including pregnancy, considering it contributes to the replacement calves).

Another allocation rule is added, derived from the AGRIBALYSE procedure, where energy requirements are attributed to the co-products in the same way (Table 1) to establish allocation factors (cull cows: all requirements of the replacement heifers; veal calves: requirements for pregnancy of the cows and a part of their maintenance and activity, plus the requirements of the dairy calf until they're sold; milk: requirements for lactation of the cows and a part of their maintenance and activity).

3. Results

3.1. Consequences of the AGRIBALYSE procedure on allocation factors

A selection of results in Table 2 presents how the impacts are distributed to each co-products for the five dairy systems studied in the AGRIBALYSE program. The resulting factors vary from one system to another, depending on its technical performances (milk production per cow, replacement rate, etc.). They also change from one impact category to another, because some impacts are specifically linked to one stage of production. For instance, considering milk production, the highest factor is always the one for non renewable energy, because of the energy consumption of the milking parlor.

Table 2. Distribution of the impacts with the AGRIBALYSE biophysical procedure for two impact categories and five dairy systems.

Impact category		**IPCC GWP 100a**			**Non renewable Energy fossil + nuclear**		
Co-products		Calf	Cull cow	Milk	Calf	Cull cow	Milk
Functional unit		1 kg LW	1 kg LW	1 kg FPCM	1 kg LW	1 kg LW	1 kg FPCM
Dairy systems	Lowland - Maize	1.5%	17.8%	80.7%	1.6%	12.9%	85.5%
	Lowland - Maize + Grass	1.5%	22.9%	75.6%	1.7%	15.7%	82.6%
	Lowland - Grass	1.9%	29.2%	68.9%	3.1%	17.1%	79.8%
	Lowland - Grass - Organic	2.0%	23.6%	74.4%	2.3%	15.0%	82.7%
	Highland	2.6%	19.7%	77.7%	3.0%	8.8%	88.2%

LW: Live Weight; FPCM: Fat and Protein Corrected Milk.

Amongst the co-products of a whole pig production system (breeding and fattening), the impacts are mainly supported by the fattened pigs, while cull sows carry less burdens. It is due to the fact that nearly 20 pigs are produced per sow per year. The fattening pigs are the product that the farms intend to produce and the sows are a tool of production even if their meat is valorized. Two contrasting types of production (conventional and organic) (Table 3) show the high allocation factors for fattening pigs for the impact climate change (86% and 92%). The allocation factor for fattening pigs is higher for organic production because the housing mode of the pigs is on litter. More GHG are emitted than on the slatted floor of the conventional production. Despites this high allocation factor for fattening pigs, the impact values per kg live animal are higher for culled sows than for fattening pigs (11.54 kg CO_2 eq. / kg of culled sow *vs* 2.4 kg CO_2 eq. / kg of fattening pig). This is due to the live weight production of each animal class. This allocation factor doesn't reflect the economic value of the products, respectively 93.5% of the income coming from pig sales and 6.6% from sows.

Table 3. Biophysical allocation factors obtained for two impact categories and two pig systems.

Impact category		**IPCC GWP 100a**		**Non renewable Energy fossil + nuclear**	
Co-products		Pig for pork	Culled sow	Pig for pork	Culled sow
Functional unit		1 kg LW	1 kg LW	1 kg LW	1 kg LW
Pig production	Organic	91.8%	8.2%	84.4%	15.6%
	Conventional	85.6%	14.4%	85.3%	14.7%

3.2. Sensitivity analysis results

The sensitivity analysis performed shows that the carbon footprint (CF) of the milk in the maize + grass system varied from 0.70 to 1.14 kg CO_2 eq./ kg FPCM (Table 4) depending on the co-product handling. These results are in the range of values from the literature. The CF varies from -27% to +17% comparing with the value provided by AGRIBALYSE. It has much more consequences on the impact of the carbon footprint of live weight animals, dedicated to produce meat directly (cull cows) or to be finished (calf): from -54% to +110%.

Table 4. Effect of the co-product handling procedure on allocation factors (in %) and carbon footprints (CF) of milk, cull cow and veal calf for a French lowland dairy system based on silage maize and grass dairy system (in kg CO_2 eq. per kg of FPCM and per kg of LW)

	Veal calf		Cull cow		Milk	
	factor	CF	factor	CF	factor	CF
Economic allocation	1.2%	6.10	10.4%	4.01	88.4%	1.14
Protein allocation	1.0%	5.01	13.0%	5.01	86.0%	1.11
Biophysical allocation (IDF)	1.5%	7.45	19.4%	7.45	79.1%	1.02
Biophysical allocation (Dollé & Gac, 2012)	2.9%	14.71	19.3%	7.40	77.8%	1.00
Biophysical allocation – derived from AGRIBALYSE	5.3%	27.02	19.3%	7.40	75.4%	0.97
Division + allocation - ABRIBALYSE® -	1.5%	7.73	22.9%	8.80	75.6%	0.98
System expansion	-	16.23	-	16.23	-	0.70

4. Discussion

Advantages and limits of each allocation procedure tested are discussed here. In our example, economic allocation provides the highest carbon footprint of the milk. It allows attributing impacts to each co-product, related to its market value. It shows the real interest for each of the co-products. However, the economic value of a dairy calf at the dairy farm gate does not represent the final use of this co-product which continues its life cycle in a finishing unit. To exclude the effects of short-term price variability, economic allocation should be done using average prices based on data for several years, however, this has not been possible here. Another point concerning economic allocation is that it could be not relevant when comparing productions from different countries, with different races. The example of sheep production in France and New Zealand is relevant: in France, wool provides little economic profit, while in NZ, because of the more productive races and an existing market for carpet making, the wool has a good value (Gac et al. 2012).

Protein allocation is oriented by the protein content of each co-product leaving the farm, in relation to their destination as human food. It doesn't help distinguishing cull cows and calves as they have both the same functional unit (kg of live weight). The results of carbon footprints are close to those obtained with the economic approach.

The IDF (2010) method provides also the same results for cull cows and calves. That is explained by the fact that this physical allocation method is based on a milk/meat ratio which treats all animals dedicated to meat production in the same way. This is probably linked to the fact that this allocation method was developed specifically for the dairy sector and didn't aim at specifying each co-product.

The biophysical allocation methods of Dollé and Gac (2012) and the one derived from AGRIBALYSE assign less energy requirements to milk. This results in a lower carbon footprint for milk and a higher carbon footprint for live animals, in particular for the veal calf. When those allocation procedures are applied, the carbon footprint of dairy animals at the farm gate is much closer to that of animals from suckler beef systems. This point is relevant because these two types of beef are sold in the same market. Beef from dairy cows is important, as it represents 23.5% of the French beef production (Institut de l'Elevage, 2013). This method helps also to properly consider French mixed races (Normande, Montbelliarde) which produce less milk and more meat than specialized milk breeds such as Holstein Frisian.

System expansion yielded the lowest carbon footprint of milk. It considered that beef from dairy herds is comparable to other types of beef. This is based on the fact that beef from culled dairy cows is sold in the same markets and for the same uses (mainly human food), despite their difference in terms of quality and price. However, in the way we applied system expansion, it was not possible to distinguish the kilograms of live weight of cull cows and of calves: the former is dedicated to being slaughtered, while the latter will be finished in specific farming units. System expansion should have included finishing of dairy calves and the comparison with suckler calves to be consistent regarding all three co-products (milk, dairy calves, cull cows). Anyway, this way of handling co-products provides impact values for the main product (milk), but does not provide impact values for the other co-products. System expansion could be applied on a dairy system to determine the impacts of calves and cull cows by substituting cow milk by milk of other species (goat, sheep). However, this is quite an unrealistic hypothesis, since goat and sheep milk really serve different markets and needs than cow milk (mainly cheese processes). This example illustrates a weak point of the system expansion approach, as finding an equivalent product is often difficult. Furthermore the system expansion approach is quite subjective because the result is closely dependant on the scenario of substitution that was chosen.

Finally, the procedure applied in the AGRIBALYSE program provides intermediate results, both for milk and for living animals. The corresponding allocation factors are very close from those of Dollé and Gac (2012) for carbon footprint, due to similar methodology: the main difference is the attribution of the maintenance and activity energy needed by cows which are there distributed between milk and calf. However, the allocation factors can deviate when considering other impacts (Table 2). Indeed, the specificity of this approach is that it provides allocation factors specifically for each impact category. This makes sense because, even if feed intake is the main driver of animal excretion and most of the emissions and impacts (climate change, acidification, water use), but this is not the case for all impact categories, specifically for energy demand and land occupation, and eutrophication to a less extent.

5. Conclusion

This paper proposes a new way to handle animal co-products at farm gate, based on a bio-physical approach, coupling subdivision of the system and allocation for the first time. This method is relevant for all livestock systems; it is applicable either for milk, meat, egg or wool. It is also relevant for all impact categories, whenever if they are led or not by animals consumptions and excretions. System subdivision allows determining environmental impacts at for each animal development stage, which can be useful to consider impacts of every type of living animal at the farm gate, even if they don't have the same destination: slaughtering, finishing or replacement. In this way, inputs and emissions are directly attributed to the corresponding stage and product. From the farmer's perspective, this approach would help to reconsider the multifunctionality of the production even on specialized systems. Mitigation options or practices improvements would then either be chosen to be adopted on the whole farm or to firstly lower the environmental footprint of the main product.

However, this method requires an appropriate data collection tool and detailed primary data per animal class, which can be quite difficult to obtain. If this is not possible, the alternative is the application of biophysical allocation factors, such as the one proposed derived from the AGRIBALYSE procedure, uniformly on the different impact categories. This first application at a large scale, should know probably be improved by using national models for feed requirements and the way in which the physiological functions are attributed to the different co-products is open for discussion and for further improvement.

ABSTRACT

In the context of climate change and non-renewable energy depletion, the transition toward increasing the contribution of renewable energy requires insight into environmental consequences of such energy production, such as anaerobic digestion (AD). In a pig farm producing crops used as ingredients for pig feed, biomass (fertilized with pig manure), crop residues and intercrops are highly valuable substrates for AD. Thus, the aim of this work was to assess the influence of on-farm digestion of pig slurry to produce bio-energy on environmental impacts of pig production from a life cycle perspective. This system allows maximum autonomy for the farmer, regardless of the availability of digester nutrients. It had lower negative impacts for most impact categories than a more energy-dependent system, even for hotspot impacts of climate change and cumulative energy demand. More accurate data about carbon mineralization of digestates are necessary to make conclusions about potential impacts on soil organic matter dynamics.

Keywords: anaerobic digestion, pig production, soil organic matter change

1. Introduction

In the context of climate change and non-renewable energy depletion, the demand for renewable energy is rising, and the European Union aims to obtain 20% of its energy from renewable sources by 2020 (EU 2009). This transition requires insight into environmental consequences, such as climate change (CC) and cumulative energy demand (CED), of renewable energy production. Change in soil organic matter (SOM) is also a hotspot indicator for soil quality (Garrigues et al. 2012) in the case of bio-energy produced from biomass by anaerobic digestion (AD) in the form of heat and electricity. The product that remains after AD is digestate, which can be recycled as organic fertilizer for crop cultivation. On a pig farm in which the main crops used as ingredients for pig feed are produced on the farm, biomass (fertilized with pig manure), crop residues and intercrops are highly valuable substrates for AD. Thus, the aim of this work was to assess the influence of on-farm co-digestion of pig slurry to produce bio-energy on environmental impacts of pig production from a life cycle assessment (LCA) perspective.

2. Methods

2.1. System definition

The agricultural system is assessed via its function of food production. System boundaries of the pig breeder/fattener system are from cradle to the farm gate. The system includes infrastructure, inputs, related resources and emissions for pig production and the crops used as ingredients in the pig feed. For crops used as pig-feed ingredients, the main crop rotation in its region of origin was assumed. For crops produced on the pig farm, crop rotations were considered in greater detail. Temporal system boundaries of crop rotations end with the harvest of the crop analyzed and begin after the harvest of the preceding crop. The functional unit is 1 kg of pig liveweight produced. Impact categories assessed were those of the CML-IA, plus CED and two soil-quality indicators: compaction and SOM change (Garrigues et al. 2012).

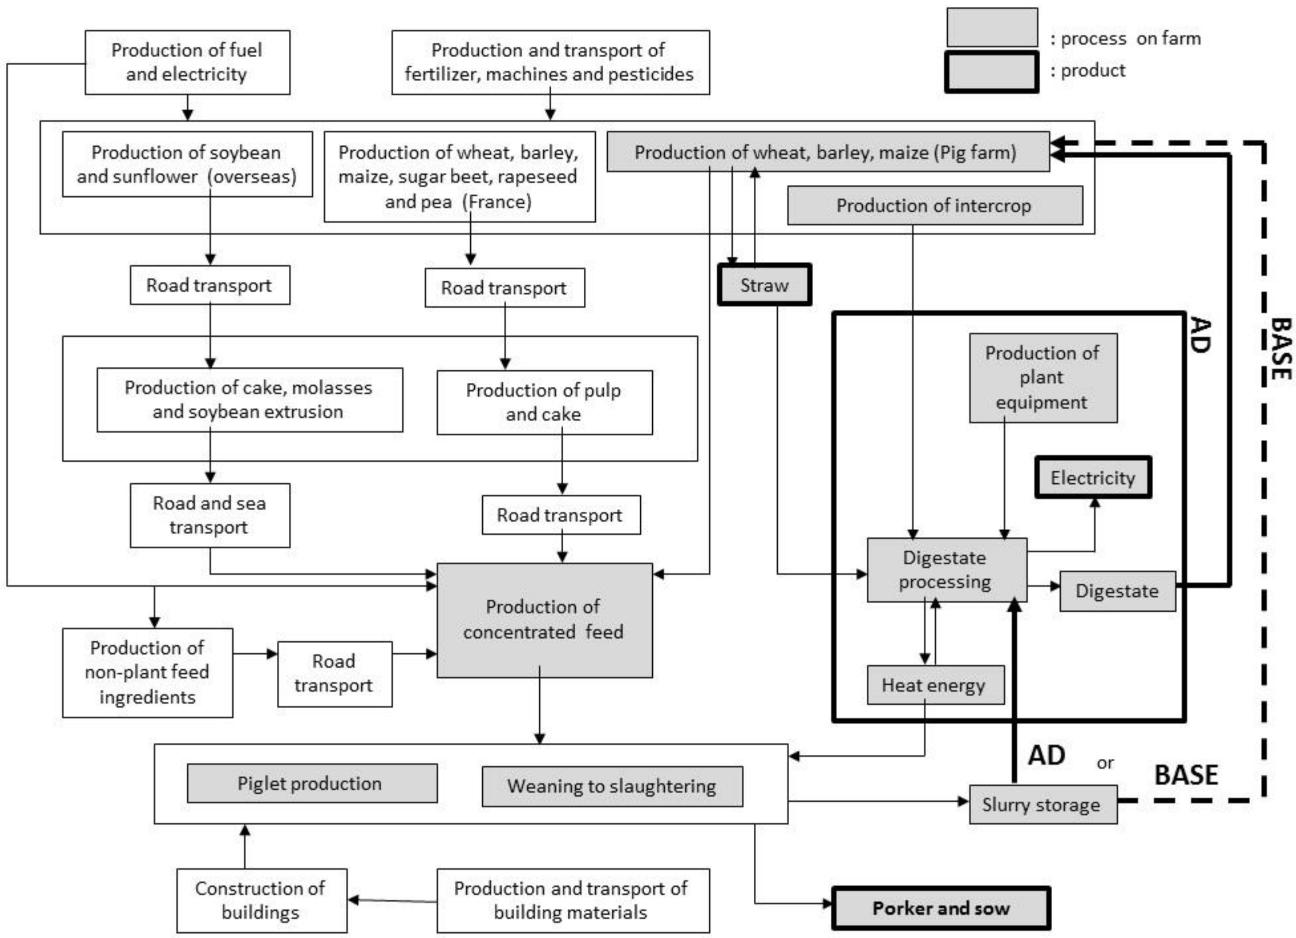

Figure 1. System boundaries for baseline (BASE) and anaerobic digestion (AD) scenarios

2.2. Definition of scenarios

We compared two scenarios (Fig. 1): (1) standard manure storage and spreading on a representative pig farm in Brittany, France (BASE scenario), and (2) the same pig farm with a 50 kW AD plant with digestate spreading on fields instead of slurry (AD scenario). The representative farm produces 4800 pigs per year with 225 permanent sows. Maize, wheat and barley are produced on 115 ha with phacelia as an intercrop. Four rotations are represented: wheat-maize and wheat-barley-maize on 48 ha each, wheat-maize-maize on 15 ha and maize monoculture on 4 ha. In the AD scenario, oats and triticale are also grown as intercrops with phacelia to feed the AD plant (Table 2). Fertilizer applications (mineral and organic) were calculated to maintain yield and to prevent pollution risk. Characteristics of the pig farm (e.g., volume of pig production, area, crops) were based on examples of existing pig farms in Brittany that remained economically viable after adding AD to the farm (Brittany Chamber of Agriculture, pers. comm.).

2.3. Life cycle inventory assumptions and model used for SOM change

2.3.1. Composition of pig feed in the two scenarios

Pig production in the breeder/fattener system uses seven different feeds, with compositions defined by the French Pork and Pig Institute (IFIP) according to the pig-production stage (Table 1). The farmer fabricates all feeds on the farm. All crop production is used to feed the sows, piglets and pigs and represents 88% of the maize, 82% of the barley and 70% of the wheat needed for the feeds. The rest of the ingredients are bought on national and international markets (Table 1).

Table 1. Ingredient composition (percentage by mass) and sources of representative pig feed produced in Brittany.

Ingredient	Maize	Wheat	Wheat middlings	Barley	Rape-seed oil	Rapeseed cake	Soya cake	Sunflower cake	Sugarbeet pulp
Origin	France (Brittany)	France (Brittany)		France (Brittany)	France (Brittany)		Brazil (Santa Catarina)	Argentina (Balcarce)	France (Picardy)
Source crop	Maize	Winter wheat		Barley	Rapeseed		Soya	Sunflower	Sugarbeet
Economic allocation[a] (%)	100.0	100.0	14.0	100.0	75.6	24.4	66.0	37.6	15.6
Pregnant sow feed (%)	6.8	40.0	3.2	30.0	0	6.7	0	5.0	5.0
Lactating sow feed (%)	12.7	30.0	0	32.0	0	5.7	13.0	2.0	1.0
Piglet prestarter feed (%)	0	61.9	0	0	4.6	0	27.6	0	0
Piglet starter feed (%)	0	42.0	0	32.0	0	0	20.0	0	0
Post-weaning feed (%)	0	58.0	0	20.0	0	0	19.0	0	0
Growing pig feed (%)	20.0	43.0	0	15.0	0	0	19.0	0	0
Finishing pig feed (%)	50.1	28.0	0	0	0	0	17.0	0	0

[a] Economic allocation based on Olympic mean price from 2006-2010 (ISTA 2009 & 2011).

2.3.2. AD scenario

In seeking maximum autonomy for the farmer, dimensions of the AD plant (energy produced and substrate quantities needed) aim for economic viability of the pig farm: no need to import substrates for AD other than those produced on the farm and spreading of all digestate produced on farm crops as fertilizer.

The AD is operated at a mesophilic temperature (around 35°C) with a hydraulic retention time of 66 days. CH_4 production from the AD is 110,832 m^3/year, with an electricity-production capacity of 50 kW and energy efficiency of 36%. Operating the AD requires 3% of the electricity produced and consumes 36% of the heat produced. The heat produced covers all heating needs of pig buildings and provides a surplus in summer. This scenario reflects simple biogas installations, which produce less electricity but also cost less to install.

Table 2. Substrates of the anaerobic digestion (AD) plant and their organic matter (OM) before and after AD

Substrates	% of substrate produced on-farm used for digestion	t/year	OM before digestion (t)	OM after digestion and storage (t)
Pig slurry	100	207	147	100
Wheat chaff	100	71	65	31
Barley chaff	100	17	15	7
Grass silage	100	12	11	4
Oats (intercrop)	100	56	53	9
Triticale (intercrop)	100	60	56	13
Barley straw	50	28	26	15
Maize stalks	33	64	59	34

To obtain a liquid rather than solid digestate, not all of the available straw and maize stalks are placed into the digester. The digestate is liquid enough (5.8% DM) to be spread as fertilizer, in the same way that slurry is spread in the BASE scenario. In the AD scenario, slurry and digestate are stored separately in covered concrete tanks, and the remaining 50% of the wheat straw is sold. CH_4 and N_2O emissions of the AD plant (storage and digestion) were calculated with the DIGES tool (Gac et al. 2006). Since emission factors for digestate applied to fields were not available, we assumed them to be the same as those for pig slurry. In the BASE scenario, slurry is stored in and open concrete tank, and 100% of the wheat straw is sold. During storage, nutrient leaching from the slurry or digestate is assumed to be negligible in both scenarios.

2.3.3. Soil carbon change modeling

RothC (version 26.3) simulates dynamics of organic carbon (C) in soil (Coleman *et al.* 1997; Coleman and Jenkinson 2008). The effects of soil type, temperature, moisture content and plant cover are considered in the turnover process. Soil organic C is split into four active compartments and a small amount of inert organic matter (IOM). The four active compartments are decomposable plant material (DPM), resistant plant material (RPM), microbial biomass (BIO) and humified organic matter (HUM). When exogenous organic matter is added to the soil, it is split between the DPM, RPM and possibly HUM pools according to partition coefficients, such as DPM/RPM. For crop residues, we used a DPM/RPM ratio of 1.44, i.e. DPM of 59% and RPM of 41%. For slurry and digestate, DPM and RPM was calculated from their Van Soest biochemical fractions via an indicator of remaining organic C (I_{ROC}) (Lashermes et al. 2009) based on equations developed by Peltre et al. (2012):

$$DPM = -1.254 \times I_{ROC} + 115.922 \qquad \text{Eq. 1}$$

$$RPM = 0.979 \times I_{ROC} - 8.928 \qquad \text{Eq. 2}$$

We used DPM of 63.9% and RPM of 31.7% for slurry and DPM of 29.5% and RPM of 58.5% for digestate.

We simulated 20 years of the same management practice and divided the total change in soil organic C by 20 to provide the mean rate over one year. When analyzing crop rotations, temporal system boundaries differed from those of individual crops, for which the C brought to the soil by crop residues was considered from just after the harvest of the crop of interest (when residues are left in the soil) to the harvest of the following crop. We thus followed back-effects of the C supplied. The change in soil C could be positive or negative, indicating soil C storage or loss, respectively.

3. Results

Table 3. Potential impacts of the (BASE)line and anerobic digestion (AD) scenarios per kg of pig liveweight according to the CML-IA method.

Impact category	Unit	BASE	AD	AD vs. BASE (%)
Abiotic depletion	kg Sb eq	3.96E-03	3.66E-03	-7.6
Acidification	kg SO_2 eq	5.45E-02	5.57E-02	+2.1
Eutrophication	kg PO_4^{---} eq	1.53E-02	1.57E-02	+2.5
Climate change (GWP100)	kg CO_2 eq	1.90E+00	1.86E+00	-1.9
Ozone layer depletion	kg CFC-11 eq	9.07E-08	8.66E-08	-4.5
Human toxicity	kg 1.4-DB eq	9.36E-01	9.21E-01	-1.6
Fresh water aquatic ecotoxicity	kg 1.4-DB eq	9.33E-01	9.22E-01	-1.2
Marine aquatic ecotoxicity	kg 1.4-DB eq	3.65E+02	3.58E+02	-2.0
Terrestrial ecotoxicity	kg 1.4-DB eq	1.52E-01	1.50E-01	-1.1
Photochemical oxidation	kg C_2H_4	8.81E-04	8.79E-04	-0.3
Land occupation	m^2y	3.93E+00	3.94E+00	+0.2
Total cumulative energy demand	MJ	1.18E+01	1.09E+01	-8.1
Soil organic matter change	kg C	1.35E+01	1.12E+01	-17.5
Compaction	m^3	1.21E+01	1.90E+01	+36.4

LCA of the two scenarios showed lower environmental impacts per kg of pig liveweight of the farm with AD (Table 3). Installation of an AD plant reduced CC by 1.9% (BASE: 1.90 kg CO_2-eq/kg; AD: 1.86 kg CO_2-eq/kg) and CED by 8.1% (BASE: 11.84 MJ/kg; AD: 10.88 MJ/kg). SOM was sequestered in both scenarios (positive impacts) despite less soil C storage when straw was exported compared to a scenario (results not shown here) in which straw was left on the soil. The BASE scenario sequestered a mean of 13.5 kg C/kg and the AD scenario 11.2 kg C/kg. The AD scenario had higher acidification and eutrophication impacts than the BASE scenario (by 2.1 and 2.5% respectively). The greatest increase in impact due to the installation of an AD plant was for soil compaction, which increased by 36.4%. The AD scenario had lower impacts than the BASE scenario for the other categories.

4. Discussion

Introducing biogas technology in a pig farm in Brittany reduced greenhouse gas emissions, mainly by replacing natural gas for heating piglet nurseries. In France, where most electricity is produced by nuclear energy, CC impacts from electricity production were similar for both scenarios. Even though the AD plant studied was small, CED decreased due to direct production and use of heat and electricity.

The increase in SOM was lower in the AD scenario than the BASE scenario. AD's digestate has a lower C content than the substrates used to create it because of the loss of C via CH_4, but it has greater stability, which decreases long-term loss of SOM. In a Danish study (Thomsen et al. 2013), a three-pool model used to simulate

C mineralization predicted similar long-term C sequestration in soil for initial turnover of plant biomass in the soil, ruminant digestive tracts, an AD plant or a combination of the latter two. In that study, C pools in the model were calibrated with laboratory incubations. In our study, the RothC model was initialized with pedotransfer functions. Although both scenarios sequester C, the lower C sequestration due to spreading digestate instead of slurry can be compensated by changing straw management: C sequestration was 19.5 kg C/kg (74% higher) if all straw was returned to the soil in the AD scenario.

Adopting AD technology on a pig farm appears to increase compaction due to the greater number of field operations required for the new intercrops grown to feed the AD plant. Since the compaction indicator only considers neutral (plowing) or negative impacts of field passes, the more field operations, the higher the predicted compaction (Garrigues et al. 2013). Furthermore, the new operations occurred when soil water content was high (spring and autumn), thereby increasing compaction risk. The compaction indicator represents the potential impact well if these practices are performed every year. Indirect implications of soil compaction, such as lower future yields, should not be neglected, but crop rotations should decrease this risk. Despite this, AD of slurry, straw and intercrops is well accepted in France. Replacing the intercrops with crops to feed the digester would probably decrease compaction and increase efficiency of the AD, but this practice is not currently accepted in France. A sensitivity analysis is planned to assess the relative influence of farm and AD plant characteristics.

5. Conclusion

Installation of a small AD plant on a pig farm producing most of the ingredients in its animal feed provides maximum autonomy for the farmer, who does not have to depend on the availability of plant substrates for AD. The AD system tended to have lower environmental impacts than a more energy-dependent system, even for the hotspot impacts of climate change and cumulative energy demand. Careful attention must be paid to SOM management through C amendment with digestate and straw. Digestates are quite new types of exogenous organic matter with a wide diversity of C mineralization characteristics depending on the plant substrate. More accurate data about carbon mineralization of digestates are necessary to make conclusions about potential impacts on SOM dynamics.

ABSTRACT

Both herbicide-tolerant and insect-resistant GMO varieties as well as combinations thereof are now widely used in corn production in the US. The introduction of these traits has led to changes in farm management practices most notably adapted pesticide usage and adoption of no-till cultivation practice. This study assesses the social, economic and environmental impact of GMO corn cultivation in Nebraska using an LCA-based approach. The Nebraska Crop Budgets published by the University of Nebraska, Lincoln, are used as main input data. Whereas the social impact remains similar in the sum of all aspects considered, the economic and environmental impact assessment showed clear advantages of the use of GMO traits in all economic and most ecological aspects considered. Overall, the study shows that production and use of fertilizer as well as the yield achieved are the main drivers for sustainable corn production. The environmental impact of pesticide production and its adapted use through the introduction of GMO varieties is comparably limited although the economic benefits of reduced pesticide use associated with GMO corn varieties are significant.

Keywords: GMO, corn, farm management, no-till, pesticide use

1. Introduction

Corn is the dominant crop in the US grown on 95,6 mio acres in 2013 (USDA National Agricultural Statistics Service; http://www.nass.usda.gov). Corn is used mainly as a source of starch and protein rich feed, for the production of bio-ethanol and processed as high-fructose corn syrup in food production. Corn productivity has increased substantially from 72 to 153 bushels per acre in the time between 1970 and 2010 (USDA National Agricultural Statistics Service; http://www.nass.usda.gov). Since their introduction in 1996, GMO traits have been rapidly adopted by farmers in the US with roughly 90% of all corn being GMO corn in 2013.

GMO traits that are being used by farmers on a regular basis now include herbicide-tolerance for efficient weed management and insect-resistance to control major Lepidopteran pests such as the corn borer (e.g. Ostrinia nubilalis) or corn rootworm (e.g. Diabrotica sp.). In particular, herbicide-tolerant crops expressing a mutant version of the 5-enolphyruvylshikimate-3-phosphate synthase gene conferring tolerance to the application of the broadband herbicide glyphosate also known under its brand name RoundUp (RR) is widely used. Alternative herbicide-tolerance traits to be used in combination with glufosinate, dicamba or 2,4-D are available to farmers. For insect-resistance, corn expressing different versions of *Bacillus thuringiensis* toxins (Bt) in different parts of the plant or constitutively are generally used by farmers to control pests. Furthermore, a variety of stacks of different Bt traits as well as in combination with herbicide-tolerance traits such as Agrisure or SmartStax in which 8 different transgenes in one corn variety is combined are the latest in development of GMO corn varieties.

For farmers the economic benefits of GMOs in terms of better weed and pest management and resulting higher yields and profits are evident (Brookes and Barfoot 2009). An important factor for the rapid and vast adoption of GMOs in corn production also seems to be a better management of yield risks associated with for example pest infestation (Shi et al., 2013). In terms of environmental benefits, herbicide-tolerant GMO corn in the US alone is associated with a 10,9% reduction in use of pesticides or 180,2 million kg of active ingredient and insect-resistant GMO corn in the US with a 41,9% reduction or 40,7 million kg of active ingredient cumulatively in the period between 1996 and 2011 (Brookes and Barfoot 2013). The same analysis furthermore calculates that herbicide-tolerant crops in the US have saved 77 million liters of fuel due to the adoption of no-till practices and consequential changes in field operations in the year 2011 alone.

The benefits of GMO corn reported above are impressive though they represent singular benefits at farm level. For a comprehensive analysis if GMO varieties contribute to sustainable development in corn production, the social, economic and ecological impacts need to be assessed and impacts both at farm as well as within the value chain need to be considered

In this study we have applied an LCA-based methodology to assess the social, economic and environmental impacts associated with the cultivation of 4 different corn varieties in Nebraska. Whereas one corn varieties was a conventional variety produced by "classical" breeding methods, the three other varieties had either only a GMO herbicide-tolerance trait, a combination of herbicide-tolerance and insect-resistance or incorporated the current maximum of traits as in SmartStax.

Lifecycle assessment (LCA) has been used before to assess environmental and economic impact of corn production, but mostly in relation to its use as feedstock for bio-ethanol production from corn grain or stover (see for example Pieragostini et al. 2014; Whitman et al. 2011). LCA has not been applied so far to specifically assess the impact of GMO traits in corn production.

Incorporation of herbicide-tolerance and insect-resistance GMO traits into corn varieties directly translate into changes in farm management practices such as new crop protection regimes. These GMO traits also greatly favour adoption of new soil management practices such as no-till cultivation. These changes in farm management are specifically accounted for. In scenario analysis, the robustness of the model and options for further improving the sustainability of corn production are evaluated.

2. Methods

2.1. Goal and scope

The aim of this study is to assess the impact of the introduction of GMO traits on corn production in the state of Nebraska, USA. Since 1996, GMO traits conferring tolerance to the application of broad-band herbicides, mainly glyphosate or RoundUp (RR), or traits to control major Lepidopteran pests such as the corn borer (e.g. Ostrinia nubilalis) or corn rootworm (e.g. Diabrotica sp.) by expressing insecticidal proteins from Bacillus thuringiensis (Bt) in corn. In the study the production of non-GM corn is compared to GM corn with only herbicide-tolerance based on glyphosate (RR), a commonly used combination of herbicide-tolerance and insect-resistance (RR&Bt) as well as a SmartStax corn in which multiple modes of both herbicide-tolerance and insect-resistance are stacked (SmartStax). The functional unit was defined as "the production of 1 ton of corn at field gate in the state of Nebraska using either of the 4 described corn alternatives".

2.2. Input data and assumptions

Main input data are taken from the 2011 Nebraska Crop Budgets (Wright et al 2011). The Nebraska Crop Budgets are annually updated projections for crop cultivation produced by the Extension Division of the Institute of Agriculture and Natural Resources at the University of Nebraska - Lincoln in cooperation with the Counties and the United States Department of Agriculture. Budget 8 describes the cultivation projections for non-GM corn, budget 9 for the RR&Bt alternative and budget 10 describes the main input data for SmartStax. The input data for the RR alternative were interpolated from the non-GM alternative in relation to the use of insecticides and from the RR&Bt alternative in relation to herbicide treatments and the field operations of no-till cultivation practice (see Table 1).

Table 1. Amount of herbicide and insecticide active ingredient (a.i) applied for non-GM and 3 GMO corn varieties (kg a.i/ha).

	Active ingredient	**non-GM**	**RR**	**RR&Bt**	**SmartStax**
Herbicides	Atrazine	1,82	1,85	1,85	1,85
	S-Metolachlor	1,43	1,5	1,5	1,5
	Prosulfuron	0,0075	0	0	0
	Primisulfuron-methyl	0,0025	0	0	0
	Glyphosate	0	2,37	2,37	2,37
Insecticides	Fibronil	0,29	0,29	0,058	0,015
	Chlorpyrifos	0,084	0,084	0,017	0,0042
	Bifenthrin	0,018	0,018	0,009	0,009
	zeta-Cypermethrin	0,0028	0,0028	0,0028	0,0028

Yield for the RR alternative was modelled from the RR&Bt alternative based on a yield comparison of two transgenic herbicide-tolerant and insect-resistant varieties with their isogenic non-Bt counterparts (Haegele and Below 2013) showing that the Bt trait conferred an on average 11,8% yield benefit. As stated in the Crop Budgets, the alternatives are assumed to be in a continuous corn system (i.e. no crop rotation) and rainfed (i.e. no irrigation). In consultation with an expert panel from the University of Nebraska – Lincoln and in line with the recommendation in the Crop Budgets, the study assumed equal nitrogen use efficiency for all 4 corn production alternatives. Soil erosion is at 2,24 to/ha/year for the alternative using conventional tillage and 0,62 to/ha/year for the alternatives applying no-till practices (W. Vanek, USDA-NRCS Nebraska, pers. comm.).

2.3. Impact assessment

The environmental assessment is based on established life-cycle impact assessment (LCIA) categories as used also in Eco-Efficiency Analysis (Saling et al. 2002) and a wide range of other LCA approaches. Primary energy consumption, resource depletion, emission to air, emission to water and solid waste are assessed. The ecotoxicity potential of all chemicals intentionally released into the environment, e.g., fertilizers and pesticides is accounted for (Saling et al. 2005). Land use is assessed using to the scheme of the ecosystem damage potential (EDP; Köllner and Scholz 2007, Köllner and Scholz 2008). Consumptive water use is assessed as described by Pfister et al (Pfister et al. 2009).

Additionally, environmental indicators addressing the specific impacts of agricultural activity on biodiversity in agricultural areas, and on soil health and conservation, have been incorporated into the methodology (see Schoeneboom et al, 2011 and references therein). More specifically, biodiversity is assessed using the “driving force – state – response” model which is proposed by OECD to structure the complex relationships between agriculture and biodiversity (OECD 2003). The indicator set for biodiversity compiles factors which negatively affect biodiversity resulting in a decline of the state of biodiversity such as low crop rotation or high farming intensity. It also takes into account the effect of the applied pesticides by integrating ecotoxicological characterization factors from USEtox (Rosenbaum et al. 2008). The “state” indicator quantifies the status quo of biodiversity using a proxy such as the widely accepted bird indicator (Bird indicator 2013). “Response” indicators reflect activities which are able to promote or conserve biodiversity such as high crop rotation or the adoption of field margins or flower strips (for details see Saling et al. 2014).

The impact category of soil health is comprised of indicators assessing soil organic matter balance, soil erosion, soil compaction and the nutrient balances of the main nutrients N, P, K. More specifically, the depletion and build-up of soil organic matter is assessed as a balance derived from estimations by the IPCC LULUCF for cropland (IPCC LULUCF), or alternatively on the standard German cross-compliance ‘humus balance’ model (VDLUFA 2004). An assessment function, developed by Hülsbergen in 2003 (quoted in Ehrmann & Kleinhanss, 2008 and Christen 2009) is then used to evaluate the balance results. Nutrient balance is assassed as a function of the amount of fertilizer applied and the amount of nutrients retrieved through harvest. This balance is furthermore corrected for the ability of the soil to mineralize and thereby provide nutrients as indicated by soil nutrient supply classes. The nitrogen balance also considers different sources e.g. nitrogen fixation by leguminoses. The result of the nutrient balances is subsequently evaluated, using nutrients specific models with optimal scores around an equal nutrient balance of zero and decreasing scores for either nutrient deprivation or over-fertilisation. (Christen 2009). The potential for soil erosion is calculated default using the Universal Soil Loss Equation (USLE). This equation predicts the long term average annual rate of erosion on a field, based on slope, rainfall pattern, soil type, topography, crop system, and management practices (Hudson 1993).

In terms of economic assessment, both production costs as well as economic performance are taken into account. Production costs are grouped into variable and fixed costs and quantified using an overall total cost of ownership for the defined functional unit (Kicherer et al. 2007). Economic performance is assessed using indicators for farm profitability as the central criterion for economic sustainability, subsidies which may excert distorting economic effects and productivity as measured as the production value of agricultural goods per hectare weighted by the contribution of the agricultural sector to the national GDP.

The social assessment in AgBalance is derived from the SEEBALANCE method for social LCA, which was developed in 2005 by Universities of Karlsruhe and Jena, the Öko-Institut (Institute for Applied Ecology) Freiburg e.V., and BASF (Schmidt et al. 2005, Kölsch et al. 2008). Based on the UNEP-SETAC guidelines for social LCA of products 5 stakeholder categories were defined: Farmer, consumer, local community, internal community and future generations. The SEEBALANCE indicators and data sources are employed to assess the social impacts of industrial up- and downstream processes. For the agricultural activities in the life cycle, a set of adapted social impact indicators was integrated into the AgBalance method which were designed to match closely the same social sustainability topics addressed in the assessment of the upstream and downstream processes.

3. Results

3.1. Environmental impact assessment

The number of field operations as described in the Nebraska Crop Budgets are 14 in case of non-GM corn and 8 for the GM alternatives. The adoption of no-till practices makes the field operations of chiseling and chopping stalks obsolete and changed type of fertilizer used and its mode of application. These changes in field management reduced labor and machinery costs, but also significantly reduced fuel use for field operations from 62,78 l/ha for the non-GM alternative to 33,62 l/ha for SmartStax. Expressed in relation to the customer benefit of 1 ton of corn, fuel use for field operations is reduced by 60,4%.

The significantly reduced fuel consumption per functional unit is also reflected in better scores in the impact categories energy consumption and resource consumption. Both categories however are dominated by the energy and resource requirement for fertilizer production (see Figure 1 for energy consumption). In fact the production and use of fertilizer constitutes roughly 3 quarters or more of the impact in these categories.

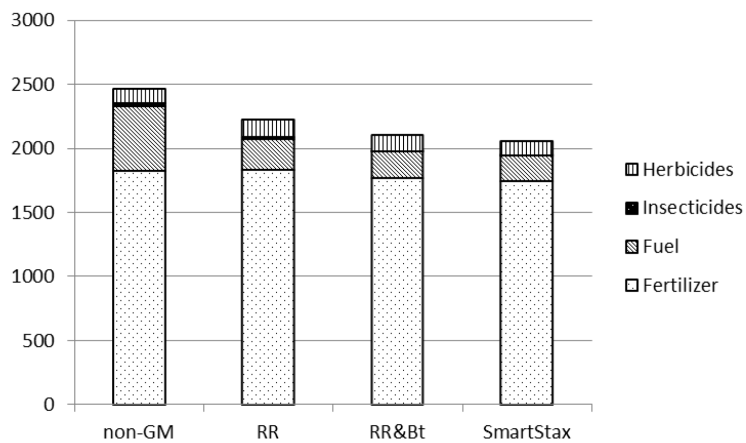

Figure 1: Total energy consumption derived from the production and use of the major inputs (in MJ/customer benefit of 1 ton of corn)

The footprint of all 8 environmental impact categories considered (Figure 2) shows furthermore the positive effect of higher productivity on land use - which is for over 95 % determined by land used for agriculture - and reduced by 26 % from non-GM to SmartStax due to higher yields.

The impact on the local biodiversity potential is determined among others by the ecotoxicology of the crop protection products used: whereas the herbicide tolerance trait requires higher use of herbicides, although with a more favorable eco-toxicological profile, the insect-tolerance in the alternative RR&Bt as well as SmartStax leads to a reduced intensity of use of insecticides with a potential positive impact on beneficial insects and thus a more favourable score for the local biodiversity potential. The other indicators in this impact category are equal (e.g. crop rotation, protected areas, agri-environmental schemes) or more or less similar (nitrogen surplus).

In the impact category soil the benefits of no-till on soil erosion are taken into account whereas the figures for soil compaction, soil organic matter balance as well as the nutrient balances are more or less equal for the alternatives considered. Soil erosion is decreased by 1,61 ton/ha/year or 72 % by the adoption of no-till cultivation practice. The impact of consumptive water use seems greatest of all environmental categories, but since the study assessed rainfed corn, differences in water use are related to the application of fertilizer and pesticides only. As a consequence the result of this impact category looks very favorable for the alternatives with insect-resistance, but in absolute terms the savings in water are of limited impact.

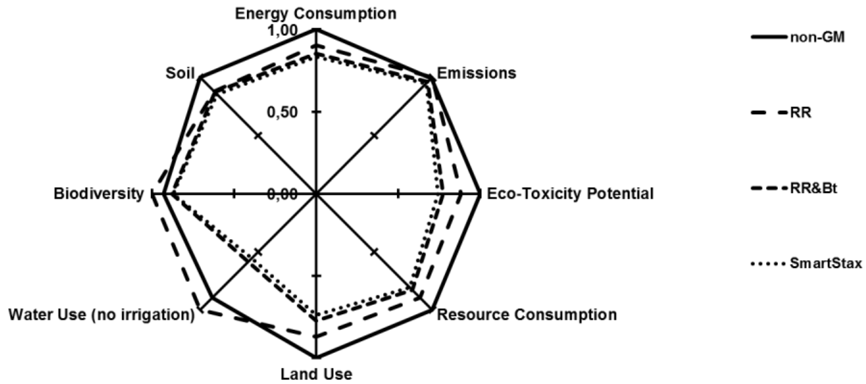

Figure 2. Representation of relative environmental impact category results for the different alternatives in fingerprint diagram. Relative improvement in each impact category is represented by smaller values on the respective axes; hence the smaller the fingerprint, the better the relative performance of the corresponding alternative.

For the impact assessment of emissions, both emissions to air and water as well as solid waste are considered. The final score is more or less unchanged in the sum of all aspects considered since this impact category is highly determined by emissions related to the production and use of nitrogen fertilizer. For example, greenhouse gas emissions are dominated by 89% in the case of the alternative non-GM to up to 95% in case of SmartStax by production of fertilizer and field emissions from nitrification processes in soils (data not shown). Since equal nitrogen use efficiency is assumed for the 4 alternatives the impact in this category are similar.

3.2. Socio-economic impact assessment

The economic assessment shows clear results both in terms of reduced fixed and variable associated with GMO corn alternatives as well as higher margins and farm profits (Table 2). Fixed costs related to machinery, buildings and equipment is reduced by up to 37% and variable costs by 22% between non-GM and SmartStax when expressed per functional unit. Profits per hectare have more than tripled.

Table 2. Overview of costs, revenue and profit.

	Unit	non-GM	RR	RR&Bt	SmartStax
Fixed cost	USD/1 t corn production	93,81	69,15	60,99	58,65
Variable cost	USD/1 t corn production	100,53	94,04	75,39	78,49
Total cost	USD/1 t corn production	194,34	163,19	136,38	137,14
Total cost	USD/ha	1036,80	993,82	941,69	989,98
Revenue	USD/ha	1280,40	1461,60	1657,20	1732,45
Profit	USD/ha	243,60	467,78	715,51	742,47

A main point of criticism for GMO corn is often the high price for seed. The results in Table 3 show that first of all, cost of seed are not the main variable cost, but rather fertilizer (see Table 3). And secondly, the higher cost for seed is more than compensated for by reduced cost for pesticides especially insecticides. For example, for SmartStax almost $ 9,97 extra seed costs per functional unit have to be paid, but this investment in return leads to reduced pesticide cost of $ 30,49 per functional unit. In other words, for every dollar spend on seeds, the farmer receives 3 dollars in return.

Table 3. Costs for main inputs ($/functional unit).

	non-GM	RR	RR&Bt	SmartStax
Seed	13,91	15,74	16,90	23,88
Fertilizer	25,83	28,23	27,59	27,31
Herbicides	13,68	11,58	10,21	9,77
Insecticides	25,22	22,10	4,24	1,36
Total	78,64	77,66	58,94	62,31

The assessment of the social impacts shows a more or less equal result for all alternatives in the sum of all impacts considered. For example, positive effects of higher productivity on the statistical occurrence of working accidents or occupational diseases are balanced by reduced employment opportunities and reduced contributions to social security funds as expressed per functional unit (data not shown). All other social impact indicators remain unchanged since the study investigates different alternatives for same crop in same region and same year.

3.3. Scenario analysis

In total 4 different scenarios are calculated to investigate the robustness of the model in relation to major assumptions made in the study as well as major trends in corn cultivation. First of all, the study calculates with a lower yield potential for non-GM corn as based on the input data from the Nebraska Crop Budgets. Whereas the yield advantage of insect-resistant corn varieties seems well established, a clear effect on yield by the herbicide-tolerance trait is more difficult to establish and seems to depend more on the context of cultivation (Shi et al. 2013). Scenario 1 therefor calculates with a yield level for non-GM similar to RR corn. As a result, the environmental impact of non-GM corn is now similar in the environmental impact categories emissions, eco-toxicity potential and land-use. Benefits for RR remain in relation to resource and energy consumption (related to reduced diesel use) and soil erosion whereas biodiversity and water consumption is unaltered (Figure 3). In the sum of all environmental and socio-economic impacts considered, there is no significant difference between non-GM and RR in this scenario whereas the performance of alternatives RR&Bt and SmartStax remains significantly better.

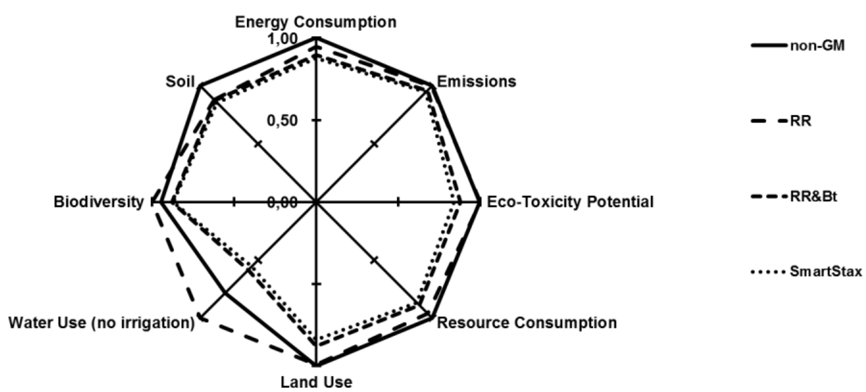

Figure 3. Representation of relative environmental impact category results for the different alternatives in scenario 1 in fingerprint diagram. Relative improvement in each impact category is represented by smaller values on the respective axes; hence the smaller the fingerprint, the better the relative performance of the corresponding alternative.

Evolution of resistance in weeds and pests to the herbicide and insecticides applied can reduce the efficacy of crop protection strategy. This is by no means restricted to the use of GMOs but is known in all areas where crop protection products are used intensively (Powles et al, 1997). Glyphosate-tolerant weeds have increasingly been reported in the US since the 2004/2005 growing seasons (Heap 2014). In recent years Bt–resistant pests (Tabashnik et al. 2013) have been reported that threaten the efficacy of Bt crops. In scenario 2 and 3, a 50% increase in the use of herbicides or insecticides, respectively, are assumed to model the potential impact of the consequential higher rates of pesticide use. The results of these scenarios show that the environmental impact of higher rates of pesticides is very limited since most environmental impact factors are dominated by fertilizer production and use as well as productivity (data not shown).

Finally, scenario 4 assessed the impact of changing from continuous corn cultivation to a system where corn follows soybean cultivation. High demand for corn as feed and for biofuel production has shifted crop rotation patterns from corn-soy rotations to continuous corn over the last decade (Plourde et al. 2013). A yield penalty has been associated with long-term continuous corn cultivation and nitrogen availability identified as a major factor (Gentry et al. 2013). The Nebraska Crop Budgets 2011 specifically include a budget for this scenario (budget 11) which assumes a 33% reduction in use of inorganic nitrogen fertilizer due to the availability of nitrogen fixed by the soybean nodule mycorhizza and an increased yield potential from 110 bu/acre to 115 bu/acre. The Crop Budgets assume no change in pesticides applied for this scenario. These assumptions were modelled on alternative RR&Bt in scenario 4. As a result, the impact of fertilizer production was greatly reduced in the categories greenhouse gas emissions, energy and resource consumption (Figure 4). Also local biodiversity potential improved through better crop rotation. The overall environmental score has improved significantly whereas the socio-economic score is highly dependent on the revenue prices for corn in relation to soybean (data not shown).

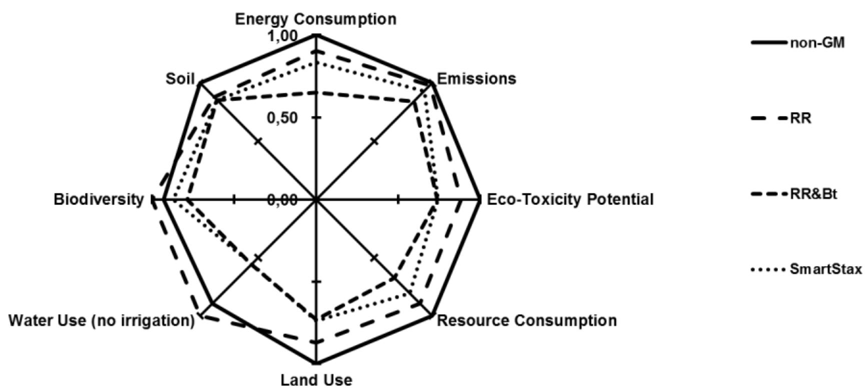

Figure 4. Representation of relative environmental impact category results for the different alternatives in scenario 4 in fingerprint diagram. Relative improvement in each impact category is represented by smaller values on the respective axes; hence the smaller the fingerprint, the better the relative performance of the corresponding alternative.

4. Discussion

Since their introduction in 1996, GMO traits have become standard technology incorporated into the major row crops in the Americas as well as cotton production globally. This rapid adoption makes clear that there are agronomic and economic benefits for the farmer from use of GMOs. This stands in contrast to the public perception that exists around GMOs. The GMO traits that are available today do not offer a direct customer benefit and this may have hampered acceptance of the technology. It is therefore even more important to assesses the potential impacts of GMO traits in a holistic and comprehensive way and use the results to inform the public and as guidance for further development. We used an LCA-based methodology assessing environmental, economic as well as social impacts of GMO traits in this study.

We could show that there are significant advantages associated with the use of GMO insect-resistance traits. It is accepted that Bt traits are responsible for higher and more stable yield levels (Shi et al., 2013). This yield advantage alone is responsible for a largely more positive ecological footprint. Reduction in use of insecticides furthermore has positive effects on biodiversity since less non-selective products are sprayed that harm both pest and beneficial insects. Insecticides are also a major variable cost and the investment in insect-resistant traits certainly pays-off for the farmer and it is easy to understand these GMO have become popular where Lepidopteran pests are common. The rising occurrence of insects resistant to Bt is now threatening the benefits of this trait. We could show in a scenario analysis that a 50% increased use of insecticides does not translate into a higher overall environmental burden. However, when Bt resistant insects can no longer be controlled effectively by increasing amounts of pesticides and negative effects on yield levels are occurring, this would directly negatively affect the environmental footprint as well as the economic performance of these traits. Appropriate resistance management programs need to be adopted by farmers to avoid any further development of resistant pest.

The impact of the herbicide-tolerance GMO trait is more ambivalent. A positive yield effect of herbicide-tolerant crops is more difficult to establish and seems to depend on type of herbicide-tolerance as well as geographical context (Shi et al., 2013). The scenario analysis assuming similar yield between non-GM and RR shows that without a yield benefit, the sustainability impacts of both systems are very much comparable. In contrast to earlier reports (see for example Brookes and Barfoot 2013), this study suggests herbicide-tolerant GMO corn is associated with higher levels of herbicide application. It is important to note however that the (eco-)toxicological profile of glyphosate, the herbicide that is most commonly used in combination with a herbicide-tolerant GMO corn, is more favorable than most other herbicides. As a result, even in a scenario where 50% higher application of glyphosate is assumed, the overall impact of herbicides on the environmental footprint of corn cultivation is low. Again, and analogous to Bt resistant pests discussed above, when herbicide-tolerant weeds can no longer been controlled effectively and negative impacts on yields are occurring, this most certainly will negatively impact the sustainability of this GMO trait.

Although no-till systems are adopted in regions and crops where GMO traits are not prevailing, it is generally acknowledged that herbicide-tolerant crop varieties have favored the adoption of no-till in soybean and corn in South and North America (Brookes and Barfoot, 2013). The advantages in soil conservation – i.e. preventing soil erosion and to a lesser extend enabling build-up of organic matter – are well described and are an important factor for long-term farming sustainability. Also in this study, soil erosion is reduced by 1,61 ton/ha/year or 72 % by the adoption of no-till cultivation practices. No-till is also the main driver for the reduction by over 60% in fuel use for field operations. This study has not accounted for a beneficial effect on greenhouse gas emissions through carbon sequestration in soil and this remains an upside potential for no-tillage cultivation systems that remains to be explored.

Whereas the impact from the production and use of pesticides was shown to be limited, this study clearly demonstrated that the highest ecological impact in corn cultivation is associated with the production and use of inorganic fertilizer. The production of the fertilizer requires large quantities of natural gas and accounts for roughly 75 % of all energy and resources consumed. Concurrently, emissions from production facilities together with emissions from its use in the field due to nitrification processes in the soil accounts for up to 95% of greenhouse gas emissions related to corn production. From these figures it becomes clear that any strategy to reduce inorganic fertilizer input for example by genetically increasing the nitrogen use efficiency of the crop (Xu et al 2012) or reducing the nitrification processes in soil (Liu et al 2013) will benefit the sustainability of corn production substantially.

The high impact of fertilizer production is also illustrated in a scenario looking at potential impacts of a corn-soybean rotation instead of continuous corn cultivation. A 33% reduction in inorganic nitrogenous fertilizer directly translates into significant reductions in air emission as well as energy and resource consumption. In addition, this crop rotation has a favourable impact on biodiversity and could be integrated into resistant management practices needed to maintain efficacy insect-resistance traits. These environmental benefits of a soy-corn rotation should be investigated further in a comprehensive and consequential assessment of both elements in crop rotation together with a proper economic assessment.

Next to fertilizer, the yield level of the different alternatives is of course a major factor in any assessment which uses a productivity factor as functional unit such as “a ton of corn produced” in this study. The yield level is a product of the genetic potential of the crop, the environment it is grown in and the cultivation practice used and these factors are highly interdependent. As such the yield levels of the alternatives in this study are a product of continued breeding efforts, incorporation of traits through biotechnology and changes in management practices. From reports of side-by-side comparison of GMO varieties with their non-GM isogenic counterparts a positive effect on yield is demonstrated for the insect-resistant trait (Haegele and Below 2013). Likewise other genetic approaches to increase the intrinsic yield potential (Condon et al 2002) or enhance resilience of crops against pest, diseases or stresses have great potential to benefit the sustainability of corn production.

5. Conclusion

The study shows that GMO traits contribute to more sustainable corn production in Nebraska. The positive impact of the Bt insect-resistance trait is associated mainly with higher yield levels or less yield risk, reduced cost and to a lesser extent reduced environmental burden from insecticide use. Glyphosate herbicide-tolerance can have a positive impact too if the trait contributes to higher yields - or at least not less yield - and leads to a higher adoption of no-till cultivation practice which in turn is favorable for soil erosion and leads to reduction in field operations and associated fuel use.

Overall the study shows that the environmental impact of the production and use of pesticides is low and that highest burden is from the production and use of inorganic fertilizer. Yield is another main driver for the sustainability of corn production. Likewise, crop varieties, farming practices or technologies that reduce the need for inorganic fertilizer, increase the yield potential or its resilience against pest, diseases and stresses should be the main targets for sustainable development in corn production..

ABSTRACT

The environmental impact of transporting milk from farms to processing plants depends mainly on the distance and the operating parameters of the vehicles (Foster et al. 2006). The aim of this study is to compare different LCA approaches for the quantification of the environmental impact of a milk collection round trip in Switzerland. We considered two approaches: The simplified approach, where the average distance between farms and processing plant and standard emission factors for the relevant truck type were used and a detailed approach, where the effectively driven round trip was considered. For all analyzed impact categories, the simplified approach results in a smaller impact compared to the detailed approach. The selection of a modeling approach for transports depends on the way how a transport is being organized but also on the importance of transport's impact of the whole life cycle.

Keywords: LCA, transport, milk, collection round trip

1. Introduction

In Europe, food and drink products are responsible for 20-30 % of the environmental impacts of private consumption (Tukker et al., 2006). Although transport occurs between each step of supply chains, it often has an insignificant influence on the total environmental impact of agricultural products, especially of animal products such as milk. Bystricky et al. (2014) conclude after analyzing five different agricultural products (plant and animal products) from different provenance that the part of the total environmental impact of transportation is larger for products with small environmental impact per unit such as potatoes. Foster et al. (2006) give a value of 0.0068 kg CO_2 for direct emissions per kilogram milk transported, which corresponds to 0.66 % of the total greenhouse gas (GHG) emissions from milk at farm gate. Due to this negligible role of transports on the total environmental impact of food products, transports are often modelled with average parameters in LCA. For example, Pattara et al. (2012) calculated the environmental impact of wine transportation using averaged values. Further examples can be found in the publications of González-Garcia et al. (2013), Heller et al. 2008 and Browne et al. (2005). In all those studies, transports were considered based on average transport distances between point of collection and point of delivery and average life cycle inventories. Average life cycle inventories for transport, such as those in ecoinvent, are based on average load and empty trip factors. In the case of ecoinvent, the load factor including empty trips for lorry transports used is 50 % (Spielmann et al. 2007). However, the variability between single transport services is very high, thus such average factors might not be representative. In the case of line haul transports for example, load factors can be as high as 100 % with no empty trips. In this situation a fully loaded truck will only drive the distance once to transport its products, in a situation where the truck would have been only half loaded, it would have to drive the distance twice to transport the same amount. Considering a higher fuel consumption of fully loaded trucks of approx. 21 %, which is the difference in fuel consumption of the two processes "operation, lorry 20-28t, fleet average" and "operation, lorry 20-28t, full, fleet average" (both from Spielmann et al. 2007), total fuel consumption for a transport in a fully loaded truck would still be about 40 % lower compared to a transport in a half loaded truck. Thus, using average emission factors for line haul transports would lead to an overestimation of the environmental impact. On the other hand, for transports with lower load and higher empty trip factors, averaged data would lead to an underestimation. This might be the case for transports organized as collection or delivery round trips, which are distinguished from common transport services by the European standard EN16258:2012 – "Methodology for calculation and declaration of energy consumption and GHG emissions of transport services (freight and passengers)".

An agricultural product that is typically transported in collection round trips is milk. The goal of this study is to find out whether there is a significant difference between a detailed LCA of the collection round trip and a simplified approach using average transport inventories and average direct distances from the points of collection to the point of delivery.

2. Methods

Two different LCA approaches for the quantification of the environmental impact of a milk collection round trip in Switzerland are compared. One approach is a simplified approach, where standard life cycle inventories for the relevant truck type and average distances between farms and dairy processing plants were used. The second approach is more detailed, as the effectively driven distance and specific fuel consumption are considered following the recommendations for collection round trips of the European standard EN16258:2012 (CEN, 2012). The calculations are performed on one exemplary milk collection round trip in the canton of Thurgau in Switzerland. A carrier specialized in milk transports provided the primary data, background data were taken from the ecoinvent V2.2 database (ecoinvent, 2010).

2.1. Functional unit and system boundaries

The functional unit is the delivery of one kilogram milk. The system boundaries comprise all transport related life cycle phases such as direct emissions, fuel production, vehicle manufacturing, maintenance and disposal, and road infrastructure. The milk production, processing, trade and consumption are excluded in this study (Figure 1). The time boundary is the year 2013.

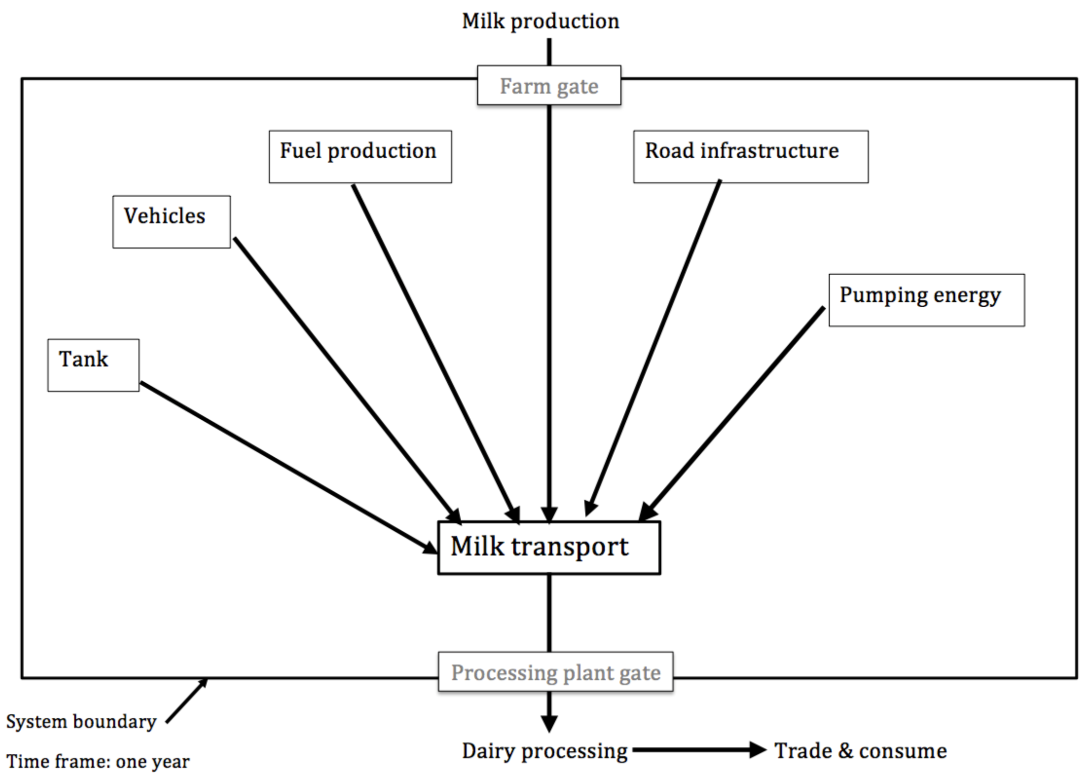

Figure 1. Initial system boundaries definition.

2.2. Impact categories

The European standard EN16258:2012 (CEN 2012) is a guideline for the calculation of GHG emissions and energy consumption of transport services. Therefore we decided to use those two impact categories for our study, assessing the global warming potential (GWP) as well as the non-renewable energy demand (NRED) (fossil and nuclear energy). These two categories are thought to be the most important categories for environmental impact quantification of transport services since they are directly influenced by the fuel combustion process and production, respectively. In order to complete the picture, we decided to integrate the impact category human toxicity (HT), as it was the impact category contributing the third-most to the aggregated environmental impact when using the impact assessment method ReCiPe 2008 (H) with normalization for Europe. Table 1 shows the considered impact categories and the applied methods.

Table 1. Impact categories and corresponding impacts assessment method and impact factor's unit.

Impact category	Impacts assessment method	Impact factor's unit
Non-renewable energy demand (NRED)	According to ecoinvent; Frischknecht et al. 1998	MJ eq
Global warming potential (GWP)	IPCC 2007, 100a	kg CO_2e
Human toxicity (HT)	USES-LCA 2.0	kg 1,4-DB eq

2.3. Data collection

2.3.1. Selection of the round trip

A milk collection round trip in the canton of Thurgau in the northeast of Switzerland was selected. As only one round trip is analyzed, and the variability of milk collection round trips are probably high, results for this route are not expected to be representative. However, it will allow us to highlight some trends in the environmental impact calculations of transport.

The analyzed round trip is done by truck and runs every second day of the year. It collects milk from 21 farms and is approximately 80 km long. The driven distance includes empty runs. At the farms, a pump powered by the truck's engine pumps the milk into the truck's tank which means that the truck engine never stops running during the whole collection round trip (oral communication).

2.3.2. Data sources

The carrier provided primary data for the round trip, truck type and fuel consumption. The tank vendor provided data for the tank. All data was collected for the calendar year 2013. The provided fuel consumption data was not measured, but estimated by the carrier. They were 30 % higher compared to the average fuel consumption of the same truck type from the corresponding ecoinvent process, which can be explained by the extra diesel consumption for the pumps, and therefore we considered them as plausible. Data for road and vehicle infrastructure were based on ecoinvent v2.2 and literature. Demand factors were calculated following the same procedure as in ecoinvent (Spielmann and Scholz, 2005).

2.3.2. The two modelling approaches

The simplified approach is calculated with the ecoinvent transport process "transport, lorry 20-28t, fleet average", a truck type comparable to the one used for the studied transport service. This process includes all the above mentioned transport related life cycle phases for transports with average load factors. The functional unit of this process is a ton kilometer. The ton kilometers needed for the delivery of one kilogram milk are calculated taking the average of the distances from each farm on the collection round trip to the processing plant.

The detailed approach is based on the same ecoinvent process, with some adaptations to reflect the real situation in a better way. First, instead of using ton kilometers, the process "transport, lorry 20-28t, fleet average" is converted from ton kilometers to vehicle kilometers, which allowed us to consider the whole collection round trip, starting and ending at the parking place of the truck according to the definition of vehicle operation systems (VOS) in the European standard EN16258:2012 (CEN 2012). The truck manufacturing, maintenance and disposal is changed according to the effective vehicle weight and complemented with the tank. For the operation of the truck, fuel consumption on the round trip is adapted, so that it includes the required energy for the pumping of the milk into the tank at the farms and collecting sites. Afterwards the total emissions of this trip are divided by the amount of milk delivered per trip, resulting in emissions for the delivery of one kilogram milk.

3. Results

Transport life cycle was divided into eleven phases for the detailed approach: 1) truck manufacturing; 2) truck maintenance; 3) road operation, maintenance; 4) road construction; 5) truck tank; 6) trailer tank; 7) truck operation; 8) truck disposal; 9) road disposal; 10) truck tank disposal; 11) trailer tank disposal. The results are shown in Figure 2.

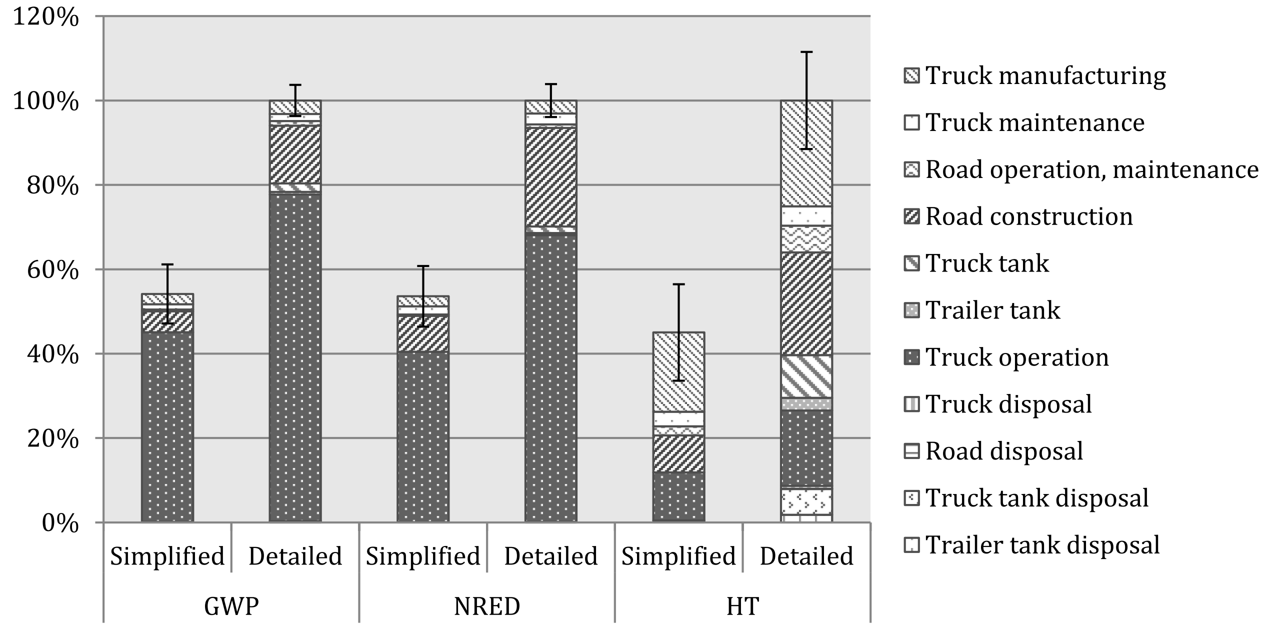

Figure 2. Comparison of the simplified and detailed approaches for the impact categories GWP, NRED and HT.

For the categories global warming potential (GWP) and non-renewable energy demand (NRED), the impacts of the simplified approach are approx. 50 % lower than those of the detailed approach and for the category human toxicity (HT) approx. 55 % lower.

In our detailed approach, the total GWP is 0.00517 kg CO_2e / kg delivered milk. The truck operation contributes 77 %, due to the direct emissions of the fuel combustion and from the fuel production linked emissions. The rest of the CO_2e emissions are caused mainly by the road construction which contributes 14 % to the GWP.

Total NRED in the detailed approach is 0.08170 MJ eq / kg delivered milk. Like for GWP, the truck operation contributes the most with 68 % of total NRED. This apparent correlation between the category GWP and NRED arises from the fuel consumption. NRED impact is determined by the fossil energy use. The impact on GWP is determined mainly by the combustion of the fuel for transportation.

For HT, the transport cause 0.00068 kg 1,4-DB eq / kg delivered milk. This impact is, compared to GWP and NRED, caused by other sources: 25 % of the total impact is caused by truck manufacturing and further 24 % by road construction. During the manufacturing of the truck reinforcing steel dust is generated and needs to be disposed. The impact on HT of the road construction arises from the bitumen which is produced with crude oil. During the crude oil extraction, formation water needs to be drained. Further, two other phases influence this impact category: truck tank (10 %) and truck operation (18 %). Same as for the road construction, the impact of the truck operation arises from the fuel production which requires crude oil extraction. Moreover, the impact on HT of the truck tank is due mainly to the chrome steel production which requires the burning of bituminous coal as energy source. This source of energy emits a lot of particles to the air (mining and burning) and, in addition, ashes emerge which need to be disposed in a residue landfill.

4. Discussion

4.1. Most important sources for environmental impacts of transports

Considering the main contributors to transport emissions, the results of this study are in line with the results of other LCA studies on transportation. The main cause for environmental impacts of transport arises from the fuel production and combustion for the impact categories GWP and NRED. These results correspond to the findings of Spielmann and Scholz (2005), who affirm that the operation component has the largest environmental impact of transport services. Eriksson et al. (1996) also determined the fuel combustion as having the largest impact followed by the fuel production.

For HT, Spielmann and Scholz (2005) found that the particulate matter 2.5 (PM2.5) and non-methane hydrocarbons (NMHC) emissions are influenced mainly by the transport infrastructure. PM2.5 can arise to some extent from the bituminous coal extraction and burning (WHO 1986). In our studied transport, the main causes for HT are also related to transport infrastructure, such as roads and vehicles.

4.2. Putting it into the larger context – the impact of transport in relation to the whole life cycle of products

According to the results of Browne et al. (2005), who reviewed different studies concerning supply chain LCA, the proportion of energy accounted for by commercial freight transport varies in many cases from 2 to 9 %. In a study on the carbon footprint of milk in Switzerland, Alig et al. (2011) calculate an impact of 5 MJ eq per kilogram milk at farm gate. The value for the category NRED obtained in the present work for milk collection transportation represents 1.6 % of this value. For the whole life cycle of milk, the importance of the energy consumption of milk collection will be even lower, proving that the transport life cycle phase is almost not relevant for animal products. This was also observed by Bystricky et al. (2014).

For GWP, Alig et al. (2011) found emissions of 1.3 to 1.4 kg CO_2e per kilogram milk at farm gate, thus our 0.00517 kg CO_2e per kilogram delivered milk only result in 0.4 % of this impact, which is a very small share. Our transport related values for GWP per kg of delivered milk are slightly lower than found in other studies. Foster et al. (2006) give a value of 0.0068 kg CO_2 for direct emissions per kilogram milk transported. Since the procedure and assumptions for the modeling of transportation are not documented in the study of Foster et al. (2006), it is difficult to assess the differences in results. One explanation could be that the study of Foster et al. (2006) was conducted in Great Britain and that the transport infrastructure and distances differ there from the ones in Switzerland. In our analyzed collection tour, all farms situated within a small perimeter from the processing plant. Another difference could arise from the used transport inventories and emission factors.

Like other studies already pointed out (Eide 2002; Flysjö et al. 2011; Foster et al. 2006; IDF 2009), the transportation impact on GWP and on NRED in the milk production life cycle is very low. The farming phase is much more important with about 75 to 95 % of the total environmental impact of milk production (Berlin 2002; Flysjö et al. 2011; Foster et al. 2006; IDF 2009).

4.3. Why does transport still matter?

Most literature studies use average direct distances for the modeling of transport in their calculations. For example, Pattara et al. (2012) calculated the environmental impact of wine transportation based on “the number of bottles delivered, average distance travelled from the firm to the final market, type of vehicle used and its loading capacity”. Further examples are to be found in the publications of González-Garcia et al. (2013), Heller et al. (2008) and Browne et al. (2005) as average transport distances, average datasets and distance between the point of collection and delivery are considered respectively. However, if transports are organized as collection round trips, using average direct distances from the collecting points to delivery point and average emission factors might lead to an underestimation of transport’s impact. If such a transport is modelled with the effective driven distance, the environmental impacts on the categories GWP, NRED and HT are significantly higher, in our case by a factor of two. Even if in the case of milk transports are still rather insignificant, for products, where transports do matter, such as some plant products and products that are transported over long distances, it might be worth to have a closer look at transport processes. Average transport processes are what they are – just average. Real transport impacts could be both, much higher or lower.

5. Conclusion

In the supply chain of agricultural goods, transportation occurs many times and in different ways. In the present study, transportation of milk from farm to processing plant has been studied on a typical collection round trip in Switzerland. It could be shown that there is a significant difference in the results on transportation environmental impact between a simplified approach based on average distances and standard emission factors and a detailed approach based on the effective driven distance and specific emission factors. In all three analyzed impact categories GWP, NRED and HT, the simplified approach resulted in approximation half as much impact compared to the detailed approach. These differences arise mainly from the fact that the effectively driven distance of round trips are higher, leading to more use of road infrastructure and higher fuel quantity. At the moment, most LCA studies on agricultural goods including transportation in their scope do mostly calculate transportation with data based on average direct distances from collection to delivery points and use standard emission factors. Depending on how those transports are organized, this might lead to an under- or overestimation of transport's impact, as effectively driven distances or vehicle load factors might differ from those of average transports. In our example of milk transport, the impact of transport compared to the one of milk production itself was rather small, and even a doubling of transport's impact did not make it a major contributor to the impact of the whole milk life cycle. However, in cases where goods are transported over longer distances or for plant products that often have a lower environmental impact than animal products, we recommend to have a closer look at how transportation is calculated.

ABSTRACT

Soil, climate and management practices make greenhouse gas (GHG) emission estimates associated with crop production highly uncertain. Biophysical modelling provides reliable reactive nitrogen (Nr) estimates for environmental assessment. In this paper LCA and ecosystem modelling are combined to improve GHG estimation from cropping systems in the Paris (France) area, and to compare environmental impacts of two cropping systems at regional level. A cropping system aimed at productivity with high environmental performance (PHEP), while the other one aimed to reduce (GHG) emissions by half (50%GHG). Model-derived GHG estimates for crop production were at least 7% lower than estimates from the standard methodology applied to LCA, emphasizing the importance of regional factors in agricultural LCAs. The 50%GHG cropping system appears promising (184% reduction in the life-cycle GHG emissions) for climate mitigation of arable crops, pending trade-offs with other impact categories.

Keywords: LCA, GHG, regional level, CERES-EGC model, cropping systems.

1. Introduction

Modern agriculture contributes a large share of the anthropogenic emission of greenhouse gases (GHGs), in particular in the form of nitrous oxide (N_2O), a potent GHG driven by the application of fertilizer nitrogen (N) inputs (Saggar 2010). Agriculture can be a sink for CO_2 through soil C sequestration, by fixing carbon from the atmosphere and storing it on the short term with residues and soil organic matter (Brady and Weil 2002). Life-cycle assessment provides a relevant means of balancing these effects to estimate the carbon footprint of agriculture, and exploring mitigation strategies. However it has to date mostly been applied on a crop-specific basis (Brentrup et al. 2004a; Charles et al. 2006; JRC et al. 2007), whereas environmental impacts are better assessed with a cropping systems approach taking into account the interactions between successive crops and their environment (Goglio et al. 2014; Goglio et al. 2012). Also, most of the previous work on the LCA of crops involved short-term durations (one to a few years), too short to capture variations of soil organic carbon (SOC) stocks, and relied on simple models to estimate N_2O emissions (Brentrup et al. 2004b; MacWilliam et al. 2014; Nemecek et al. 2011a; Nemecek et al. 2011b). Since soil carbon and nitrogen (N) dynamics are highly influenced by farm management such as tillage, fertilizer application, residues management and their interaction with soil and climate (Brady and Weil 2002), local conditions should be considered to improve the estimation of GHG emissions. Direct measurements, especially for N_2O and NO, are often costly and time consuming, while the IPCC methodology, commonly used for N_2O estimations, does not account for local conditions. Agroecosystem models on the other hand are sensitive to these factors but require large amount of data (Gabrielle and Gagnaire 2008).

Despite this advantage in principle, only a few studies have integrated LCA with agroecosystem modelling to estimate GHG and other impacts during long term cultivation (Adler et al. 2007; Gabrielle and Gagnaire 2008; Goglio et al. 2014; JRC et al. 2007). However, all these studies were based outside Europe or involved a limited set of crops; for example, JRC et al. (2007) evaluated only biofuels crops for one year. Thus, the aim of the present work is to evaluate field emissions of CO_2 and reactive N (Nr) from contrasted cropping systems using the agro-ecosystem model CERES-EGC for the Ile de France region. The cropping systems were specifically designed with an *ex ante* evaluation to estimate the possible reduction in soil borne emissions using specific crop management. CERES-EGC model was run to simulate Nr emissions (as N_2O, NO, NH_3 and nitrate), along with soil C variations for 20 years. These fluxes were included in a cradle-to-farm-gate LCA of the biomass produced by the two cropping systems.

2. Methods

2.1. Cropping systems

The two cropping systems assessed over the Ile the France region were established in the ICC (Innovative cropping systems with constraints) trial in Grignon (40 km west of Paris) on a silty loam soil with the following aims: (1) to attain altogether High Environmental Performances and Productivity for the reference system (PHEP), and (2) to reduce by half the GHG emissions from the 50%GHG system compared to the PHEP system, while achieving the same environmental criteria (other than GHG emissions) as the PHEP system (Colnenne David et al. 2011).

The PHEP cropping system involved the following crop rotation: faba bean (*Vicia faba* var *minor* (Harz) Beck), winter wheat (*Triticum aestivum* L.), rapeseed (*Brassica napus* L.), winter wheat (*Triticum aestivum* L.), white mustard (*Sinapis arvensis* L.) or black mustard *(Brassica nigra* L.) as catch crop and spring barley (*Hordeum vulgare* L.). Main crop management characteristics of the PHEP system are given in Table 1.

Table 1. Selected characteristics of crop management for the cropping systems analysed on the Ile the France region (PHEP, 50%GHG), crop yields recorded during the 2009-2012 seasons.

System	Crop	Tillage	N fertiliser application[a] (kg ha^{-1})	Yield (Mg of dry grain ha^{-1})
50% GHG	**Spring Faba bean**	No tillage		0.63
	Rapeseed	No tillage	N 10	3.66
	Winter wheat	No tillage	N 70+43	7.52
	Winter Barley	No tillage	N 70+49	5.64
	Maize	No tillage	N 60+45	8.12
	Triticale	No tillage	N 72	6.48
PHEP	**Winter Faba bean**	Minimum tillage		1.37
	Winter wheat	Minimum tillage	N 50+37	7.34
	Rapeseed	Minimum tillage	N 50+60	3.74
	Winter wheat	Minimum tillage	N 70+58	7.34
	Spring Barley	Ploughing	N 65	5.70

[a]granular ammonium nitrate with no retarders

The 50%GHG cropping system maximizes the accumulation of soil organic carbon with the use of high biomass yielding cereals and by increasing the rate of crop residue return to soils. This is achieved with no tillage. Nitrous oxide emissions are mitigated by reducing mineral nitrogen fertilizer inputs with the introduction of legumes both as main crops in the rotation and as cover crops. Cover crops were also introduced to decrease the accumulation of soil nitrate and the subsequent emissions of N_2O from nitrate denitrification. Rapeseed was introduced to reduce nitrate leaching and the ensuing emissions of N_2O. The rotation is: (cover crop) faba bean, rapeseed, (cover crop) winter wheat, (cover crop) winter barley, (cover crop) maize (*Zea mays* L.), triticale (*XTriticosecale* (Camus) Wittm.). Main crop management details are given in Table 1 (Colnenne David et al. 2011).

2.2. Regional modelling

Crop yields, soil C dynamics and emissions of reactive N (Nr), including N_2O in particular were simulated with the agro-ecosystem model CERES-EGC over the Ile de France region, following the methodology of Gabrielle et al. (2014). The region is a 150 km x 150 km square area surrounding Paris, with 55% cropland. A GIS database was constructed with available geo-referenced data on this region, including administrative borders, land-cover type, crop management practices, soil properties and climate. The corresponding layers of spatial information were mostly in vector format, and overlaid to delineate elementary spatial units representing unique combinations of soil types, weather data, and agricultural management. These units were subsequently used in the CERES-EGC simulations at the field-scale, in a bottom-up approach to map the emissions. We used weather data predicted for the 2010-2030 time slice by the DRIAS project in France (Lémond et al. 2011), using the IPSL-CM4 model with the A1B GHG emission scenario from IPCC, which appeared as an intermediate scenario for air temperature and rainfall among the range of models and forcings tested by this project. Compared to the 1961-1990 period, air temperature would rise by 1.35 °C, with an average of 11.7 °C for the 2010-2031 time slice, and rainfall would remain constant at an average of 641 mm yr^{-1}. CERES-EGC was run for the current land-use (2010).

2.3. Life-cycle assessment

LCA was performed following a cradle to farm gate approach (Goglio et al. 2014; Goglio et al. 2012), considering grains as final products. System boundaries encompassed all agricultural inputs and farm machinery production from raw material extraction to transport to farm (Brentrup et al. 2004b). LCA was carried out using one ha of land and one GJ of grain energy output as functional units, according to previous research (Nemecek et al. 2011a; Nemecek et al. 2011b).

The impact categories evaluated were cumulative energy demand, global warming potential (GWP) with a 100 year horizon, acidification potential, and eutrophication potential, using the CML 2001 method integrated in SimaPro 7.3 (2012) (Guinée et al. 2001; Nemecek et al. 2011a; Nemecek et al. 2011b; SimaPro 7.3 2012). Toxicity impacts were evaluated with the EDIP 2003 method available in SIMAPRO 7.3 (Nemecek et al. 2011a; Nemecek et al. 2011b; SimaPro 7.3 2012), involving the following categories: human ecotoxicity for water, soil and air; chronic ecotoxicity for soil and water; acute ecotoxicity for water. The 5% and 95% percentiles of the modelled field emissions were used to evaluate the effect of spatial and temporal variability of emissions on LCA indicators. This procedure was adopted for all the reactive N species considered in this study (i.e. nitrous oxide, nitric oxide (NO), ammonia (NH_3) volatilisation and nitrate (NO_3^-) leaching) and also for soil CO_2 exchanges.

Within the system boundaries, farm transport from the field to the farm centre was the only post-harvest process considered. During cultivation, transport of farm machinery from the farm centre to the field and its return journey was also accounted for (Brentrup et al. 2004b; Gasol et al. 2012). No drying process, except hay drying was included in the present system according to local conditions, since all the grain is directly sold to the wholesale company at field moisture.

The life cycle elaboration was carried out with the SIMAPRO software with different data sources: *ex ante* evaluation data from the ICC trials, databases integrated in the SIMAPRO software (SimaPro 7.3 2012), data taken from literature (Audsley et al. 1997; Brentrup et al. 2004a; Brentrup et al. 2004b), CERES-EGC model results for soil GHG emissions in agreement with the ISO standards 14040 and 14044 (ISO 2006a; ISO 2006b) (Table 2).

Table 2. Main data sources for different processes included in the analysis of crop management for the cropping systems analysed in the Ile the France region (PHEP, 50%GHG)

Upstream processes for agriculture	**Technical operation during cultivation**	**Fuel and material consumption for each field operation**	**Soil GHG emissions and reactive N species**	**Pesticide fate emission**	**Transport processes**
Elaborated using databases integrated in SIMAPRO together with data taken from literature (Audsley et al. 1997; Brentrup et al. 2004b; SimaPro 7.3 2012)	*Ex ante* evaluation of the ICC trial	Elaborated on the basis of the tractor power (ASABE 2003; Audsley et al. 1997; Brentrup et al. 2004b; Peruzzi and Sartori 1997)	Modelled with CERES-EGC	Elaborated according to Audsley et al. (1997)	databases integrated in SIMAPRO (SimaPro 7.3 2012)

Crop management differences among the cropping systems are described in Table 1. It was assumed that farm transport of fertilisers and pesticides involved a 80.9 kW tractor either with a fertiliser spreader or pesticide

sprayer. All seeds for sowing were transported to the field within the seed drill with a 95.6 kW tractor. The same machinery is subsequently utilised to sow the various crops present in the rotation.
Harrowing in the PHEP system and mulching in the 50%GHG system was assumed to be carried out with a 80.9 kW tractor, together with pesticide treatments; while ploughing in PHEP was done with a 118 kW tractor. Cultivator pass in PHEP and roller pass in both systems were performed with the 95.6 kW tractor. Finally, a 180 kW combined harvester was assumed to be used for grain harvest together with a 10 Mg maximum load trailer and a 80.9 kW tractor.

Regarding fertilizer production, all data needed to account for raw material extraction, fertiliser manufacture and transport from raw material extraction sites to local storehouse were accounted with SimaPro 7.3 (2012). Fate factors for P and K fertilizers into the various environmental compartments were taken from Audsley et al. (1997) (Table 2).

The crop management of the two cropping systems analysed made use of several different pesticides: herbicides, molluscicides, insecticides and fungicides. Due to the high heterogeneity of pesticides and herbicides used, a common procedure was utilised to estimate the emissions to the air, water, and soil compartments, on the basis of the amount and type of active ingredient, which was also used to evaluate upstream impacts (Audsley et al. 1997; Brentrup et al. 2004a) (Table 2); while pesticide transport impact was computed on a total weight basis (Goglio et al. 2012).

3. Results

3.1. Simulation of field emissions

The emissions of reactive N (as N_2O, NH_3, NO and NO_3) simulated by the ecosystem model over Ile de France are given in Table 3, along with the annual change of soil organic C (SOC) for the two cropping systems due to soil mineralization. As expected, the 50%GHG system achieved higher C sequestration rates than the reference system (PHEP), with a 6-fold relative difference due to higher returns of crop residues to the soil. Surprisingly, N_2O emissions were 20.6% higher for the 50%GHG system in comparison with the PHEP system. NO emissions followed a similar pattern, being controlled by the same soil processes as N_2O.

Table 3. Simulated emissions of reactive N and soil C change for the two cropping systems over the Ile de France region. Data correspond to the spatially-weighted average over the 18 (50%GHG system) to 20-year (PHPE) simulation periods, with the 5-95% percentiles given in brackets.

Cropping system	**Emissions of reactive N (kg N ha^{-1} yr^{-1})**				**Soil organic C change (kg C ha^{-1} yr^{-1})**
	N_2O (direct)	NO	NH_3	Nitrate	
PHPE	0.29 (0.05 – 0.94)	0.44 (0.34 – 0.51)	0.43 (-0.11 – 1.40)	14.6 (4.17 – 42.34)	-140 (-540 – 95)
50%GHG	0.35 (0.05 – 0.98)	0.50 (0.15 – 0.62)	0.34 (-0.09 – 1.19)	13.0 (3.15 – 33.5)	1000 (210 – 1460)
Relative difference (50%GHG – PHPE)/PHPE	+20.6%	-13.7%	-20.7%	-11%	+ 610%

Conversely, the 50%GHG system presented 10 to 20% lower ammonia and nitrate losses than PHEP on average, due to the systematic presence of catch crops over the winter, which limited the build-up of nitrate and ammonium near the soil surface. Over the entire region and the 680 spatial simulation units (representing different combinations of soil properties and climate data series), Nr fluxes per hectare had large variability around their spatial means (Table 2), as their percentiles values showed. Except for the C variation rates, the distribution of the 5% percentiles and 95% percentiles largely overlapped between the two systems, implying that their differences were not significant.

3.2. LCA results

The 50%GHG system was successful in reducing some of the impacts analysed compared to the reference PHEP system. It abated GWP by 184%, air human toxicity by more than 2% and water chronic ecotoxicity by more than 3% (Table 4). Its GWP was actually negative, with a regional average of -2 Mg of CO_2 eq ha^{-1} and -22.5 kg of CO_2 eq GJ^{-1} of grain energy thank to soil CO_2 uptake (Tables 3 & 4). The minimum change in GWP among treatments was 6.66% corresponding to the difference between GWP of the 95% percentile of the 50%GHG system and the GWP of the 5% percentile for the PHEP system. However the 50%GHG system had 16% higher water chronic ecotoxicity and 7% larger water human toxicity and water acute ecotoxicity than PHEP system with both functional units (Table 4). For the other impact categories, differences were limited (1-2%) (Table 4).

Table 4. LCA results for the two cropping systems (50%GHG and PHEP) across the Ile de France region. Data correspond to the mean value for each impact category with the impact results estimated from the 5% and 95% percentiles of reactive N species and CO_2 emissions in brackets

		50%GHG	**PHEP**		**50%GHG**	**PHEP**
Impact category	**Category unit**	**(ha^{-1})**	**(ha^{-1})**	**Category unit**	**(GJ^{-1})**	**(GJ^{-1})**
Cumulative energy demand	GJ eq[a]	28.1 (28.1-28.1)	28.5 (28.5-28.5)	MJ eq[b]	317 (317-317)	322 (322-322)
Global warming 100a	Mg CO_2 eq	-1.99 (-3.86-1.27)	2.38 (1.36-4.25)	kg CO_2 eq	-22.5 (-43.5-14.3)	26.9 (15.4-48.1)
Acidification	kg SO_2 eq	16.5 (15.9-16.6)	16.2 (16.0-16.3)	g SO_2 eq	185 (179-188)	183 (181-185)
Eutrophication	kg PO_4^{-3} eq	21.4 (16.8-30.5)	21.6 (17.0-33.9)	kg PO_4^{-3} eq	0.241 (0.190-0.344)	0.245 (0.192-0.384)
Air human toxicity	m^3	2.43E7 (2.42E7-2.44E7)	2.48E7 (2.47E7-2.49E7)	m^3	2.74E5 (2.73E5-2.75E5	2.81E5 (2.80E5-2.82E5)
Water human toxicity	m^3	1.21E5 (1.21E5-1.21E5)	1.12E5 (1.12E5-1.12E5)	m^3	1.37E3 (1.37E3-1.37E3)	1.27E3 (1.27E3-1.27E3)
Soil human toxicity	m^3	258 (258-258)	251 (251-251)	m^3	2.91 (2.91-2.91)	2.84 (2.84-2.84)
Water chronic ecotoxicity	m^3	5.27E6 (5.27E6-5.27E6)	4.42E6 (4.42E6-4.42E6)	m^3	5.94E4 (5.94E4-5.94E4)	5.00E4 (5.00E4-5.00E4)
Water acute ecotoxicity	m^3	2.03E5 (2.03E5-2.03E5)	1.89E5 (1.89E5-1.89E5)	m^3	2.29E3 (2.29E3-2.29E3)	2.14E3 (2.14E3-2.14E3)
Soil chronic ecotoxicity	m^3	1.20E6 (1.20E6-1.20E6)	1.23E6 (1.23E6-1.23E6)	m^3	1.35E4 (1.35E4-1.35E4)	1.39E4 (1.39E4-1.39E4)

[a] 1GJ eq corresponds to 1 GJ of energy from difference sources
[b] 1MJ eq corresponds to 1 MJ of energy from difference sources

In terms of variability only for cumulative energy demand, GWP, and toxicity impacts, the impact distributions could be considered different (Table 3). For the other impact categories impact differences were not significant despite having different means because their impact distribution overlaps. Table 4 shows that some impacts are not affected by variability in reactive N species and CO_2 emissions including cumulative energy demand and all the toxicity impacts except water human toxicity.

4. Discussion

4.1. Field emissions

Regional modelling was mostly aimed at generalizing results obtained at the local scale in the Grignon trial to a larger area; an administrative region featuring about 1 Mha of cropland on which the two cropping systems could be applied. A major limitation in this exercise was that the spatial and inter-annual variability of management practices were ignored since all cropping operations occurred at fixed dates from one experimental site and a few years, regardless of the climatic conditions of the year and the soil types. In practice cropping operations depend strongly on soil conditions, weather and field conditions so that this assumption is quite questionable. Thus, these simulations can only convey a sense of the spatial and temporal variability associated with the diversity of soil and climate combinations occurring within a large region (through the means and percentiles in the emission fluxes), and their impacts on the performance of cropping systems. The implementation of decision rules (e.g. a balance-sheet method for N inputs in spring) would also be an interesting avenue to improve on this point (Bergez et al. 2010).

Modelled yields for the field trial in Grignon were within 5% of the observed values during the 2009-2012 seasons, thanks to the calibration of parameters related to crop phenology and dry matter partitioning. Regional means with the model were slightly lower than the yields obtained in the Grignon trial (e.g. 15% lower for winter wheat), but this could be expected since the soil in Grignon is a deep loam with a relatively high yield potential. In a previous modelling exercise in the same region (Ile de France), Gabrielle et al. (2014) found that simulated yields compared well with yield records for the 2000-2010 time period for winter wheat, but noted a possible over-estimation bias for rapeseed. Some of the crops present in the cropping systems tested here are relatively uncommon (e.g. faba beans), and have seldom been attempted with crop models. Little information was available in the literature to parameterize the CERES-EGC model for these crops, and their simulation therefore carried a high degree of uncertainty.

Simulated emissions of Nr were relatively small compared to estimates based on emission factors such as the Tier 1 methodology from IPCC guidelines for N_2O (De Klein et al. 2006). Given the average N application rates (around 100 kg N ha^{-1} yr^{-1}), the latter would have yielded about 1 kg N_2O-N ha^{-1} yr^{-1}, compared to the 0.05–1.00 kg N_2O-N ha^{-1} yr^{-1} obtained here. Such trend was already noted and discussed by Gabrielle et al. (2014) observing that a top-down study based on atmospheric inversion showed that emission factors were lower in the context of France for N_2O than the Tier 1 default values. Regarding the other gaseous emissions (NH_3 and NO), emissions were also in the lower end of values reported for cropland. Conversely, the rate of C sequestration simulated for the 50%GHG system is in the higher range of literature values. For instance, a recent review on C sequestration rates cited a maximum figure of 1 Mg C ha^{-1} yr^{-1} for set-aside (as a cropland management option) in cool-moist climates such as Ile de France (Smith et al. 2008). On the other hand, the slight C loss rate predicted for the reference system (PHEP) is consistent with values recorded after 10 years in a nearby arable plot under minimum tillage (Loubet et al. 2011).

4.2. Differences in LCA results across systems

Compared to PHEP, the 50%GHG system reduced GWP by 184% across Ile de France, with both functional units (hectare and GJ of harvested biomass). The original 50% target assigned to 50%GHG was then largely achieved. Even considering the worst-case scenario for this system (the 95% percentile) and the best case for the PHEP system (the 5% percentile), the abatement still amounted to 6.66%. This difference in GWP among cropping systems was mostly due to soil C changes. The slight increase in N_2O emissions with the 50%GHG system was largely offset by the decrease in CO_2 emissions (Brady and Weil 2002; Six et al. 2004). Negative GWP values (as obtained with the 50%GHG system) were observed in previous work in relation to tillage, with an effect on SOC dynamics. For instance, Six et al. (2004) evaluated a negative GWP in humid conditions of up to 2.07 Mg of CO_2 eq ha^{-1}, which is in agreement with the findings of this study. However the large range of the 5% and 95% percentile GWP values for both systems confirmed the high variability highlighted by Six et al. (2004). The GWP range for the PHEP cropping system was comparable with figures obtained by Kim et al. (2009) for continuous maize in the US, who estimated reactive N species and carbon storage with the DAYCENT model and integrated its results in a LCA. They reported GWP ranges of 17.3-56.1 kg of CO_2 eq GJ^{-1} and 1.87-5.19 kg of CO_2 eq ha^{-1}, respectively. However, the latter applied to only one crop whereas the systems evaluated here included 4 to 6 different crops, and to a different agro-ecological zone.

Most of the agricultural LCAs found in the literature rely on IPCC emission factors and simple models to evaluate reactive N fluxes, and disregard soil C dynamics (Brentrup et al. 2004b; Charles et al. 2006; Goglio et al. 2012; Nemecek et al. 2011a; Nemecek et al. 2011b; Pelletier et al. 2008). Despite these differences with the methodology proposed here, some of these studies were comparable with the data elaborated here for the PHEP system. For instance, Brentrup et al. (2004b) reported GWP ranges of 8.2-26.5 kg of CO_2 eq GJ^{-1} and 0.29-4.10 Mg CO_2 eq ha^{-1} for wheat using different fertilizer rates. For the same crop in Switzerland, Charles et al. (2006) reported GWP values of 2.42 Mg of CO_2 eq ha^{-1} and 22.4 kg of CO_2 eq GJ^{-1}. The PHEP system had slightly lower GWP values than those reported by Nemecek et al. (2011b), for Swiss intensive and extensive cropping systems involving grain cereals (with a range of 2.89-5.03 Mg of CO_2 eq ha^{-1}). Notwithstanding, the GWP of the

PHEP system was more in line with the integrated and organic management of cropping systems with grain cereals (with a 2.15-5.03 Mg of CO_2 eq ha^{-1} range), estimated by Nemecek et al. (2011a).

There were less pronounced variations across the two cropping systems for the other impact categories, except for chronic and acute water ecotoxicity and human toxicity to water (with more than 7% difference). The two systems had similar energy consumption, both on ha basis and GJ basis. This was due to two compensating factors: the substitution of most mechanical weeding and tillage in the PHEP system with frequent pesticide treatments in the 50%GHG system for crop protection, and a limited difference in fertilizer application rates. The latter are known to largely affect energy consumption of agricultural products (Brentrup et al. 2004b; Charles et al. 2006; Goglio et al. 2012).

The energy demand for both systems was slightly greater than reported by Kim et al. (2009) for maize cultivation with and without tillage in a series of locations in the Corn belt (with ranges of 14.2-27.2 GJ ha^{-1} and 143-224 MJ GJ^{-1}, respectively). Other research evaluated only non-renewable energy demand for intensive and extensive (11-22 GJ ha^{-1}) (Nemecek et al. 2011b) or integrated and organic (10-22 GJ ha^{-1}, Nemecek et al. (2011a)) cropping systems with cereal grains in Swiss conditions and showed at least 21.7% less energy consumption on ha basis than the present assessment.

Acidification potentials presented here were consistent with numbers obtained for maize by Kim et al. (2009) on GJ basis (184-531 g of SO_2 eq GJ^{-1}), but lower than the range the latter reported on a ha basis (22.4-53.0 kg of SO_2 eq ha^{-1}). The same pattern occurred with the estimates of Charles et al. (2006) for wheat in Swiss conditions (with a 17.8 kg of SO_2 eq ha^{-1} value). Conversely, our data were somewhat larger than the range reported by Brentrup et al. (2004b) for wheat cultivation in the UK (3.1-15.9 kg of SO_2 eq ha^{-1}).

The eutrophication potentials calculated here were larger than Kim et al. (2009) (>14.5 kg PO_4^{-3} eq ha^{-1} and >156 g PO_4^{-3} eq GJ^{-1}) for maize cultivation. Using simple models to estimate reactive N species, Charles et al. (2006) reported lower values than eutrophication potentials elaborated here for the two cropping systems (over 3.47 kg PO_4^{-3} eq ha^{-1} and 0.0032 kg PO_4^{-3} eq GJ^{-1}, respectively). However both studies (Charles et al. 2006; Kim et al. 2009), evaluated either maize or wheat while the present cropping systems included also rapeseed, barley, faba beans, triticale and several cover crops. Regarding toxicity impacts, the PHEP system had lower water ecotoxicity (both chronic and acute) and water and soil human toxicity than 50%GHG. These differences might arise from the different types of pesticides used in both systems. Soil chronic ecotoxicity impacts estimated in this research were within range with those estimated with EDIP 97 method in integrated and organic cropping systems (3.7 e4-6.19 e6 m^3 ha^{-1}) (Nemecek et al. 2011a) and for intensive and extensive cropping systems including cereals in Switzerland (0.10-3.23 e6 m^3 ha^{-1}) (Nemecek et al. 2011b). These discrepancies might be due to different climatic conditions, but also to other crops present in the cropping systems evaluated by Nemecek et al. (2011a; 2011b).

5. Conclusion

Compared to the reference system representing current practice (PHEP), the 50%GHG cropping system achieved lower environmental impacts for some impact categories, including GWP (by 184%), on average, whether on a hectare or GJ basis. Using the latter functional unit, which may be deemed more relevant to the primary function of the cropping systems (which is providing biomass for food, feed or energy purposes), the relative differences between the two systems varied between -184% and 16% for the various LCA indicators. This demonstrates the benefits of the 50%GHG system and validates its *ex ante* design, although the large variability around the mean indicators tends to mitigate these benefits at the regional scale.

The present work emphasized the interest of evaluating the performance of agricultural crops at the cropping system level since it is the only relevant scale for most of environmental impacts because of the interactions between crops and the interplay with climate conditions. In terms of time scale, field emissions of Nr and especially of carbon dioxide involve dynamics that are hardly detectable on an annual level. Thus, long field trial evaluation is a key factor to have a better estimation of these dynamics and their interplay with climatic conditions. Indeed, long term trial data allow the evaluation of real crop management in relation to seasonal effects, avoiding a mean crop management independent from climatic seasonality.

The CERES-EGC model proved to be a useful tool to evaluate cropping systems on a time scale relevant to capture the differences gradually occurring between the two crop management options tested here. It gave the possibility of generalizing the results obtained in one location to the surrounding administrative region, taking into account interactions with soil and climate factors. Despite the absence of decision rules to account for management x environment interactions, and the lack of data to test model outputs at this scale, this exercise proved useful to explore routes to the mitigation of environmental impacts of arable crops via a systemic approach.

ABSTRACT

Life cycle assessments require many input parameters and many of these parameters are uncertain; therefore, a sensitivity analysis is an essential part of the final interpretation. The aim of this study is to compare seven sensitivity methods applied to three types of case studies. Two (hypothetical) case studies describing electricity production: one shows linear and another shows non-linear behavior. The third case study describes a large (existing) case study of seafood production containing high input uncertainties. The methods are compared based on their results, i.e. variance decomposition and ranking of the input parameters. Results show that Sobol' sensitivity indices perform the best for all three case studies. The Sobol' method can be a useful method in case of non-linear LCA models or LCA models that include outliers.

Keywords: matrix perturbation, method of elementary effect, key issue analysis, random balance design, Sobol' sensitivity index

1. Introduction

A life cycle assessment (LCA) calculates the environmental impact of a product from cradle to grave. LCAs require many input parameters and many of these parameters are uncertain. A sensitivity analysis, therefore, is an essential part of the final interpretation. This is mentioned in the ISO standards for LCA, but no guidance is given on how to do or how to select an appropriate sensitivity analysis. A sensitive parameter is a parameter of which a change considerably influences the result, or that contributes to the variance of the output. A sensitivity analysis can help identifying parameters that should be known accurately before drawing conclusions, or identifying non-sensitive parameters for which the variance can be fixed in the region of its variance in order to simplify a model, also known as 'factor-fixing' (Saltelli et al. 2008).

Sensitivity analysis in LCA can be performed using a one-at-a-time approach (OAT), meaning that a subset of the input parameters are changed one at a time to see how much influence it has on the results. Although this approach has many advantages, e.g. it is easy to perform and to understand, this type of sensitivity analysis is time-consuming for a large system and might not consistently take all parameters into account and, therefore, could overlook possible sensitive parameters. Sensitivity analyses that consistently analyze the sensitivity of each parameter in the model are usually performed with sampling based approaches, such as Monte Carlo simulation, with an added procedure for variance decomposition.

In general we can differentiate between three types of sensitivity analysis: local sensitivity analysis (e.g. OAT); screening (e.g. method of elementary effect) and variance based sensitivity analysis or global sensitivity analysis (e.g. regression analysis). An overview is given in Table 1. The methods differ in their input requirements (e.g. knowledge about probability distribution function and parameter of dispersion) and type of output: either a ranking and/or variance decomposition of the input parameters.

Table 1. Types of sensitivity methods discussed in this paper.

Type	Method
Local	Matrix perturbation (MP); one-at-a-time approaches (OAT)
Screening	Method of elementary effect (MEE)
Global	Standardized regression coefficients (SRC); key issue analysis (KIA); random balance design (RBD); Sobol' indices (SME and STE)

For most of the sensitivity methods mentioned in Table 1, it is not yet known under which conditions they optimally perform, or if they can outperform the standard practices in LCA (i.e. OAT, MP, SRC, KIA). The aim of this study is to compare seven sensitivity methods applied to three types of case studies: one showing linear, another showing non-linear behavior and a large linear case study, but with large input uncertainties. The methods are compared based on their performance i.e. variance decomposition and ranking of the input parameters

2. Methods

2.1. Case studies

In this study we applied the sensitivity methods to two case studies of the production of 1 MWh electricity (the original version of the case studies appeared in (Heijungs 2002; Heijungs and Suh 2002). Both case studies consisted of two processes: fuel production and electricity production. The first case study produces electricity thereby using fuel (figure 1). In the second case study, electricity is in turn necessary for fuel production, creating a loop (figure 2). The parameters of the second case study are known to be locally (very) non-linear (Heijungs 2002). For both case studies we assumed that each input parameter is normally distributed with a standard deviation equal to 10% of the mean. Furthermore we assumed that the parameters are uncorrelated and independent. For both case studies the parameters are numbered as follows: 1 (production of electricity); 2 (use of fuel for electricity production); 3 (use of electricity for fuel production, which is zero in the first case study); 4 (production of fuel); 5 (emissions of CO_2 during electricity production); and 6 (emissions of CO_2 during fuel production).

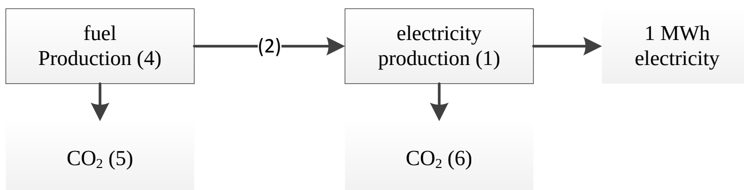

Figure 1. Case study 1: production of 1000 kWh electricity requires 200 liter fuel.

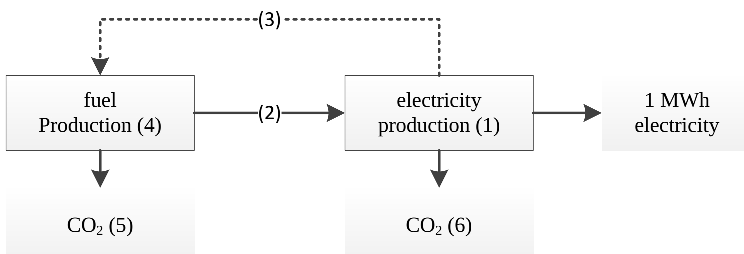

Figure 2. Case study 2: production of fuel requires electricity.

The third case study describes a trawler operating in the Northeast Atlantic, targeting mainly cod and haddock. The case study consists of 115 input parameters, describing e.g. production of vessel and gear, fuels, anti-fouling and cooling agents (figure 3). We assumed that the input parameters come with high uncertainty, each standard deviation of each parameter varies with 30% of the mean. All parameters are log-normally distributed.

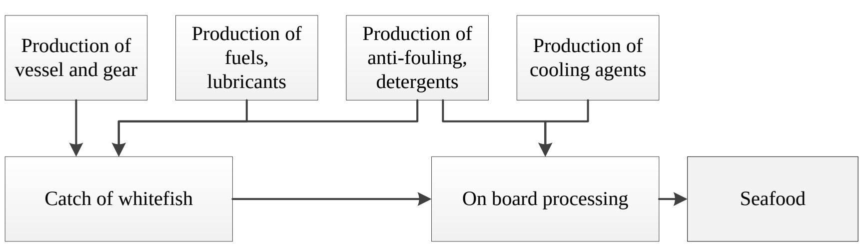

Figure 3. Case study 3: production of seafood.

The trawler takes trips of about ten to fourteen days, landing its catch in Tromso, Norway. The functional unit consists of 1 tonne landed whitefish.

2.2. Methods for sensitivity analysis

2.2.1. One-at-a-time

One-at-a-time (AOT) approaches take a subset of the input parameters, which are changed one at a time (either within its range or using an arbitrary value) to see how much influence it has on the result. The method is easy to perform and to understand, but this type of sensitivity analysis is time-consuming for a large system and, therefore, might not consistently take all parameters into account and could overlook possible sensitive parameters.

2.2.2. Matrix perturbation

Matrix perturbation (MP) as a method of (local) sensitivity analysis was introduced in LCA by Heijungs and Suh (2002). MP makes use of the first order partial derivatives as estimators of local sensitivity, which can be converted into relative multipliers. If the multiplier is larger, a change in the input parameter will change the result more than when the multiplier is almost zero. Information such as the type of distribution function or parameter of dispersion is not used. The result of this method shows how much the results will change if the input parameters are slightly changed (perturbed). This means that the multipliers predict the magnitude and direction of the change in the result of a small change around the original value of each parameter. A disadvantage of applying MP is that the method considers the model in its current configuration, and therefore the result (in general) only holds for small changes around the original parameter values. Moreover, information on which input parameter is quite certain and which is not (i.e. of the ranges of the parameters), is not used.

2.2.3. Method of elementary effects

The method of elementary effects (MEE) is a screening method that was originally designed by Morris (1991) and adjusted by Campolongo et al. (2007). MEE has been applied in LCA by Mutel et al. (2013) and de Koning et al. (2010). In order to apply MEE the ranges of the individual parameters are taken into account, where a range is defined as the upper and lower boundary of an input parameter. MEE can be seen as an extended one-at-a-time approach (Saltelli et al. 2008). MEE combines alternative values of each parameter (at predefined proportional steps in the range defined) and calculates the result. The difference between the original model and the new result of each combination is the elementary effect. Another indicator that can be calculated is the standard deviation of the elementary effect, which is an indicator for the interaction or non-linear effects: if the elementary effect of a certain parameter changes considerably for each run, the magnitude of the elementary effect depends on either the configuration of the model or the presence of nonlinear effects. MEE can be used as a precursor to the more computationally demanding sampling methods as regression. A disadvantage of this method is that the results are not an estimation of the actual variance decomposition.

2.2.4. Key issue analysis (Taylor expansion)

Key issue analysis (KIA) was introduced in LCA by Heijungs (2002) as a method for (analytically) determining the contribution to variance (or variance decomposition) by means of a first order Taylor expansion. KIA has been applied in LCA for example by Heijungs and Huijbregts (2004) and Heijungs et al. (2005). It combines the steepness of a function (described in section 2.2.1 above) with the variance of the individual parameters. KIA calculates the variance decomposition up to first order (or “main effects”), as covariance between input parameters are mostly unknown (Heijungs, 2002). To apply this method only the variances of the individual parameters are used. A disadvantage of KIA is that it does not produce a distribution function of the output, making it more difficult to compare two or more studies.

2.2.5. Standardized regression coefficients (using Monte Carlo sampling)

Standardized regression coefficients (SRC) are obtained from the slope of the line from least square fitting and estimate the contribution to output variance for each input parameter. Pseudo-random samples are taken from all input parameters and for each run the output is calculated. Subsequently, for each input parameter the regression coefficient is calculated; the coefficients are standardized with respect to their standard deviation. An advantage of calculating SRC is that it is commonly applied (in and outside) LCA, a disadvantage is that many runs are needed to calculate the variance decomposition.

2.2.6. Random balance design

The foundation of random balance designs (RBD) are from Cukier et al. (1978). In this study we use the format similar to Tarantola et al. (2006). RBD has been not yet been applied in LCA to our knowledge, although a very closely related method Fourier amplitude sensitivity test, has been applied by de Koning et al. (2010). Random balance designs estimate the contribution to variance by using Fourier transformations. A periodic sampling is applied and for each input parameter the Fourier spectrum is calculated, which is an estimate for the first order sensitivity index. A disadvantage of RBD is that only the main effect can be calculated.

2.2.7. Sobol' sensitivity index

The method by Sobol' (2001) assigns a sensitivity measure to each input parameter by calculating how much of the output variance can be allocated to each input parameter. The idea of the method is that a model can be decomposed into terms of increasing order, where the first order terms, also called the Sobol' main effects (SME), are equal to the contribution of variance caused by each input parameter to the output variance (Saltelli et al. 2010). The method also allows calculation of the interaction effects (variance caused by varying two or more parameters simultaneously) and the total effect index. The Sobol' total effect index (STE) gives the variance caused by the sum of the main and interaction effects of an input parameter. A disadvantage of Sobol's method is that many runs are needed to calculate the indices; hence the model is computationally expensive.

3. Results

3.1. Results of local methods

First the results of the local methods are presented, because it is not accurate to compare local with global methods, as they do not display similar information. Global sensitivity methods (or variance-based methods) include uncertainty information such as the variance into their results, while local methods estimate the change in the outcome based on the configuration of the (LCA) model at hand. The ranking of parameters by applying the local methods can be found in Table 2.

Table 2. Ranking of the parameters of the local methods for case study 1, 2 and 3, e.g. parameter 1 is most sensitive for case study 1 and 2. OAT: one-at-a-time approach; MP: matrix perturbation. The meaning of the parameters of case study 1 and 2 can be found in figure 2. FE: fuel use; EP: emission factor of fuel production; FP: fuel production; EC: emission factor of fuel combustion; LF: landed fish.

	Case study 1		**Case study 2**		**Case study 3**	
Rank	**OAT**	**MP**	**OAT**	**MP**	**OAT**	**MP**
1	1	1	2	1	LF	LF
2	5	5	1	2, 4	EC	EC
3	2	2, 4, 6	3	3	FP	FP
4	6		4	5	EP	EP
5	4		5	6	FE	FE
6			6			

For case study 1 both methods give similar results. For case study 2 the results differed slightly, although the actual values for parameter 1 to 4 were very close for both methods. Case study 3 gives also similar results.

3.2. Global methods: case study 1 electricity production

Applying the global methods to the first case study showed that the ranking of the input parameters were (almost) similar for each method (Table 3). The variance decomposition is given between brackets, but cannot be calculated for MEE as this method only gives a ranking of parameters. For example, in case of applying KIA parameter 1 is responsible for 56% of the output variance.

Table 3. Ranking of the parameters for case study 1, e.g. parameter 1 is most sensitive. MEE: method of elementary effect; KIA: key issue analysis; SRC: standardized regression coefficient; RBD: random balance design; SME: Sobol' main effect index; STE: Sobol' total effect index.

Rank	**MEE**	**KIA**	**SRC**	**RBD**	**SME**	**STE**
1	1	1 (56%)	1 (57%)	1 (58%)	1 (53%)	1 (58%)
2	5	5 (39%)	5 (37%)	5 (40%)	5 (33%)	5 (38%)
3	2	2, 4, 6 (1.6%)	2 (1.7%)	6 (2.5%)	4 (3.8%)	2 (1.7%)
4	6		6 (1.6%)	2 (2.4%)	2 (3.1%)	6 (1.6%)
5	4		4 (1.5%)	4 (2.1%)	6 (2.4%)	4 (1.6%)

KIA required only a single calculation, which means (in case of LCA) that these methods are computationally very fast. MEE required relatively few runs compared to the other sampling based methods. SRC, RBD and the Sobol' indices made use of sampling, SRC and the Sobol' indices requiring the largest number of runs. Although the individual contributions differed between methods, the overall picture is the same.

3.3. Global methods: case study 2 electricity production

Applying the methods to the second case study, we found that SRC, RBD and SME did not give reasonable results (Table 4), all parameters showed a contribution of about 0%. Although the ranking of the parameters is somewhat different, it should be noted that the difference in sensitivity between parameter 1, 2, 3 and 4 were very small in case of MEE and KIA (Table 4). Only the Sobol' total index (STE) explicitly indicated parameter 3 as begin responsible for most of the output variance. The variance decomposition given by KIA and STE are given in Table 4 (SRC, RBD and SME are not shown as they did not gave reasonable results). KIA shows the main effects, indicating that parameter 1-4 are responsible for 25% of the output variance, the STE shows that, taking all interaction into account between, e.g., parameter 3 and the other parameters in the model, that parameter 3 is responsible for almost 93% of the output variance.

Table 4. Ranking of the parameters for case study 2. MEE: method of elementary effect; KIA: key issue analysis; SRC: standardized regression coefficient; RBD: random balance design; SME: Sobol' main effect index; STE: Sobol' total effect index.

Rank	**MEE**	**KIA**	**SRC**	**RBD**	**SME**	**STE**
1	3	1 (25%)	-	-	-	3 (93%)
2	4	2, 3, 4 (25%)				2 (50%)
3	2	5 (0%)				4 (50%)
4	1	6 (0%)				1 (50%)
5	5					5 (0%)
6	6					6 (0%)

3.4. Global methods: case study 3 production of seafood

Applying the global methods to the third case study showed that the ranking of the input parameters were (almost) similar for each method (Table 5), just as for case study 1. The five most sensitive parameters are shown, that contribute more than 1% to the output variance. The variance decomposition is given between brackets.

Table 5. Ranking of the parameters for case study 3. MEE: method of elementary effect; KIA: key issue analysis; SRC: standardized regression coefficient; RBD: random balance design; SME: Sobol' main effect index; STE: Sobol' total effect index. FE: fuel use; EP: emission factor of fuel production; FP: fuel production; EC: emission factor of fuel combustion; LF: landed fish.

Rank	MEE	KIA	SRC	RBD	SME	STE
1	LF	LF (56%)	LF (46%)	LF (51%)	LF (55%)	LF (59%)
2	EC	EC (41%)	EC (38%)	EC (36%)	EC (38%)	EC (41%)
3	FP	FP (~1%)	FP (~1%)	FP (~1%)	FP (~1%)	FP (~1%)
4	EP	EP (~1%)	EP (~1%)	EP (~1%)	EP (~1%)	EP (~1%)
5	FE	FE (~1%)	FE (~1%)	FE (~1%)	FE (~1%)	FE (~1%)

An interesting difference with case study 1, now that we have increased the uncertainty of the input parameters, is that STE is able to explain more of the variance than SME. SRC underestimates the contribution of parameters LF compared to the other methods. The sum of SRC, RBD and SME equals approximately 90%, indicating that the LCA model contains outliers. The sum of the variance decomposition according to KIA however, still sums up to 100% and does not show the presence of outliers.

4. Discussion

We did not take correlations between input parameters into account. If correlations are not taken into account, the result of the variance decomposition might be over- or underestimated. Nevertheless, we think that the results in this paper will also hold for LCA models containing correlated input parameters.

5. Conclusion

The results of a sensitivity analysis in LCA are important because they can be used to identify parameters that can considerably change the result, and which might need further investigation. They can also be used to identify parameters that are responsible for most of the output uncertainty and therefore should be known accurately before presenting results. Based on this study, we prefer the use of matrix perturbation in case of assessing the local sensitivity as it is more consistent than OAT where only a subset of the input parameters can be analyzed. MEE is a useful method in case of large models as a precursor to more computationally expensive sampling based methods. In case of interest in variance decomposition, we recommend the use of the Sobol' sensitivity indices in combination with KIA. Sobol' indices allow the calculation of main, interaction and total effect indices and the total index can also be calculated when the case study at hand shows non-linear behaviour. When the LCA practitioner is only interested in the main effect in case of a linear case study, KIA can be used.

ABSTRACT

In light of resource depletion and anthropogenic influences on the greenhouse effect, food waste has garnered increased public interest in recent years. The aim of this study is to analyze the environmental impacts of food waste and to determine to what extent consumers` behavior influences the environmental burden of food consumption in households (hereafter called 'use'). An LCA study of three food products is conducted and addresses the impact categories climate change (GWP100), eutrophication (EP), and acidification (AP). Primary energy demand (PED) is also calculated. For adequate representation of consumer behavior, scenarios based on various consumer types are generated. If consumer acts careless towards the environment, the use stage appears as the main hotspot in the LCA of food products. Moreover, results show that the avoidance of wasting unconsumed food can reduce the environmental impact significantly.

Keywords: food waste, consumer behavior, disposal options, environmental impact

1. Introduction

Food is an essential element of human life. The human body demands high-energy organic compounds to function. Furthermore, food contributes to mental, physiological and social comfort (Baccini and Bader 1996).

In the light of global resource depletion and anthropogenic influences on the greenhouse effect, and as these relate to shortages in developing countries, the environmental effects of food production and consumption as well as the influence of food waste in industrialized countries has gained public attention in recent years (Gustavsson et al. 2011; Thurn 2011). Throwing away edible food affects the environment all along the value chain via production, logistic and disposal processes (FAO 2012). This paper aims to examine the amount and effects of unconsumed food in German households, where "unconsumed food" is defined as food products which were still edible at the time of disposal.

Participant food waste diaries of the EU-project "GreenCook" (GreenCook 2011; Ludwig 2013), which were kept for a period of three months, and a review of scientific literature (Gruber 2013) was used to select three food products for further investigation. A life cycle assessment (LCA) was performed for each food, concentrating on the use stage. Results indicate how consumers can influence the environmental profile of food in the use stage. Food-related activities, such as purchasing, storage, preparation and disposal, are also analyzed via LCA. Finally, the burden on the environment of the whole life cycle of wasted edible food is determined.

2. Methods

This study follows the ISO 14040/44 life cycle assessment (LCA) guidelines (ISO 14040 2006; ISO 14044 2009). The LCA software GaBi 6 and related databases were used for LCA modelling (PE International 1992-2013). Environmental impacts were calculated according to the CML 2001 method. Climate change (GWP100), eutrophication (EP) and acidification (AP) were analyzed. Primary energy demand (PED) was calculated additionally.

2.1. Selection of food

Three food products – potatoes, milk and rice – were selected according to the following criteria: (1) high level of disposal, (2) a clear designation in the household diary, (3) no convenience products or food with unclear composition and (4) staple food without seasonal limitation for consumption. Moreover, the use phase should contain at least one process relevant to the energy demand, e.g. refrigerated storage or required cooking. The selected food items and the amounts wasted per person per year are compiled in Table 1.

Table 1. Selected food and wasted edible amount per person during one year (Ludwig 2013)

Food	Waste amount [kg/person·year]
Potatoes	15.1
Milk	11.6
Rice	3.1

2.2. System boundaries and functional unit

The entire life cycle, from cradle to grave, of potatoes, milk and rice was modelled. Germany is used as the geographical reference, with the exception of the agricultural production and industrial processing of rice: here China was chosen as reference country. The time frame is based on current production conditions and the data used reflects the state of the art. The functional unit (FU) was chosen to be 1 kg food disposed after the use phase.

The system boundary, including all relevant processes such as primary production, industrial processing, wholesale and retail, is displayed in Figure 1 for the three different foods. The following differences occur in the use stage. (1) Potatoes and rice are stored at ambient temperature. (2) In contrast to potatoes and rice, milk requires no energy mix prior to consumption in the use stage. Pasteurized whole milk was chosen and was assumed to be consumed uncooked. Pasteurization is done in the industrial processing stage.

The model also includes the consumption of food via digestion in the human body. Although the consumption of food is not part of the functional unit itself, it was considered as a reference for the environmental impact of different disposal routes. A direct comparison of the environmental impact of consumption and the different disposal options does not take place, because abstention from food consumption is no appropriate solution to reduce the environmental impact. The function of food is to supply the human body with energy rich organic compounds (Baccini and Bader 1996).

The disposal routes for the three foods were chosen according to the data from the household diaries (Ludwig 2013). Milk is mainly disposed of in the sink and is delivered to the wastewater treatment facility of a municipal sewage plant, while potatoes and rice are either disposed of with residual solid waste in waste incineration plants or with biological waste in composting plants. Composting was chosen for geographic reasons instead of fermentation in biogas plants, as it is a more common practice for the disposal of biological waste in Germany (Kern et. al 2010).

Capital goods were included in the background datasets for primary production, waste incineration, wastewater treatment and transportation processes. It was estimated that capital goods have a relatively low environmental impact, due to high mass flows during the life span of the infrastructure. Machines, buildings and infrastructure were excluded from use stage processes and from the composting plant model due to lack of complete and clearly assignable data. Also not taken into consideration were transportation of auxiliary materials, refrigerant emissions from cooling appliances in wholesale and retail as well as dishwashing in households. Food waste besides the use phase was not taken into account due to missing data on the wasted amount of specific food products during agricultural production, industrial processing, wholesale and retail (Kranert et al. 2012).

Allocation problems occur in processes that capture the utilization of various products at the same time. This applies to processes such as the storage of food in wholesale and retail. Mass allocation was conducted by computing the share in quantity of a product. The energy demand for the heating of the warehouse and supermarket and for the refrigerated storage of milk was allocated by mass to each respective food. Transport processes were also allocated by mass.

2.3 Data sources and data quality

Datasets from the GaBi database were used for designing and adjusting the models as far as possible (PE International 1992-2013). Missing data were complemented by scientific literature, with the exception of composting of biological waste, where primary data were collected and a model of a composting plant was built. All data used in the model were in the timeframe 2000 to 2013.

An LCA model developed by Muñoz et al. (2007) describes the biochemical transformation of food in the human body and was used in this study to model digestion processes. For the treatment of wastewater datasets from GaBi database were used (PE International 1992-2013).

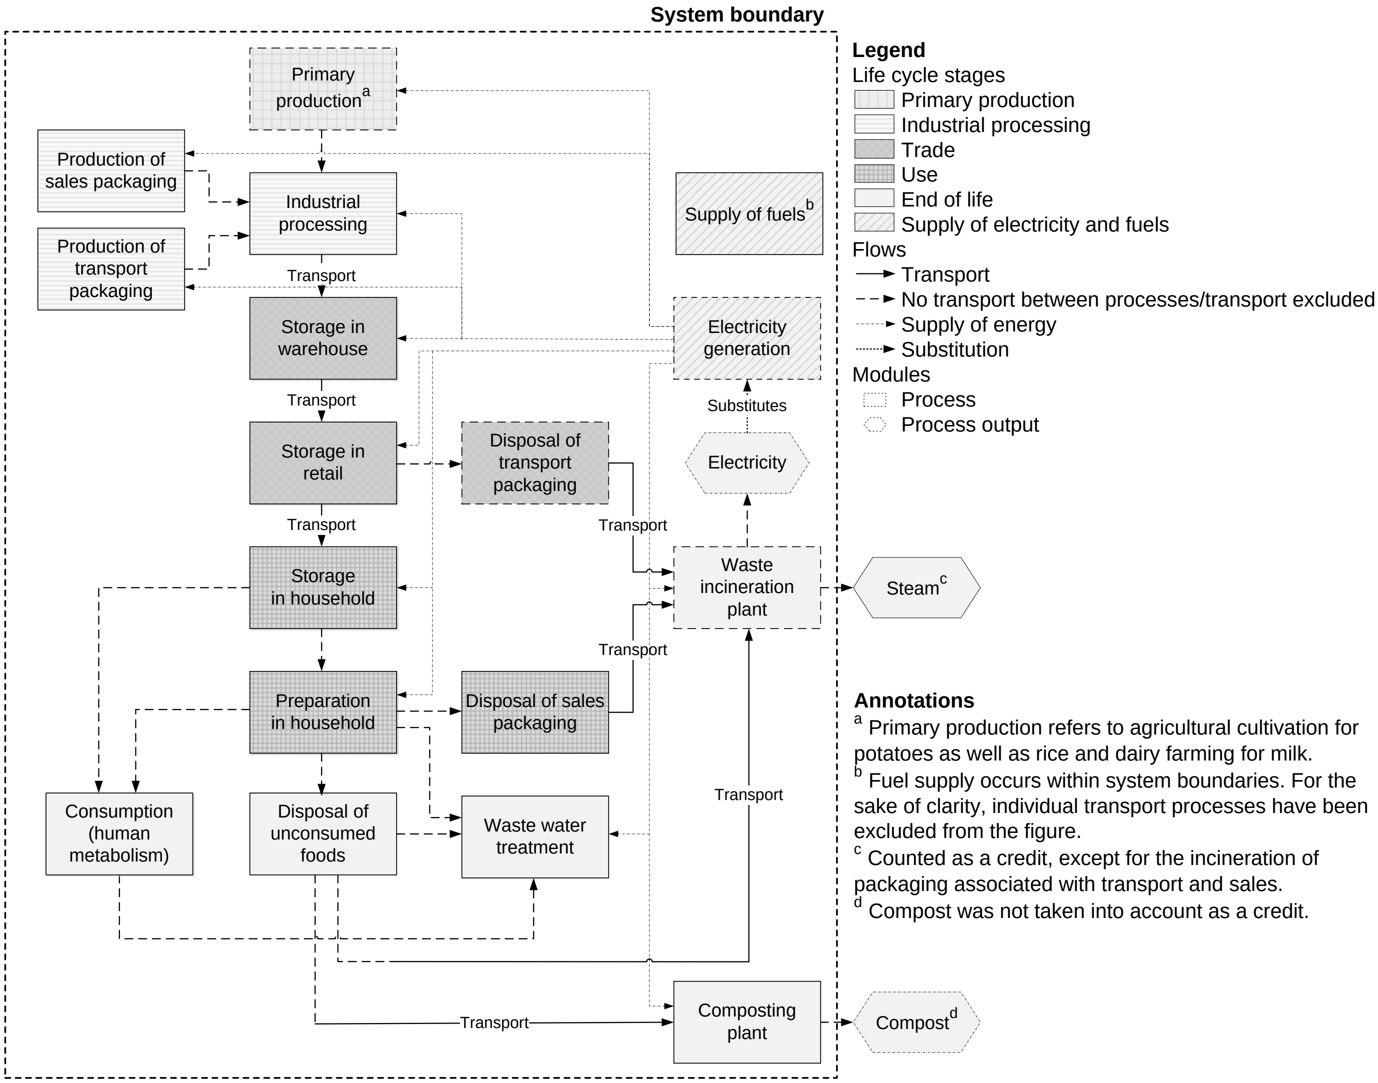

Figure 1. Schematic flow chart of the product system

2.4. Scenario definition

Scenarios based on three different consumer types were generated for adequate representation of consumer behavior during the use phase. (1) The base scenario (base-s) represents the “average consumer”. (2) The “environmental conscious consumer” (conscious-s) acts with ecological awareness due to practicing a lifestyle that minimizes damage to the environment by consciously keeping resource consumption and energy as low as possible. (3) The “careless consumer” (careless-s) remains indifferent to potential environmental impacts of his actions. According to these assumptions, parameters for the purchase, storage, and preparation of the food products were defined. The end-of-life disposal routes for the unconsumed food were set according to the household diaries. In base-s, it was assumed that food is not wasted but consumed. In conscious-s, the food waste was assumed to be separated from the general waste. Unconsumed food is disposed of in the organic waste bin. In careless-s, wasted food is disposed of with the residual solid waste.

2.5. Purchasing

Purchasing is done in the base-s and careless-s cases by car. The distance travelled from household to retail (and return) was set to 10 km according to Tengelmann (2009). In the conscious-s case, where purchasing is not done by a fuel-powered vehicle, the parameter is set to 0 km, because it is assumed that travelling by foot or bi-cycle has no impact on the environment. Shopping trips combined with other activities, e.g. travelling to work and shopping, were not taken into account as combined trips often lead to longer transport distances. Allocation among the different causes was not possible due to insufficient data.

In base-s and conscious-s, it was assumed that the consumer purchases several products, weighing a total of 10 kg, including the relevant food product. In careless-s it was assumed that consumer is badly organized and only one sales unit of the relevant food is bought. Here it was assumed that base-s and conscious-s plan and organize their shopping trips and purchase can also contain non-food products. Table 2 shows the purchase quantity for the scenarios and the weights of sales units including packaging.

Table 2. Weights of sales units of potatoes, milk and rice

Purchase quantity	**Base-s**	**Conscious-s**	**Careless-s**
Total purchase quantity [kg]			
Scenarios potatoes	10	10	2.51[a]
Scenarios milk	10	10	1.06[b]
Scenarios rice	10	10	1.01[c]
Share of considered food product [%]			
Potatoes	20.51	20.51	100
Milk	10.07	10.07	100
Rice	10.00	10.00	100

[a] 2.50 kg potatoes, weight of sales packaging 0.014 kg ; [b]1.03 kg milk, weight of sales packaging 0.03 kg; [c] 1.00 kg rice, weight of sales packaging 0.005 kg

2.6. Storage

Potatoes and rice were stored in households at ambient temperature; their storage contributed no environmental burden. The electric energy demand for storage of milk in the refrigerator [MJ/FU] was calculated by a parameterized equation (Eq. 1) based on (Nielsen et al. 2013; Sonesson and Janestad 2003; Geppert 2011). Parameters of Eq. 1 and the data used in the scenarios are listed in Table 3.

Caused by the interaction between consumer and kitchen appliances the electric energy consumption of the refrigerator is increased by about 60 % compared to the operation of a refrigerator under ideal conditions (Defra 2008). Energy losses may result from (1) door of the refrigerator left open too long, (2) irregular defrosting, (3) a dusty heat exchanger, (4) too warm location of the refrigerator, and (5) storage of hot dishes (Utopia AG 2013). Therefore the equation was complemented with the parameter e_K describing these energy losses.

$$E_{KS} = e_K \cdot \left(\left(\frac{E_{Kspez.}}{V_K} \cdot \frac{100}{n} \cdot V_P \cdot t \right) + \left(m_P \cdot c_V \cdot \left(T_A - T_K \right) \right) \right) \qquad \text{Eq. 1}$$

Table 3. Parameter description of Eq. 1 and parameter values used in the scenarios

			Value for scenario		
Parameter	**Description**	**Unit**	**Base-s**	**Conscious-s**	**Careless-s**
e_K	Parameter for interaction between consumer and refrigerator[a]	[-]	1.2	1.0	1.4
$E_{Kspez.}$	Specific electric energy demand of the refrigerator[b]	[MJ/d]	1.5	1.0	2.0
V_K	Capacity[b]	[dm³]	117	117	117
n	Rate of utilization of the capacity[a]	[%]	50	50	50
V_P	Volume of product for storage[c]	[dm³]	1	1	1
t	Duration of storage[d]	[d]	5	2	1
m_P	Mass of product for storage	[kg]	1.07	1.07	1.07
c_V	Specific heat capacity of the product for storage[e]	[MJ/kg·K]	0.00377	0.00377	0.00377
T_A	Temperature of the product at the beginning of storage[f]	[K]	292	292	292
T_K	Average temperature in refrigerator[g]	[K]	278	278	278
E_{KS}	Electric energy demand for the storage of milk	[MJ/FU]	0.56	0.16	1.61

[a] according to (Defra 2008); [b] based on (Siemens-Electrogeräte GmbH 2013); [c] calculated volume of one sales unit of milk, density of milk 1.03 kg/dm³ (Töpel 2004); [d] according to (FrieslandCampina 2013); [e] according to (Töpel 2004); [f] assumed to be ambient temperature; [g] according to (Utopia AG 2013)

2.7. Preparation

Potatoes and rice have to be cooked before consumption. Electric energy demand for cooking was calculated in the model based on (Oberascher et al. 2011) who analyzed cooking of potatoes in two different ways. (1) In the ideal case the potatoes were cooked in a pot with closed lid on the highest power setting of the stove up to the boiling point. Then, the heat was reduced. (2) In the non-ideal case the pot is not covered with a lid. The highest heat setting is chosen and not reduced after reaching the boiling point. The ideal case was taken as a basis for conscious-s, the careless-s is modelled after the non-ideal case and a calculated average of the two cases was set as base-s. The electric energy demand for cooking of potatoes and rice was considered to be equal (Table 4).

Table 4. Demand of electric energy for cooking of 1 kg potatoes or rice (Oberascher et al. 2011)

Scenario	Electric energy demand [MJ]
Base scenario (base-s)	1.4
Environmental conscious scenario (conscious-s)	0.7
Careless scenario (careless-s)	2.1

2.8. Disposal routes

After storage and if it is necessary preparation, the food is disposed. The disposal routes were set according to the household diaries and listed in Table 5 with the different scenarios. The model of the composting plant was built based on primary data from the German composting plant Kirchheim unter Teck (Kompostwerk Kirchheim unter Teck 2013).

Table 5. Disposal routes for the scenarios of potatoes, milk and rice (Ludwig 2013)

Scenario	Potatoes	Milk	Rice
Base scenario (base-s)	Consumption	Consumption	Consumption
Environmental conscious scenario (conscious-s)	Composting	Consumption	Composting
Careless scenario (careless-s)	Waste incineration	Sink/Waste water treatment	Waste incineration

3. Results

In Table 6 the results per functional unit (FU) of the LCA of potatoes are listed. The results of the use stage are displayed as a total and in detail for purchasing, preparation and the disposal of the sales packing via waste incineration. Results of the life cycle stages primary production and retail trade were similar for all scenarios, since the same assumptions were made in the model. Primary production and industrial processing (datasets out of the GaBi database by PE International 1992-2013) were summarized in the following to simplify matters and hereinafter called production. Retail trade was modelled in a similar way for potatoes, milk and rice. There were no differences assumed for primary production and retail trade for the different scenarios, thus the results were identical.

Table 6. Results per functional unit (FU) for LCA of potatoes

Life cycle impact assessment categories	Production[a]	Retail trade	Purchasing	Preparation	Disposal of sales packaging	Use (total)	End of life
GWP [kg CO_2-eq/FU]							
Base-s	0.059	0.029	0.174	0.206	0.014	0.394	0.473[b]
Conscious-s	0.059	0.029	0.000	0.094	0.014	0.109	0.480[c]
Careless-s	0.059	0.029	0.692	0.315	0.014	1.021	0.555[d]
EP [g PO_4^{3-}-eq/FU]							
Base-s	0.021	0.010	0.074	0.041	0.000	0.116	0.197[b]
Conscious-s	0.021	0.010	0.000	0.020	0.000	0.020	0.051[c]
Careless-s	0.021	0.010	0.295	0.062	0.000	0.357	0.045[d]
AP [g SO_2-eq/FU]							
Base-s	0.126	0.059	0.374	0.347	0.004	0.725	0.227[b]
Conscious-s	0.126	0.059	0.000	0.159	0.004	0.162	0.261[c]
Careless-s	0.126	0.059	1.489	0.531	0.004	2.023	0.061[d]
PED [MJ/FU]							
Base-s	1.330	0.406	2.587	3.623	0.009	6.220	1.035[b]
Conscious-s	1.330	0.406	0.000	1.649	0.009	1.658	1.253[c]
Careless-s	1.330	0.406	10.292	5.548	0.009	15.850	-4.770[d]

[a] includes primary production and industrial processing; [b] consumption; [c] composting; [d] waste incineration

The use and end-of-life stages of base-s dominate all considered impact categories and have the highest PED. In the conscious-s case, the main contributor is the end of life; in case of careless-s the use stage has the highest environmental impact. The negative value for PED (-4.770 MJ/FU) of careless-s is due to a credit of -5.599 MJ/FU for the generation of electric energy and steam from the incineration of waste. In the use stage, the purchase of food contributes the highest environmental impact in the base scenario as well as in careless-s. During fuel combustion, CO_2 and volatile organic compounds (VOCs) were emitted. These emissions result in a GWP for purchasing of 0.692 kg CO_2-eq/FU in careless-s and 0.174 kg CO_2-eq/FU in base-s. No environmental impact was associated with purchasing of conscious-s. The environmental impact of end of life scenarios were not compared to base-s, because of the function of food (see section 2.2).

Table 7 shows the results per FU of the LCA of milk in this study. The use stage is presented in detail for purchasing, storage and the disposal of the sales packaging via waste incineration. In contrast to the results of potatoes, the production is the main contributor to all impact categories and has the highest PED (32.8 MJ/FU) in all scenarios. In careless-s the use stage dominates the environmental burden. The purchase of milk has the highest environmental impact in the use stage of careless-s. The environmental impact of the storage of the milk is lower than of the purchase. With a GWP of 0.031 kg CO_2-eq/FU the disposal of the sales packaging is similar to the storage of milk in base-s with 0.032 kg CO_2-eq/FU. In conscious-s the GWP of the storage (0.009 kg CO2-eq/FU) is even 29 % lower. The contribution to the EP with 0.203 g PO_4^{3-}-eq/FU is for the consumption significantly higher than for the disposal of milk with 0.008 g PO_4^{3-}-eq/FU. This is caused by a greater amount of organically loaded wastewater resulting from consumption.

Table 7. Results per functional unit (FU) for LCA of milk

Life cycle impact assessment categories	Production[a]	Retail trade	Purchasing	Storage	Disposal of sales packaging	Use (total)	End of life
GWP [kg CO_2-eq/FU]							
Base-s	0.842	0.026	0.178	0.032	0.031	0.241	0.360[b]
Conscious-s	0.842	0.026	0.000	0.009	0.031	0.041	0.360[b]

Conscious-s	1.361	0.043	0.000	0.016	0.021	0.036	0.235[b]
Careless-s	1.361	0.043	3.583	0.154	0.021	3.757	0.009[c]
PED [MJ/FU]							
Base-s	32.808	0.230	2.650	0.560	0.107	3.317	1.071[b]
Conscious-s	32.808	0.230	0.000	0.164	0.107	0.270	1.071[b]
Careless-s	32.808	0.230	24.769	1.613	0.107	26.489	0.040[c]

[a] includes primary production and industrial processing; [b] consumption; [c] waste water treatment

In Table 8 the results of the LCA per FU of rice are listed. The results of the use stage are displayed in detail for purchasing, preparation and disposal of the sales packaging via waste incineration. Production of base-s has an EP of 0.278 g PO_4^{3-}-eq/FU and AP of 2.623 g SO_2-eq/FU. In careless-s the use phase is the main contributor to all impact categories. Similar to the potato PED results, rice has a negative value for end of life, due to a credit of -5.599 MJ/FU for the generation of electricity and steam from the incineration of waste. In the use stage of careless-s, purchasing of rice dominates all impact categories and the PED with 6.398 MJ/FU, respectively. A closer look on the end of life shows that GWP of the disposal option composting (conscious-s) and of consumption (base-s) is similar with 0.480 kg CO_2-eq/FU and 0.602 kg CO_2-eq/FU, respectively, since both processes describe the biological degradation of organic compounds.

Table 8. Results per functional unit (FU) for LCA of rice

Life cycle impact assessment categories	Production[a]	Retail trade	Purchasing	Preparation	Disposal of sales packaging	Use (total)	End of life
GWP [kg CO_2-eq/FU]							
Base-s	0.152	0.089	0.182	0.215	0.043	0.440	0.602[b]

Careless-s	2.346	1.470	25.731	5.571	0.041	31.343	-4.770[d]

[a] includes primary production and industrial processing; [b] consumption; [c] composting; [d] waste incineration

Table 9 shows an extrapolation of the LCA results for the annual consumption per capita in Germany. LCA results of base-s were takenfor production, retail trade and the use stage.. For unconsumed potatoes and rice, a combination of the disposal options composting and waste incineration was created. Milk is only disposed via sink. The amount of unconsumed food is taken from Table 1. In the case of the consumed food results of base-s were taken for the end of life. According to the German Statistisches Bundesamt (2012), 56.6 kg potatoes, 101.3 kg fresh milk products and 5.4 kg rice were consumed per capita in 2012. No data was available for consumed milk, therefore the amount of fresh milk products was used.

Through avoidance of waste from unconsumed potatoes, a general consumer can reduce GWP by approximately 22 %, EP by 13 %, AP by 20 % and PED by 16 %, respectively. In the case of milk, GWP, EP, AP and PED can be reduced by approximately 10 %. Avoiding unconsumed rice waste reduces emissions and PED by 30-37 %. Table 9 illustrates the avoided environmental impacts, as compared with the environmental impacts of a diesel-powered car. Considering a family of five, the avoided GWP of unconsumed potatoes corresponds to a route halfway across Germany (approximately 500 km). The GWP resulting from unconsumed milk is equivalent to about 440 km and the GWP of unconsumed rice corresponds to about 120 km.

Table 9. Extrapolation of LCA results to the annual consumption per capita in Germany (Statistisches Bundesamt 2012; Ludwig 2013)

Food product	GWP [kg CO_2-eq/FU]	EP [g PO_4^{3-}-eq/FU]	AP [g SO_2-eq/FU]	PED [MJ/FU]
Potatoes				
Unconsumed (wasted edible food)[a]	15.12	2.95	16.21	93.78
Consumed	54.02	19.45	64.39	508.89
Milk				
Unconsumed (wasted edible food)[a]	12.89	5.31	21.62	420.86
Consumed[b]	148.81	66.25	212.32	3791.25
Rice				
Unconsumed (wasted edible food)[a]	3.56	1.50	11.70	35.10
Consumed	6.92	3.36	20.37	60.38

4. Discussion

The results of this LCA study are hardly comparable to previous studies. Differences from previous studies include different system boundaries and levels of detail for examination of the life cycle stages as well as the representation of consumer behavior in the model. The consumer modelling included four parameters: (1) distance travelled for purchasing, (2) purchased amount of food products, (3) storage and preparation of food in households and (4) amount of unconsumed food in households. An evaluation of 36 LCA studies of food products, which can be found in Gruber (2013), showed that no general conclusions can be drawn as to which life cycle stage of different food products is most important as the level and type of environmental impact from individual life cycle stages varies according to the considered food product. In the current study, however, the most important factor influencing environmental impact is consumer behavior as identified by the authors. This is clearly seen when looking at the results of the different scenarios of the highly-processed staple products milk and rice. Depending on how the consumer behaves during the use stage, the primary production including the industrial processing or the use stage dominates the environmental impacts and the PED.

Modelling assumptions and estimations were based on literature data, which must be critically examined. Therefore, this study has some limitations. First of all, data gaps on the food losses of individual food products during the whole life cycle exist, as this is a seldom examined issue in LCA and the collection of this data requires much effort. The end-of-life inventory data for the waste incineration plant and the municipal wastewater treatment plant could are not adjusted for the input of a specific food product. In the case of waste incineration, the process describes an incineration of mixed municipal solid waste. The input flow of the waste water treatment plant is polluted municipal sewage water. Neither process reflects the specific composition of the emissions related to the disposal of the individual food products. The LCA model of the composting plant describes the composting of mixed organic waste and therefore also does not reflect the specific emissions of the disposal of individual food products. Due to this insufficient data availability, the comparability of the disposal options in this study is limited.

Despite the limitations of the statement of this study regarding the end of life, there is no doubt that the environmental impact can be significantly reduced if the amount of wasted unconsumed food decreases. Additionally, the environmental impact can be significantly decreased in the use stage by an environmentally conscious consumer. Purchasing has the highest effect on the evaluated impact categories and on the PED. The reason for this is the fuel consumption with its related release of emissions. The mass-based allocation of purchased food products transported by car must be examined. For example, the transport of 20 kg of products by car does not require significantly more fuel than the transport of 1 kg of products. Nevertheless, in light of the goal and scope of this study it makes sense to assign the environmental impact to consumers' behavior. The purchase of several items in one shopping trip saves additional trips and related fuel, and thereby reduces the environmental impact. Additionally, consumers can reduce the resulting emissions by decreasing the electric energy demand, particularly where food storage is concerned. For example, consumers can take the following measures: (1) select a refrigerator with a high energy efficiency class, (2) use a refrigerator of the appropriate size and use it often, (3) only open the refrigerator when necessary, (4) do not store warm dishes in the refrigerator, (5) defrost regularly, (6) situate the refrigerator in a cool location, (7) set the temperature to an optimal setting (about 7 °C) and (8) clean the heat exchanger on a regular basis. Furthermore, an energy-conscious handling of kitchen appliances while cooking reduces the overall environmental impact of the use stage. The consumer can decrease the electric energy demand for cooking by covering the pot with a lid and reducing the heat setting of the stove. Since each food processing step requires resources and leads to the release of emissions, consumers can significantly decrease the environmental impact of food by avoiding food waste in terms of unconsumed and also potentially energy-intensive prepared food.

When evaluating the environmental impacts from cradle to grave of food products, it has to be taken into account that food supplies the energy required by the human body and delivers many health benefits beyond energy and nutrition (Roy et al. 2009). Considering the results of this study, it may seem that stopping or minimizing food consumption would be the easiest way to reduce the associated environmental impacts. However, given that the function of food is to provide energy for the human body, eliminating consumption is not a reasonable possibility. Therefore, it is not appropriate to compare the metabolic-based emissions of the consumption with the disposal of food products, even though the human body has been found to be an important source of emissions in GWP and EP (Muñoz et al. 2007) and therefore should be included when identifying the life-cycle hotspots of a food product. In this study the consideration of consumption was necessary because the overall environmental impact of food consumption was assessed, taking into account both the consumed and unconsumed amount of each individual food product.

5. Conclusion

Results of this study show that measures for reducing the environmental impact of food consumption must take place at different levels. One of these levels is the life-cycle use stage, as here the consumer can decide the most efficient way to reduce associated emissions. Emissions from the use stage can be reduced by environmentally responsible consumer behavior. Together, the prevention of waste in terms of unconsumed food can significantly decrease the impact on the environment.

Due to a lack of understanding and awareness of environmental issues, the average consumer often misses opportunities for beneficial environmental behavior (Vázquez-Rowe et al. 2013). Through projects and educational campaigns such as "GreenCook" (GreenCook 2011) attempts are being made to encourage consumers to think and act proactively.

The influence of consumer behavior on the LCA results has been found to be important. The life-cycle use stage of food products should not be overlooked in LCA studies. It is important to include food waste in the entire environmental assessment and not only in the use phase. Further research must be conducted to represent consumer behavior more accurately in LCA. To enable comparison among results, the LCA community needs to develop a common method for modelling consumer behavior. Moreover, end-of-life data is required for modelling waste disposal emissions in more detail.

ABSTRACT

In combination with technical advances in agriculture, human dietary change is suggested to be necessary to reduce the environmental impact of the food system. In this paper a systematic review, assessing the climate and land use impacts of dietary change, is performed. The aims are to evaluate the scientific basis of dietary scenario analysis and to estimate the potential of reducing greenhouse gas emissions and land use demand by changing the composition of the diet. The review includes 14 peer-reviewed journal articles and in total 55 scenarios assessing the greenhouse gas emissions and land use demand of different diets. The results suggest that dietary change, in areas with affluent diet, could play an important role in reaching environmental goals, with up to 50% potential to reduce greenhouse gas emissions and land use demand of the current diet.

Keywords: Review, diet, scenario, climate, land use

1. Introduction

Global food production, accounts for around 30% of total anthropogenic greenhouse gas emissions (GHGE), occupies more than a third of the world´s land surface (Garnett 2011), and is identified as a great threat to the environment (EC 2006). In combination with technical advances in agriculture, changes towards more sustainable eating patterns are suggested to be a necessary to meet environmental targets (Garnett 2011).

Knowledge of sustainable food consumption is increasing with the growing number of environmental and life cycle assessments of foods, meals, and complete diets. A method commonly used to assess the impact of different dietary patterns is dietary scenario analysis. The methodological approach of dietary scenario analysis can have decisive effect on the final results. To draw general conclusions on which dietary changes that can promote a development towards more sustainable food consumption, therefore, requires that results from several studies are analyzed and compared. However, so far, few syntheses of studies assessing the environmental impact of diet have been performed.

To synthesize the state of knowledge, this paper provides a systematic review of research articles which assessed the environmental impact of dietary scenarios. The objectives are to: i) evaluate the scientific basis of scenario analyses assessing the impact on GHGE and land use demand (LUD) of human dietary change, ii) estimate the potential of reducing GHGE and LUD via dietary change and iii) identify current gaps of knowledge. The paper can be used as an overview of the state of knowledge and evidence base of sustainable food consumption in the year of 2014.

2. Method

2.1. Literature search strategy

In order to ensure scientific quality and minimize the risk of bias, the study design and analysis of this review follows the PRISMA Statement protocol (Moher et al. 2009).

The literature search was performed in February 2014 with the use of Web of Knowledge (ISI), Scopus and Google Scholar. To assess the effect of human dietary change on GHGE and LUD, the terms: ‘diet’ or ‘food’ and ‘scenario’ were combined with the terms ‘climate’ or ‘greenhouse gas’ or ‘land’ or ‘sustain*’. In addition, related and relevant articles found in reference lists were reviewed. Articles included in this review meet the following six inclusion criteria: i) English-language publications; ii) published between 2005 and February 2014; iii) dietary scenario analysis is performed for a complete diet; iv) quantitative estimates of the effect on GHGE and/or LUD of human dietary change are provided; v) published in peer-reviewed scientific journals; vi) results are compared against reference scenarios of current (1990-2010) average food consumption in a specified population. Determination of articles that meet the inclusion criteria was made based on information available in titles and abstracts of the articles. In total, 14 articles that fulfilled the inclusion criteria were identified (Fig 1).

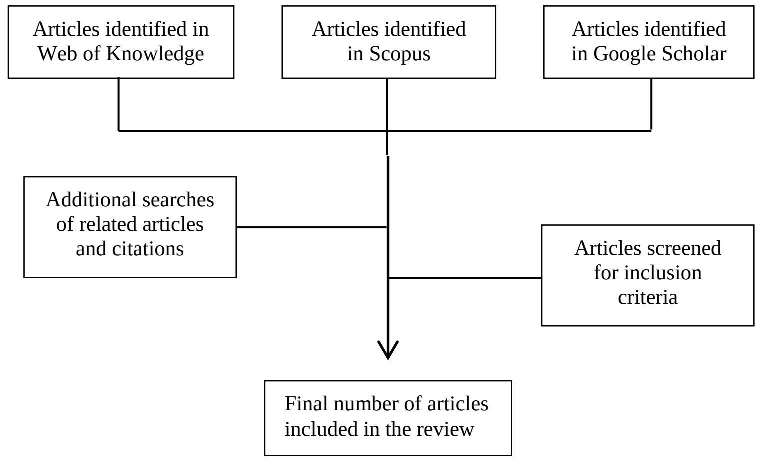

Figure 1. Literature search and selection of articles in the review

2.2. Synthesis of results

Depending on the dietary composition, scenarios were categorized into healthy diets, diets in which meat is partially replaced by plant-based foods/mixed foods/dairy products, diets in which all ruminant meat is replaced by pork and poultry, diet with balanced energy intake, vegetarian diets and vegan diets. The potential to reduce environmental impact is reported as the relative change in GHGE, expressed as tons of carbon dioxide equivalents (tCO_2e) per person per year, and LUD, expressed as square meter (m^2) per person per year, compared to the reference scenarios used in the respective studies.

3. Results

3.1. Located literature

In total, 14 articles that fulfil the inclusion criteria were identified in this assessment. Out of these 14 articles, two investigated both the effect on GHGE and LUD, two the impact of LUD only, and ten the impact of GHGE only. Five articles were published between 2009 and 2011, and nine articles between 2012 and Feb 2014 (Table 1).

In the majority of the studies the main focus is on the environmental impact of reducing or changing the consumption of meat and animal-based food (Table 2). In all articles except for Pathak et al. (2010) the effect of dietary change is studied in European populations characterized by having an affluent diet.

3.2. Potential to reduce GHGE

The impact of dietary change on GHGE from the diet is summarized in Table 2. Completely avoiding all animal-based products (vegan diet) or all meat (vegetarian diet) provides the largest potential for reducing GHGE from the diet, followed by scenarios of replacing ruminant meat by pork and poultry and eating a healthier diet.

3.3. Potential to reduce LUD

The impact of dietary change on LUD from the diet is summarized in Table 2. According to the results, a change to vegan or vegetarian diets has the largest potential to reduce the demand for agriculture land, followed by changing to a healthier diet and diets in which meat is partially replaced by plant-based food.

Table 2. Summary of results

Scenario	**Reduction of GHGE**		**Reduction of LUD**	
	(%)[a]	**(n)**	**(%)[b]**	**(n)**
Vegan diet	25-55	6	50-60	3
Vegetarian diet	20-55	9	30-50	2
Meat partially replaced by plant-based food	+5-0	2	15	1
Meat partially replaced by dairy products	0-5	2	-	0
Ruminant meat replaced by monogastric meat	20-35	2	-	0
Meat partially replaced by mixed food	5	2	-	0
Balancing energy intake and expenditure	0-10	2	-	0
Healthy diet	0-35	19	15-45	5

[a]Effect of dietary change on GHGE from the diet, in % of reduction in GHGE of current average diets. [b]Effect of dietary change on LUD, in % of reduction in total demand of agriculture land of the average diet. n = number of scenarios. "+" indicate an increase in GHGE alt. LUD.

4. Discussion

This review is, to our knowledge, one of the first to systematically assess the current state of knowledge of the environmental impact, expressed as changes in GHGE and LUD, of dietary change. The review includes peer-reviewed journal articles published over the past ten years.

4.1. Scientific basis

This review located 14 articles that met the inclusion criteria defined in this review. In accordance with what has been shown in Heller et al. (2013), this study illustrates that life cycle assessments (LCAs) of food is an expanding research field. Nine of the articles were published during just the two last years. Although there are still gaps in knowledge, the increased number of publications in this area has significantly contributed to a better understanding of sustainable production and consumption of food.

4.2. Potential to reduce GHGE

The results show that the potential to reduce GHGE from food consumption through dietary change can be substantial in regions with affluent diets. The reduction potential seems mainly to be dependent on the amount and type of meat and animal products included in the diet. Diets in which all meat and/or meat products are removed have the lowest GHGE. However, a healthier diet including meat can, according to the results, reduce the GHGE of the diet up to 35%. The impact is, however, largely dependent on what is considered to be a healthy diet, and in five of the 19 healthy dietary scenarios the reduction potential is less than 10%. The amount of red meat, and especially ruminant meat allowed in the healthy diets seem to be the decisive parameter for the climate impact of the diet. Another reason why the results vary is that some of the healthy dietary scenarios are based on organic production, which may lead to increased GHGE compared to conventional production system (Saxe et al. 2013). The difference in climate impact between different types of meat is also demonstrated by the results from the studies including scenarios where meat consumption is reduced or changed. Replacing all ruminant meat by poultry and pork can reduce the GHGE by up to 35%. Moderate reduction (up to 20%) in total meat intake (including white meat), in contrast, seems to have a negligible effect. In addition, the climate impact of the diet is, to a large extent, dependent on which foods that replace the meat, therefore, consumption of meat substitutes with high climate impact, such as cheese and air transported fruit and vegetables, should be restricted (Carlsson-Kanyama and Gonzalez 2009). Only eating necessary amounts of food has been identified as another priority measure to reduce GHGE from the diet (Garnett 2011) that also would be beneficial for health. Balancing the energy intake and expenditure can, according to the results in this review, reduce the climate impact of the diet by 0-10%, depending on the assumed energy requirements.

The GHGE from the reference scenarios, i.e. the current average diets in the studied populations, ranged from 0.9-1.7 and 1.5-3.2 tons (1.0 tons for Indian diet) of CO_2e per capita per year in the studies accounting for emissions up to farm gate and retail, respectively. The annual GHGE for the average EU citizen are around nine tons of CO_2e (EEA, 2012), which means that food consumption is responsible for about 15-35% of the total climate impact. Based on the these figures, the potential to reduce the total per capita GHGE through dietary change is about 3-20% for a transition to a vegan or vegetarian diet and up 12% by a transition to either a healthier diet with restricted intake of red and ruminant meat, or a diet in which the meat content partially been reduced and/or red or ruminant meat has been substituted by white or monogastric meat.

4.3. Potential to reduce LUD

Also the potential to reduce the LUD from the diet through dietary change may be considerable. It should, however, be kept in mind that the impact on LUD in this paper is based on only four articles. The potential to reduce the LUD of the diet appears to be largely dependent on the amount of ruminant meat consumed. Substituting all meat with plant-based food can, according to the results, reduce the land demand from the diet by up to 60%. According to Audsley et al. (2010) a replacement of 75% of the ruminant meat with pork and poultry can reduce the land demand by 40%. Replacing half of the consumption of pork and poultry with plant-based food would, on the contrary, only reduce the LUD by 5%. A healthy diet including meat may therefore also have a large potential to free land, if the consumption of red meat is limited. Diets including ruminant meat have previously been suggested to increase the number of people that can be fed from the same land area compared to vegan diets up to the point that land limited to pasture and perennial forages has been fully utilized (Peters et al. 2007). However, maximum output of food is necessarily not the primary objective, given that released land also can be used for bioenergy production, for example (Fazeni and Steinmüller 2011). Either way, as will be discussed further, differentiation between types of land is essential to fully understand the effect of diet on LUD.

The LUD of the reference dietary scenarios ranged from 1400-2100 m^2 per capita. This can be compared to the current global per capita availability of agriculture land which is about 7000 m^2 (divided between approximately 30% arable land and 70% pasture) if global croplands are assumed to be distributed equally across the population.

4.4. Identified research gaps

4.4.1. Differentiation on individual, regional and social level

The general approach to study the impact of dietary choices by using scenario analysis is to use a reference scenario based on the average per capita consumption in the population studied. Since consumption patterns and nutritional requirements differ depending on, for example, gender, age and physical activity level, it would be interesting to see more research on specific groups of the population. It is also noteworthy that all articles reviewed, except one, study the impact of dietary change in European countries/regions characterized by having affluent diets. To understand the impact of dietary change in a broader and global perspective similar studies are required in countries/regions with different habits, culture and conditions.

4.4.2. Differentiation of plant-based scenarios

Previous findings suggest that that plant-based food consumption based on self-selected diets tend to have a higher climate impact compared to plant-based consumption in hypothetical scenarios (Vieux et al. 2012). In plant-based hypothetical dietary scenarios, meat is often replaced by unprocessed foods such as pulses, cereals, salads, vegetables, fruit, nuts and seeds. Vegetarian diets are in general characterized by a higher proportion of these food groups (Craig 2010; Key et al. 2006), however, processed plant-based meat substitutes (e.g. processed soy, quorn, tofu, and tempeh) represent an increasingly important component of modern plant-based diets. The environmental impact of such processed vegetarian meat substitutes has so far only been investigated in a limited number of studies (Blonk et al. 2008; Davis et al. 2010; Finnagan 2010a; Finnigan et al. 2010b; Leuenberger et al. 2010; Nijdam et al. 2012; Nonhebel and Raats 2007; Xueqin and Ierland 2004). The results indicate that these products may have relatively high energy demands due to the higher degree of processing but a lower climate and overall environmental impact, in comparison to most types of meat. Few of the reviewed articles specify that these types of processed meat substitutes are included in the dietary scenarios. The potential and limitations for reducing the environmental impact of the diet through increased consumption of this group of food products requires further analysis.

4.4.3. Differentiation of agricultural land

Current global food supply is mainly dependent on cultivated land (Johansson 2005) why the pressure on agricultural land is especially intense on cropland. Previous studies indicate that dietary change, in particular, has the potential to free pasture land (Hallström et al. 2011). Of the land released through reductions and changes in meat consumption, for example, only 5-10% is estimated to consist of cropland (Hallström 2013). Others suggest that replacing beef with pork and poultry even may increase the total demand of cropland (Audsley et al. 2010). A net gain in cropland is also not obvious if consumption of dairy products is replaced by plant-based food or when monogastric meat is replaced by processed vegetarian meat substitutes (Audsley et al. 2010; Stehfest et al. 2009).

If the distinction is not made between different types of land, there is thus a risk of overestimating the land areas suitable for agriculture that can be released by reducing ruminant meat consumption as only a limited share of pasture land is suitable for cultivation. To avoid a situation where demand for agriculture land is exported to other countries where it might increase the risk for deforestation and other negative impacts connected to increased land use pressure, it may also be of interest to in a greater extent distinguish between domestic and foreign land use in dietary scenario analysis.

4.4.4. Accounting for uncertainty

Despite the knowledge of the uncertainty related to environmental and life cycle assessments, the environmental impact of dietary scenarios is in general reported in absolute numbers without standard deviations. This is questionable as it makes it difficult to evaluate the reliability of the results. According to the ISO standard, the interpretation phase in LCAs should include an evaluation of the completeness, sensitivity and compliance of the analysis (ISO 2006). This is required in order to help the reader to determine what conclusions can be drawn from the results and would be useful also in dietary scenario analysis.

4.5. Strengths and limitations

To minimize bias, this review includes only peer-reviewed journal articles selected by the use of predefined inclusion criteria. The aim has been to assess the articles with a high level of objectivity and transparency. A limitation with the study is that only a small number of articles which met the inclusion criteria were located. The limited number of articles can partly be explained by the novelty of the research field but is also due to the narrow inclusion criteria which excluded several relevant articles (Audsley et al. 2010; Eshel and Martin 2006; Kastner 2012; Macdiarmid et al. 2011; Marlow et al. 2009; Westhoek et al. 2011; Popp et al. 2010; Powell and Lenton 2012; Wirsenius et al. 2010; Stehfest et al. 2009). Relevant publications and data would perhaps also be found in non-English publications.

In this review, the majority of articles which quantify GHGE from the diet exclude emissions coming from direct and indirect land use change. The exceptions are Meier & Christensen (2012) and Holohan et al. (2013) who include GHGE from deforestation resulting from livestock supply chains. Greenhouse gas emissions from direct and indirect land use change are suggested to have substantial impact on the climate impact from agricultural products (Cederberg et al., 2011; Ponsioen and Blonk, 2012; Schmidinger & Stehfest, 2012), which means that the results on GHGE in this review may be underestimated.

The climate impact of diet is quantified based on the global warming potential (GWP) of GHE. In the fifth IPCC assessment report published in 2013 (Myhre et al. 2013) the GWP of methane over a time horizon of 100 years was increased from previously 25 to 34 kg CO_2e per kilograms of emissions. This review includes articles published before the new IPCC report was published and therefore use the lower GWP for methane in their calculations. This means that the climate impact of diets containing ruminant meat is likely to be higher than the results shown by this review.

In this paper the environmental impact of dietary scenarios is assessed only based on the emissions of GHGE and demand of agriculture land. These aspects can often, but not always, serve as indicators of other environmental impact categories such as eutrophication, acidification and loss of biodiversity (Rockström et al. 2009; Röös et al. 2013; van Dooren et al. 2014). However, for a full assessment of the environmental impact of the diet other environmental impact categories also have to be included. Within the wide concept of sustainable food production and consumption also several other aspects, of ecological, social and economic dimensions are included (FAO 2013). These aspects, however, go beyond the scope of this paper. In future studies interdisciplinary and holistic assessments of the diet which include more sustainability aspects are required.

5. Conclusion

This systematic review evaluates the potential of dietary change as a measure for more sustainable food systems. The results suggest that dietary change, in areas with affluent diet, can play an important role in reaching environmental goals, with up to 50% potential to reduce GHGE and LUD of the current diet. The reduction potential mainly depends on the amount and type of meat included in the diet but also on the environmental performance of the food substituting meat. In future research interdisciplinary and holistic assessments of the diet including more sustainability aspects are required. Improved knowledge is also needed on the uncertainty in dietary scenario studies, the environmental impact of substitutes and complements to meat, and the effect of dietary change in different groups of populations and geographical regions.

ABSTRACT

In life cycle assessments (LCAs) one of the fundamental methodological choices that needs to be made is allocation, especially in multiple-output systems. The difficulty with allocation is that it usually has an ambiguous basis and, thus, damages the credibility of LCA results. Allocation solutions are easily influenced by perspectives and worldviews of the analyst, and there are arguments as to whether, for instance, allocation methods, such as economic, biophysical or mass-based allocations, are suited to different case studies and decision-making situations. Therefore, rules for different multiple-output situations are needed. While there are LCA guidelines that provide rules for different multiple-output situations, they do not fulfill their purpose, being susceptible to interpretation and/or enabling different allocation choices. This is demonstrated here with an attributional LCA case study of one tonne of Finnish rainbow trout fillet.

Keywords: LCA guidelines, allocation, harmonization, rainbow trout

1. Introduction

One of the most argued about methodological choices in LCA is allocation, especially in multiple-output systems where allocation is needed between by-products (see e.g. Azapagic & Clift, 1999). Many studies have indicated that allocation can substantially influence the results, and the choice of allocation method usually has an ambiguous basis and, thus damages the credibility of LCA (see e.g. Curran, 2007; Reap et al., 2008). Allocation decisions are easily influenced by the perspectives and worldview of the analyst, and thus there are arguments as to whether, for instance, economic, biophysical or mass-based allocations are suitable in different case studies and decision-making situations. There are several ways to make allocations and different practices exist among LCA studies and also among LCA guidelines. While many of the recent LCA studies address multiple-output situations and emphasize the importance of the chosen allocation method, the choice of methods raises continuous debate within the research community. Guidelines, such as PAS2050 (PAS2050:2011, 2011) and the GHG-protocol (WRI/WBCSD, 2011), aim at providing a more unambiguous basis for LCA studies, also providing rules to solve multiple-output system situations using allocation. While such guidelines have been available for a while, only a few critical reviews have been published that estimate the success rate of LCA guidelines (see e.g. Ekvall & Finnveden, 2001). To our knowledge there have not been any reviews specifically targeting guideline allocation rules. The main objective here is to review critically the allocation rules and study the differences in recommendations of existing LCA guidelines for multiple-output situations, and, as an outcome, the possible differences in the final LCA results.

We chose Finnish rainbow trout fillet as our case product to study the existing LCA guidelines for multiple-output situations. The choice was made for three important reasons. Firstly, Finnish rainbow trout is the most cultivated food fish in Finland. In Finland, rainbow trout cultivation began to increase in the early 1980s and currently the production volume is around 12 million kilos per year, representing around 89 % of the total volume of fish cultivated in Finland (FGFRI, 2012). Secondly, in Finnish circumstances, the main environmental problem caused by fish cultivation is aquatic eutrophication. It is estimated that in Finland around 2 % of total aquatic phosphorous emissions and 1 % of total aquatic nitrogen emissions come from rainbow trout cultivation (Grönroos et al., 2006). In addition, climate impacts of rainbow trout are also an interesting subject of study because rainbow trout is considered to be a substitute for red meat, which is known for its high carbon footprint. Lastly, rainbow trout is an interesting case product because the production chain of rainbow trout has several multiple-output situations, for instance, between fish fillet and by-products of gutting and filleting. The most common multiple-output situations in seafood LCAs are between target fish and by-catch (capture fisheries), feed ingredients, by-products such as roe and by-products of gutting and filleting when the fish is processed.

During the past ten years there have been several LCA studies on seafood products and the methodologies for solving the multiple-output situations have varied. For instance, Ziegler et al. (2003) used economic allocation for cod. Meanwhile, Eyjólfsdóttir et al. (2003) allocated all environmental loads to filleting in fish processing in the LCA of cod. Winther et al. (2009) used mass allocation for seafood and Ayer & Tyedmers (2009) used system expansion for salmon, where fish processing waste replaced fertilizers. Allocation choices need to be made also between feed ingredients because many of the ingredients come from multiple-output situations. The choices for solving these multiple-output situations have varied among studies: Papatryphon et al. (2004) used economic allocation, Winther et al. (2009) chose mass allocation, and Ayer & Tyedmers (2009) used gross energy content. In general, the most used allocation methods for seafood LCAs are mass and economic allocation, but gross energy content and system expansion are also used in some studies (Ayer et al., 2007; Parker, 2012).

2. Methods

2.1. Functional unit, system boundaries and multiple-output situations

In this study we chose to do an attributional LCA study and the functional unit was one tonne of skinless rainbow trout fillet. The studied impact classes were climate change and aquatic eutrophication. The system boundaries included production of feed raw materials, production of feed, hatchery, farming, processing, packing, and transport (see Figure 1). Fish fillet, besides roe, is the only component for human consumption and the mass of the fillet is 52 % of the initial weight of the fish. The by-products of the process come from gutting and filleting and from roe. The by-products of gutting and filleting are sold to feed processing plants and used further as feed for fur-farming animals. The rainbow trout feed is a mixture of fish meal and oil (mainly sprat, eel and sandeel) and vegetable raw material, mainly soybean meal.

There are several relevant multiple-output situations in the LCA of cultivated rainbow trout. We chose to focus on the four main multiple-output situations (Figure 1):

1) fish meal and oil (both components of rainbow trout feed; ratio is 1:3)
2) soybean meal and oil (soybean meal is a component of rainbow trout feed)
3) round fish (whole fish) and roe
4) fish fillet and by-products of gutting and filleting

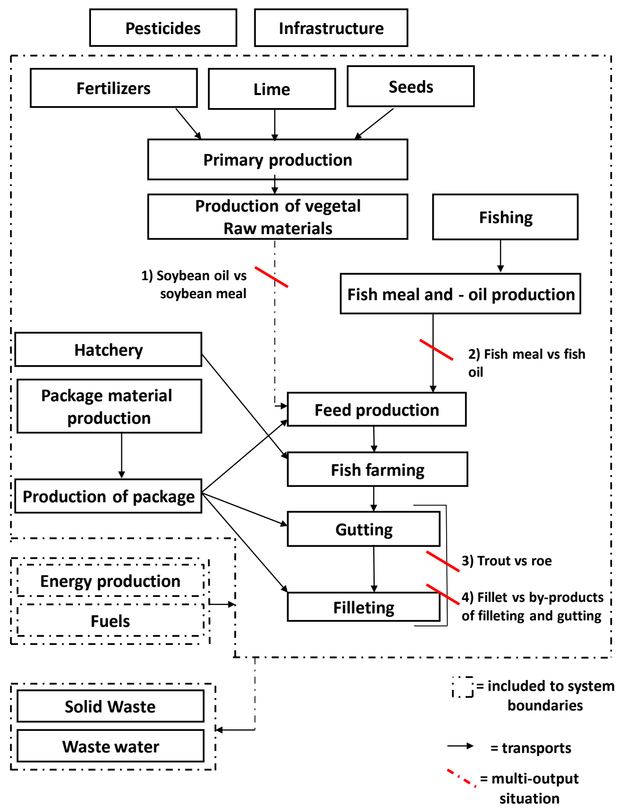

Figure 1. Multiple-output situations and system boundaries for Finnish rainbow trout.

2.2. Data sources

Rainbow trout production volumes and amounts of feed used were based on Finnish statistics and personal interviews (FGRFI, 2013; Kallioniemi, 2009, 2010). The data source of hatcheries was based on a single Finnish fish farming company (Puttonen, 2011) and the data for the nutrient emissions of the fish farm were based on official statistics (Environment Institute of South-West Finland). The fuel consumption of the boat traffic related to fish farming and electricity consumption for the fish farming were obtained from the pilot projects of the Finnish Game and Fisheries Institute (RKTL) (Kankainen et al., 2007, Setälä et al., 2009). The Plastics Europe database was used for the life cycle inventory data for polyethylene, polypropylene and polystyrene and the inventory data of the processing of the polystyrene into boxes used in fish transport. The material inputs for cultivation of one tonne of rainbow trout (round fish, before processing) are presented in Table 1.

The data for fish meal and fish oil production were based on data from a Danish producer (confidential). The modeling of the fish raw material production was based on the LCA Food-database. The inventory data for soybean cultivation were obtained from the Ecoinvent database (Jungbluth et al., 2007) and from da Silva et al. (2010).

Table 1. Energy and material inputs for production of Finnish Rainbow trout. One tonne of round fish.

Material input	
Light fuel oil, l/t	22
Electricity consumption, kWh/t	206
Nylon (Polyamid 6-6), kg/t	5.2
Polyethylene Terephthalate, kg/t	2.2
Polyethylene (HDPE), kg/t	5.8
Concrete, kg/t	13
Light fuel oil, l/t	22

2.3. Sensitivity analysis for allocation methods

In our study we built a basic case where the main four multiple-output situations were solved using allocation methods that we considered to be the most appropriate and systematic for each situation. The substitution method was not considered in the basic case because of a high level of uncertainty and because of arguments that the substitution method is not suitable for attributional LCA studies (Curran, 2007; Heijungs & Guinée, 2007). Furthermore, due to lack of practical examples of physical causality (see e.g. Schau & Magerholm Fet, 2008) we did not consider it here.

In the basic case, economic allocation was chosen for multiple-output situations between soybean oil and meal, round fish and roe, and fish fillet and by-products of gutting and filleting. In the case of soybean oil and meal, the economic value of oil is three times that of meal (FAO, 2011; Jungbluth et al., 2007) and since the products are produced for different purposes, economic allocation was chosen. In the situation between round fish and roe, roe is a very important by-product, having higher economic value (FGRFI, 2013), and thus we decided to use economic allocation. We chose to use economic allocation also between fish fillet and fish by-products of gutting and filleting because while the by-products of gutting and filleting represent around half of the weight of the fish, their economic value is very low. Furthermore, by-products of gutting and filleting would not be produced without also producing the fish fillet, and thus in our opinion more emissions should be allocated to the fillet. All in all, mass allocation was used only between fish meal and oil where mass allocation was chosen because both are of similar economic value and are used for the same purpose – as rainbow trout feed.

Besides the basic case we did a sensitivity analysis where we varied the methods to solve multiple-output situations and compared the results with those for the basic case. In addition to mass and economic allocation, the other methods used were 100-0 allocation, where all emissions were allocated to fish fillet, and a substitution method. Substitution was used between fillet and by-products of gutting and filleting. Both the processing waste from Atlantic salmon processing and captured Baltic herring from the Baltic Sea are used for fur animal feed, and thus the by-products of gutting and filleting of Finnish rainbow trout could replace both Baltic herring and the residues of Atlantic salmon processing. However, the use of Atlantic salmon processing waste as a substitute is problematic because allocation is also needed between Atlantic salmon fillet and its by-products. It should be discussed further whether the substitution method is possible if the substitute is derived using allocation. A second alternative is to assume that the by-products of rainbow trout processing replace Baltic herring, where no further allocation is needed. In this study we used the latter substitute, Baltic herring, because it does not require further allocation. What is interesting about Baltic herring is that it has negative eutrophication impact because fishing removes nutrients from the Baltic Sea.

The chosen LCA guidelines for our comparative study were ISO 14040/44 (ISO 14040, 2006; ISO 14044, 2006), ILCD-handbook (ILCD, 2010), GHG-protocol (WRI/WBCSD, 2011), PAS standard for seafood products (PAS 2050-2, 2012) and PCR Basic Module for seafood products (PCR, 2010). Only the given allocation rules of each guideline were applied.

3. Results

3.1. Basic case and sensitivity analysis

The carbon footprint of rainbow trout fillet was 4.3 t CO2-eq/t of fillet when using the basic case to solve the multiple-output situations. The sensitivity analysis showed a range of 2.3-5.2 t CO2-eq/t of fillet. The lowest result was received when only mass-based allocation was used and was highest when all was allocated to the fillet. The results of eutrophication impact were partly similar to those for carbon footprint. The eutrophication impact was 38 kg PO4-eq/t of fillet in the basic case, while when mass allocation was used, the eutrophication impact was 22 kg PO4-eq/t of fillet, and when everything was allocated to the fillet, the eutrophication impact was over 45 kg PO4-eq/t of fillet. When substitution methodology was used, the eutrophication impact was 57 kg PO4-eq/t of fillet, because fewer nutrients were removed from the Baltic Sea with captured Baltic herring. So, as a result from the sensitivity analysis, allocation had a marked effect on the final results of the LCA for Finnish rainbow trout. The sensitivity analysis showed that the most important multiple-output situations is allocation between fillet and by-products of gutting and filleting, where mass allocation halves the emissions compared with economic allocation.

3.2. Comparative study of guideline allocation rules

Overall, as shown in Table 2, the LCA results varied greatly within and among the LCA guidelines. The comparative study of allocation rules of the chosen LCA guidelines is based on our interpretation of the guidelines. To improve the transparency of results we have also explained our interpretations here.

The ISO-standard recommends substitution and that is why it was chosen when viable for multiple-output situations between fillet and by-products of gutting and filleting. The other multiple-output situations were solved using both mass and economic allocation because the standard does not recommend one over the other (ISO 14040, 2006; ISO 14044, 2006).

In applying the ILCD-handbook guidelines, substitution is not allowed in attributional LCAs. In attributional LCAs the handbook recommends avoiding allocation or solving it using physical-causal relationships, but neither was viable and therefore the third option, economic allocation, was chosen for all multiple-output situations when using the ILCD-handbook (ILCD, 2010).

The GHG Protocol substitution method was not used between fillet and the by-products of fish gutting and filleting because while the protocol recommends substitution over allocation, it states that it has to be known exactly what product is replaced and in our study it was not evident that Baltic herring was the appropriate substitute. In other multiple-output situations both mass and economic allocation were used because the Protocol does not clearly recommend one over the other (WRI/WBCSD, 2011).

In applying the PAS standard for seafood products, avoiding allocation was not a possibility, and thus the second option, mass allocation, was chosen. Furthermore, substitution was used both between fillet and the by-products of fish gutting and filleting (PAS 2050-2, 2012).

The PCR Basic Module for seafood products (PCR, 2010) recommends mass allocation. However, the choice of mass allocation was not obvious because the Supporting Annexes of PCRs state that low-value by-products should be regarded as waste and nothing should be allocated to the low-value product (EPD, 2008). However, because of the difficulties in interpreting the instructions and because of the substantial effect on the results, we decided to present both results, where emissions were first allocated to by-products of gutting and filleting based on mass, and secondly where no emissions were allocated to by-products of gutting and filleting.

Table 2. The carbon footprint (CFP) and eutrophication impact of one tonne of Finnish rainbow trout when the only variant is the allocation method based on recommendations of different LCA guidelines.

Allocation recommendation based on:	Recommended allocation method	Carbon footprint (kg CO_2-eq/ kg fillet)	Eutrophication (kg PO_4^{3}-eq/ t fillet)
ILCD-handbook	Economic	4.2	38
ISO 14040/44	Physical (mass) – Economic + Substitution (by products of gutting and filleting)	4.1 – 4.3	38 – 57
GHG Protocol	Physical (mass) – Economic	2.4 – 4.3	- (only CFP)
PAS2050-2	Mass + Substitution (by products of gutting and filleting)	4.1	- (only CFP)
PCR Basic Module for seafood products	Mass – Mass but emissions are not allocated to by-products of gutting and filleting	2.4 – 4.4	22–39

4. Discussion and conclusion

Seafood LCAs use various allocation methods and the LCA guidelines aim at providing more unambiguous rules for different multiple-output situations. In this study we did a comparative study for different LCA guidelines and interpreted the allocation rules. To our surprise it proved quite difficult to interpret guideline allocation rules even with substantial expertise – having conducted several food LCAs during past two decades. Another surprise was the variation in allocation rules within and among the current LCA guidelines. If our interpretations of the guidelines are accurate, the results vary greatly when using different recommendations, even when the only variant is choice of allocation method. Moreover, while it was not studied here, it is possible that other methodological recommendations (based on the LCA guidelines) could result in much wider variation in the results.

Application of the substitution method was also challenging. The right replacement product was not self-evident. The choice of replacement product for the by-products of gutting and filleting would have a major impact on our comparative study of guidelines. When assuming that processing waste of rainbow trout replaces Baltic herring, the eutrophication impact of fillet rises sharply because fishing of Baltic herring would actually reduce nutrients in the Baltic Sea. Overall, one of the main conclusions is that one has to be careful when using the substitution method. For instance, the GHG Protocol does not recommend substitution when there is uncertainty in defining the substitute (WRI/WBCSD, 2011).

Generally, both the sensitivity analysis and standard comparisons show that allocation has a marked effect on the final results of the LCA for Finnish rainbow trout fillet. When using mainly economic allocation, the environmental impact of a trout fillet can almost double compared with the situation where mainly mass allocation is used. One good partial solution to avoid misunderstandings and improve comparability of LCA studies is to provide arguments for the chosen allocation methods and to conduct a sensitivity analysis – presenting the results of the sensitivity analysis when communicating the final results of the LCA studies. Additionally, our study shows that because the LCA guidelines studied differ from each other they can also be interpreted differently. To reduce the ambiguity of LCA studies we suggest that more work needs to be done to improve recommendations for multiple-output situations and to harmonize the current LCA guidelines.

ABSTRACT

We compared three rice production systems, the system using a pelletized nitrogen concentrated organic fertilizer, the system using a conventional organic fertilizer, and the system using a chemical fertilizer, by calculating life cycle greenhouse gas (GHG) emissions. Two-dimensional uncertainty regions were introduced into the land-oriented expression, which was established to assess efficiency of agricultural production systems on the basis of constant returns to scale (CRS) and variable returns to scale (VRS), to analyze stability of the comparison. The results indicated that the rice production system using a high nitrogen organic fertilizer was recognized as a promising alternative and that this approach was useful in understanding the stability of the results through detecting overlaps among uncertainty regions.

Keywords: uncertainty, trade-offs, organic fertilizers, yield fluctuations, methane emissions

1. Introduction

Life cycle assessment (LCA) has been applied to measure potential environmental improvements achieved by the introduction of new agricultural practices (Notarnicola et al. 2012; van der Werf et al. 2014). A typical approach is to make comparisons among several alternative agricultural production systems. For example, many comparisons have been made between organic and conventional crop production systems using LCA (Hayashi 2013; Hokazono and Hayashi 2012; Nemecek et al. 2011; Williams et al. 2010). A remarkable result in the earlier comparisons among agricultural production systems is the presence of trade-offs between environmental and economic indicators. Since improvements in area-based environmental indicators tend to entail decrease in crop yield, it is necessary to conduct an analysis of trade-offs on the two-dimensional space. In order to illustrate the implication of the space, we coined the term “land-oriented expression”, which is contrasted to “product-oriented expression” that is equivalent to a system model using the functional unit of product weight (Hayashi 2013).

The existence of hot spots in life cycle environmental impacts, however, can make the technological improvements negligible. For example, the degree of decrease in greenhouse gas (GHG) emissions from paddy rice cultivation embodied by substituting improved agricultural inputs for conventional ones can be smaller than the range of methane emission fluctuations from paddy fields.

Therefore, we extend the trade-off analysis by explicitly introducing uncertainty modeling in order to more properly assess improvement potential of agricultural technology development. In other words, uncertainty representation is introduced into the two-dimensional land-oriented expression to focus our attention to the trade-offs and to detect stability of the results.

2. Methods

2.1. An outline of the case study

The decision problem we analyzed in this study was whether to select organic fertilizers for paddy rice cultivation in Niigata Prefecture, one of the main rice production areas in Japan. Because of increased public needs to establish environmentally sustainable rice production systems, we made a research project to establish rice production systems using organic fertilizers, which are expected to resolve the problems cause by the excess of manure from livestock production. However, the application of conventional organic fertilizers makes the prediction of the response of rice plants to the application of fertilizer nitrogen difficult. Moreover, it can be a cause of lodging and yield instability.

We expected that the development of nitrogen concentrated organic fertilizers using closed composting facilities would be a promising method to resolve the problem. Therefore, we assessed the potential improvements by applying the nitrogen concentrated organic fertilizers to paddy rice production systems using life cycle assessment.

2.2. System description

We compared three rice production systems; the system using a pelletized nitrogen concentrated (high nitrogen) organic fertilizer made from poultry manure through the use of closed-air composting techniques, the system using a conventional (low nitrogen) organic fertilizer made from poultry manure using open-air composting techniques, and the systems using a chemical compound fertilizer.

This study is an ex-ante assessment because there are no facilities for making the high nitrogen organic fertilizer in Niigata Prefecture and thus we have constructed rice production scenarios to use the organic fertilizer. High and low nitrogen fertilizers prepared at two commercial companies in Mie Prefecture were used for field experiments at Niigata Agricultural Research Institute.

Furthermore, we analyzed the effects of system expansion because the use of manure necessitates considering the application of inventory models with substitution (avoided burden) (De Vries et al. 2012; Hamelin et al. 2011; Lopez-Ridaura et al. 2009; Martinez-Blanco et al. 2011a; Martinez-Blanco et al. 2010; Martinez-Blanco et al. 2009; Martinez-Blanco et al. 2011b; Prapaspongsa et al. 2010).

2.3. Analytical framework

There are two important factors in calculating life cycle GHG emissions from paddy rice production. One is direct emissions of methane from paddy fields and the other is crop yields. Earlier applications of LCA to rice illustrates that more than half of life cycle GHG emissions from rice production can be attributed to methane emissions (Blengini and Busto 2009; Hokazono and Hayashi 2012). In comparing organic and conventional rice production systems, for example, life cycle GHG emissions per product unit for each production system are highly dependent on crop yields (Hayashi 2013). In other words, even if life cycle GHG emissions per area unit from organic production are smaller than those from conventional production, life cycle GHG emissions per product unit from organic production tend to become larger than those from conventional production. The importance of these two factors implies that uncertainties due to the two factors are also high.

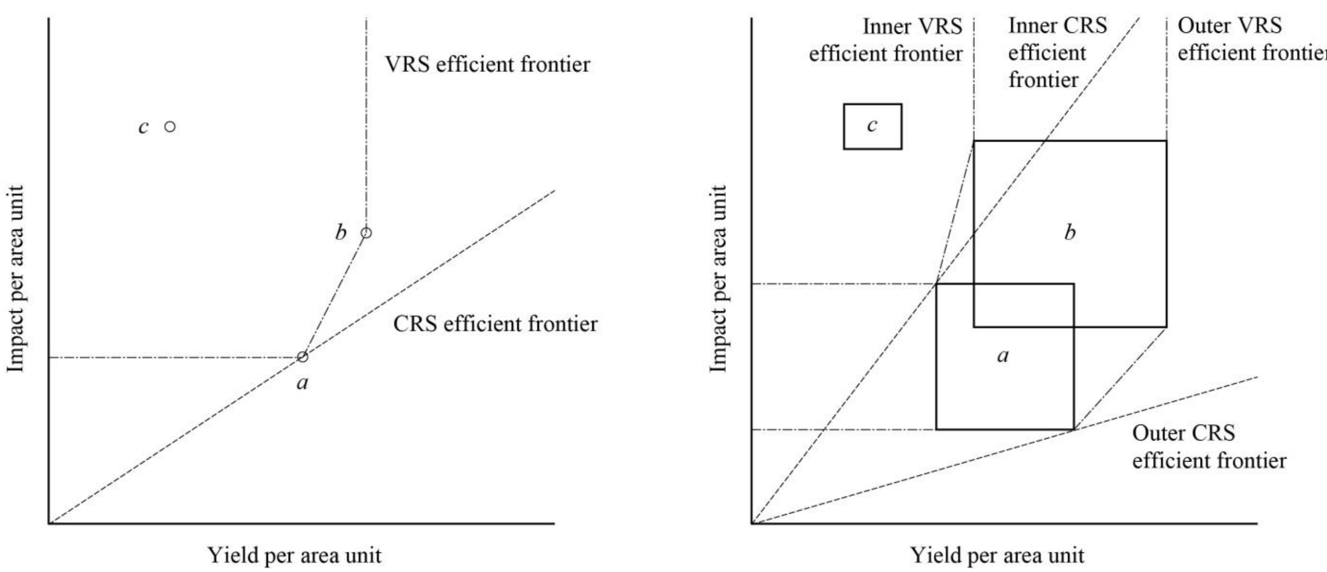

Figure 1. Two efficiency concepts defined on land-oriented expressions with and without uncertainty regions. (*a*, *b*, and *c* indicate the respective production systems.)

We apply the land-oriented expression (Hayashi 2013) to analyze the two factors. That is, using the two-dimensional space, in which the horizontal axis measures yield levels and the vertical axis measures the levels of life cycle GHG emissions, we explicitly depict uncertainties in the two factors. The land-oriented expression has an additional advantage to illustrate two efficient concepts, although the purpose of this study is the comparison and not the final selection (Figure 1). One is a concept based on constant returns to scale (CRS) and forms a straight efficient frontier, which is equivalent to the case of the product-oriented expression. The other is based on variable returns to scale (VRS) and forms a piece-wise linear efficient frontier.

In this study, we extend the expression by introducing two-dimensional uncertainty, which is depicted as an uncertainty region. As a result, outer and inner efficient frontiers are defined. In this case, the difference in efficiency between the production system a and b is somewhat inconclusive, although both a and b are more efficient than c under CRS and VRS technologies. More precisely, the efficiency orders are summarized as follows:

- the efficiency order under the CRS technology without considering uncertainty: $a \succ b \succ c$,
- the efficiency order under the VRS technology without considering uncertainty: $a \sim b \succ c$,
- the efficiency order under the CRS technology with considering uncertainty: $a \sim b \succ c$, and
- the efficiency order under the VRS technology with considering uncertainty: $a \sim b \succ c$.

2.4. Inventory data

The foreground process data were prepared on the basis of multi-year field experiments. The Japan Agricultural Life Cycle Assessment (JACLA) database (Hayashi et al. 2012) was used for background processes such as agricultural inputs including fertilizers, pesticides, and farm machines.

Data for rice cultivation are based on conventional rice production systems defined by Niigata Prefecture (Maruyama et al. 2009; Niigata Prefecture 2011). Crop yield data are gathered from field experiments at Niigata Agricultural Research Institute from 2009 to 2013 (from 2010 to 2013 for cultivation using the low nitrogen organic fertilizer). The yields are estimated using unit acreage sampling with three repetitions (Niigata Prefecture 2011).

Inventory data for organic fertilizers were prepared using experimental results conducted at Mie Prefecture Agricultural Research Institute. GHG emissions from composting processes were estimated on the basis of material balances. Emission factors for methane and dinitrogen monoxide in Greenhouse Gas Inventory Office of Japan (GIO) (2009) were used. Construction data for composting and pelletizing machines were gathered through surveys at companies.

Energy use in burning poultry manure, which was used for system expansion, was based on data available from a company in Miyazaki Prefecture. Transportation was not considered because system expansion was applied to get approximate effects of burning instead of composting.

Data on direct methane emissions from paddy fields were prepared using the results of field experiments at Niigata Agricultural Research Institute from 2009 to 2013 (from 2010 to 2013 for cultivation using the low nitrogen organic fertilizer). Measurement of methane flux was based on Minami and Yagi (1988).

2.5. Impact assessment

The impact category of global warming (IPCC 2006, 100 years) was used in impact assessment. Although we think that the other environmental impact categories such as eutrophication and acidification are important in assessing agricultural production systems with special attention to organic fertilizers, we used the category as an initial step.

3. Results

The results are illustrated in Figure 2. Horizontal ranges of the uncertainty regions show uncertainty intervals derived from annual fluctuations of crop yields. Vertical ranges are uncertainty intervals of GHG emissions derived from annual fluctuations of methane emissions. We present the results on overlaps among uncertainty regions, CRS and VRS efficiency, and the system expansion in sequence.

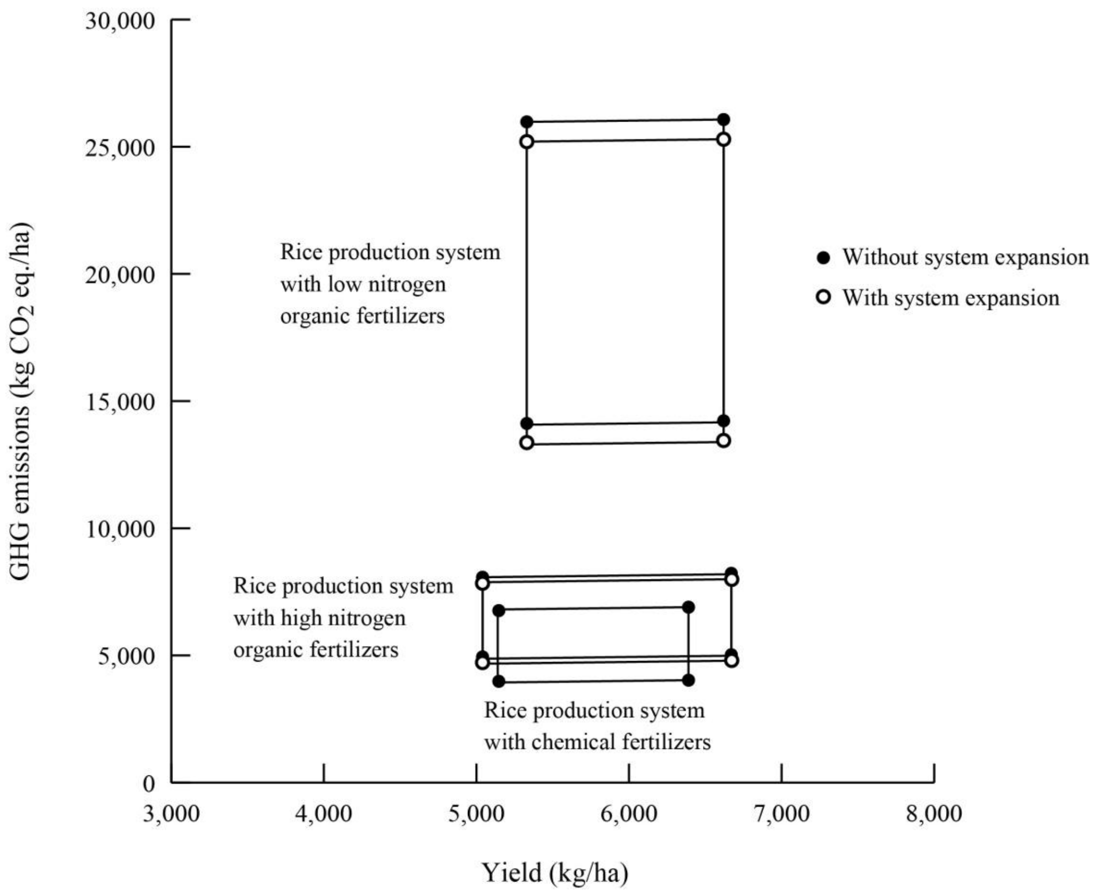

Figure 2. Uncertainty regions for each rice production system

3.1. Overlap among uncertainty regions

The configuration of two-dimensional uncertainty regions revealed that there is an overlap between the production system using the high nitrogen organic fertilizer and the system using the chemical fertilizer and that no overlap between the two systems and the system using the low nitrogen organic fertilizer.

3.2. CRS efficiency

Lines through the origin separated the following two groups: (1) the production system using the chemical fertilizer and one using the high nitrogen organic fertilizer and (2) the production system using the low nitrogen organic fertilizer. It implies that the former was CRS efficient. In other words, life cycle GHG emissions per kg of rice (as a functional unit) from the former were smaller than those from the latter.

3.3. VRS efficiency

The uncertainty region for the rice production system with the low nitrogen organic fertilizer was contained in the region between outer and inner VRS efficient frontiers. Therefore, if we use the concept of strict efficiency, we can exclude it from the systems to be selected without using preferences (weighting).

3.4. System expansion

The graphical expression also showed that the effects of systems expansion were negligible as compared with the size of the uncertainty regions. The results presented already were applicable to the both cases with and without system expansion.

4. Discussion

In summarizing these results, it is pointed out that the use of the high nitrogen organic fertilizer is promising and that the two-dimensional expressions improve our understanding about stability of results.

However, there are some limitations. The first limitation is the method to determine upper and lower bounds in intervals. Because of arbitrariness in the determination, there may be some ambiguities in judgments based on intervals. Further studies are necessary for this direction, because the problem of arbitrariness will be found in uncertainty analysis using the pedigree matrix, which is implemented in LCA software such as SimaPro and commonly used in LCA.

The second limitation is related to field measurement techniques, which are a source of arbitrariness mentioned already. Although we limited our attention to uncertainty due to annual fluctuations, uncertainty due to measurement techniques is important in agronomy and should be included into uncertainty analysis in the next step of the study.

5. Conclusion

This paper demonstrated that a method to introduce interval-based uncertainty into the two-dimensional space to detect trade-offs between productivity and GHG emissions was useful in comparing several agricultural production systems and in understanding stability of the results. The approach used in this study can be modified into the framework of land use transformation. In this case, the topic is transition from a system with chemical fertilizers to a system with organic fertilizers. An important implication of this study is that the conclusion is not straightforward in the sense that the latter is efficient as compared with the former only if organic fertilizers are made efficiently. That is, transition to a bio-based system will be established only if efficient bio-material transformation techniques are fully developed.

6. Acknowledgements

This work was supported in part by the Ministry of Agriculture, Forestry and Fisheries, Japan through a research project entitled "Development of technologies for mitigation and adaptation to climate change in Agriculture, Forestry and Fisheries" and the Japan Society for the Promotion of Science Grant-in-Aid for Scientific Research [(C) 23580321 and (C) 26340110]. We are grateful to Dr. Keiichi Murakami for his valuable comments at the earlier stage of this study.

ABSTRACT

This work is a review of Life Cycle Assessment (LCA) studies dealing with agricultural use of fertilizing residues (FR). The majority of the studies were dedicated to LCA of waste and wastewater treatment systems and, in few cases, to agricultural productions. In most of the studies on LCA of waste and wastewater treatment, FR spreading induces toxicity due to heavy metals and global warming and atmospheric pollution because of emissions of nitrogen compounds. When a livestock is studied, FR spreading is generally a minor contributor to the impact compared to livestock building and animal manure stocks. The fertilizing effect of FR is taken into account by substitution of mineral fertilizers. Substitution of mineral fertilizers is the main driver of the environmental assessment result. Unfortunately, the substitution is not always explained or presented in the different studies, which makes interpretation of the results difficult. This variability of system boundaries also affects the results.

Keywords: Field application, Residues, Waste treatment, Wastewater treatment, Biosolids.

1. Introduction

Human waste and animal manures have always been used for agricultural production, but intensive farming and the increase of wastewater treatment capacity put this issue forward. Severe environmental burdens are due to intensive manure production (Mallin and Cahoon 2003), and toxicity of heavy metals contained in biosolids are often highlighted (Benítez et al. 2001).

Agricultural use of fertilizing residues (FR) is represented in several ways in Life Cycle Assessment (LCA) studies. This work is a review of LCA studies dealing with agricultural use of FR to show current LCA practices (key parameters, modeling choices for emissions and substitution) and main results of theses works. The review is presented per FR type: biosolids, organic part of municipal wastes, animal manures, digestates, and biochars.

2. Methods

The collection of articles for this review has been carried out in two steps. First, two queries have been made on the Web of Science (Thomson Reuters 2014) and CAB Abstracts (Cabi 2014) :

- Query dedicated to FR terms: "*waste*" or "residu*" or "sludge*" or "sewage*" or "biosolid*" or "*compost*" or "digestate*" or "anaerobic digest*" or "manure*" or "slurr*" or "effluent*" or "sediment" or "ash*" or "biochar" or "struvite" or "dredg*" or "by-product*" or "by product*" or "abattoir" or "dairy" or "whey" or "bone" or "ossein" or "feather" or "exogenous organic matter" or "organic amendment*".
- Query dedicated to LCA terms: "life cycle analysis" or "life cycle assessment" or "LCA" or "life cycle management" or "LCI" or "life cycle inventor*" or "impact assessment".

These queries crossed title and abstract fields in the database (FR terms in title field and LCA terms in abstract field, and vice versa) and yielded in 2229 references. To reduce the size of this set, a manual selection has been performed by scanning the abstracts to remove references

- not dealing with LCA,
- dealing with waste treatment without agricultural use (*e.g.* biosolid incineration, organic waste landfilling),
- dealing with agricultural production without FR use.

One hundred references have been selected with this approach, which are included in this study.

3. Results

The main part of the article collection is composed of recent articles from the last decade, with an overall time frame from 1998 to 2013. Figure 1 presents a word cloud built from titles of the articles. It shows that the collected articles mainly focused on waste and associated treatment (e.g. words like “waste”, “wastewater”, “municipal”, “solid”, “treatment” and “composting”). The word cloud underlines also the aim of LCA as environmental assessment of the system (“environmental”, “systems”, “greenhouse”, “emissions”, “evaluation”, “study” …). Agricultural words (“organic”, “production”, “application” and “farming”) appear, but with low occurrences.

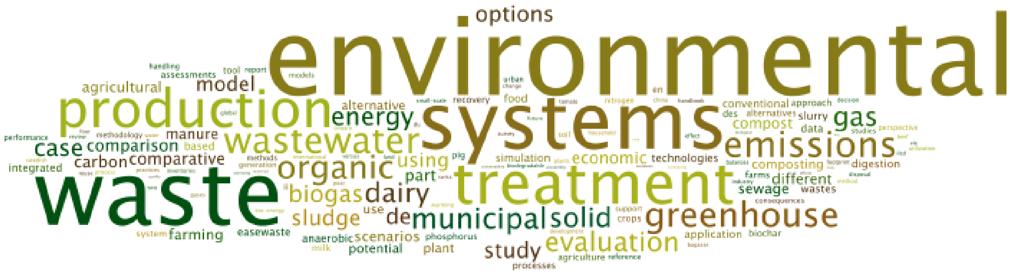

Figure 1. Word cloud from titles of the articles (words of the LCA query have been removed for better readability); The cloud was generated using the Wordle website (www.wordle.net).

4. Discussion

4.1. Overview

Few publications are dedicated only to FR uses. The main part of the literature is composed of environmental assessment of waste treatment, where agricultural use of FR is only a part of the studied system. Table 1 gives an overview of the important parameters of these publications.

When a system is multifunctional (several products or several services), substitution is often performed (avoided impacts due to avoided product). Consequently, in many cases, an agricultural use of FR is represented by an avoided mineral fertilizer production and use (41/45 references in Table 1). This allows for avoiding impacts due to production (resource consumption, plant pollution, transport …) and emissions after crop fertilization (trace metals to soil, nitrogen compounds emissions).

The key parameter for substitution of mineral fertilizers is the fertilizing effect of the FR, expressed by a Mineral Fertilize Equivalent (MFE) coefficient. But this parameter is often missing (29 references in Table 1). Noted by Heijungs and Guinée (2007) and underlined by Winkler and Bilitewski (2007), one of the main reasons for the variability of LCA results for waste treatment systems is the way how avoided impacts (due to energy or secondary matter productions) are taken into account in the system. Brockmann et al. (2014) provide a simple excel tools for MFE computation.

Emissions from spreading are dealt in three ways: (1) emissions are not taken into account (7 publications) or only partially (e.g. only heavy metals, 4 publications), (2) FR use emissions are represented, but avoided emissions not (13 publications), and (3) the difference between FR use and avoided mineral fertilizer use emissions is applied (4 publications).

4.2. Biosolids

About twenty articles deal with agricultural use of biosolids. Almost all consider the fertilizer role by substitution, but, unfortunately, the MFE value is sometimes missing, described in an internal report or it is referred to an author’s country study. When MFE values are provided (see Table 1), an important variability is observed for nitrogen equivalence, while phosphorus and potassium values are close to one.

Except for some studies (Dennison et al. 1998; Murray et al. 2008), heavy metals emissions to the environment are represented. Several authors underline the importance of this phenomenon and the induced toxicity (Hospido et al. 2004; Houillon and Jolliet 2005; Johansson et al. 2008; Wenzel et al. 2008).

Hospido and coauthors (Hospido et al. 2010) take into account thirteen drug residues in the toxicity assessment through a new characterization factor for the CML method (Muñoz et al. 2009). In this work and with this approach, the authors conclude that the drug residues’ impact is negligible compared to the heavy metals burden.

[d] EASEWASTE model references: (Kirkeby et al. 2006a; Kirkeby et al. 2006b; Christensen et al. 2007; Bhander et al. 2008; Boldrin and Thomas-Hojlund 2008; Bhander et al. 2010; Boldrin et al. 2010; Bernstad and la Cour Jansen 2011; Manfredi et al. 2011; Andersen et al. 2012)

Some works do not deal with nitrogen and phosphorus emissions to the environment due to FR spreading (Beavis and Lundie 2003; Hospido et al. 2005; Houillon and Jolliet 2005; Tarantini et al. 2007; Murray et al. 2008; Hong et al. 2009; Peters and Rowley 2009; Liu et al. 2013; McDevitt et al. 2013) and deal only with the benefit of avoided fertilizer. Other works present agricultural field emissions without description (Pasqualino et al. 2009), according to the ORWARE model (Kärrman and Jönsson 2001; Lundin et al. 2004; Tidåker et al. 2006), partially without nitrate leaching (Lundin et al. 2000), according to experimental data (Johansson et al. 2008) or determined according to models (Nemececk and Schnetzer 2012) proposed by Ecoinvent guidelines (Foley et al. 2010; Hospido et al. 2010). To finish, few works (Sablayrolles et al. 2010) consider both FR emissions and avoided emissions due to avoided mineral fertilizer use. Recently, Yoshida et al. (2013) reviewed 35 LCA studies dedicated to sewage sludge treatment (28 with agricultural use). This work shows the variability of the perimeters: 11 references with emissions to air during biosolids spreading, 11 with heavy metals emissions to soil, and 2 with carbon storage. A substitution of mineral fertilizer is done in 25 of them.

4.3. Organic fraction of municipal wastes

The use of LCA to assess waste treatment scenarios leads to dedicated simulation models. About 10 models can be found (Gentil et al. 2010), but only two have been used and take into account FR use.

ORWARE (ORganic WAste REsearch) (Dalemo et al. 1997; Eriksson et al. 2002) is a Swedish model, which has been used for real cases of waste management (Sonesson et al. 1997; Sonesson et al. 2000; Mendes et al. 2003; Eriksson et al. 2005). The model focuses mainly on climate change, acidification and eutrophication; toxicity is not addressed. FR spreading is represented with a substitution and field emissions: a simplified model of the nitrogen cycle allows determining nitrogen emissions (N_2O, NH_3, NO_3^-) and the nitrogen content replacing mineral nitrogen in the first year and the long-term. Ammonia losses are determined by Swedish experimental values, nitrate leaching by a simulation model with soil features, and nitrous oxide emissions according to IPPC recommendations. Phosphorus dynamics are assumed analogous for FR and mineral fertilizer. Dalemo et al. (1998) discuss the importance of nitrogen emissions due to FR use for the assessment of waste management scenarios. Thomsson (1999) uses ORWARE and mentions heavy metals, but without assessment because of complexity of the soil-plant mass balance.

EASEWASTE (Environmental Assessment of Solid Waste Systems and Technologies) (Kirkeby et al. 2006a; Bhander et al. 2008; Bhander et al. 2010) is a Danish model and is probably the most used LCA waste treatment tool. Assessment is carried out with the EDIP method (Wenzel et al. 1997). The model includes mineral fertilizer substitution and nitrogen, phosphorus, heavy metals and trace organic compounds emissions. Carbon storage is also modeled. However, the FR use module of the EASEWASTE model is only described in a Danish document (Hansen 2004). Effects of FR use on soil quality are not represented because of the complexity of the relation. This model shows the consequences of heavy metal emissions from agricultural residues (Kirkeby et al. 2006b) and underlines the major role of final waste destination to waste treatment assessment (Christensen et al. 2007).

EASEWASTE has been used to compare incineration, landfilling and composting of individual waste fractions (Manfredi et al. 2011). The authors observe a benefit for the composting scenario on ecotoxicity because of avoided emissions of mineral fertilizer production (chromium and mercury). EASEWASTE has been used to assess commercial compost from food waste and garden waste, which is used as growth media preparation instead of peat (Boldrin and Thomas-Hojlund 2008; Boldrin et al. 2010). The benefit of this compost on climate change (because of biogenic carbon) and eutrophication (avoided nitrogen emissions of mineral fertilizer production) is shown, but it is tempered by heavy metals emissions to soil.

Some authors (Bernstad and la Cour Jansen 2011; Andersen et al. 2012) represent the organic matter supply effect of the use of compost from household food waste by a peat substitution (substitution according to volume, 1 m^3 of peat for 1 m^3 of compost). They consider that the environmental burden is mainly determined by greenhouse gases emissions from the composting process and the benefit from the substitution (climate change, eutrophication, toxicity and ecotoxicity). Andersen et al. (2010) investigated substitution practices for compost use in gardening in two Danish towns (Aarhus and Copenhagen). This work shows a substitution only for 22 and 24% of the situations for peat, 12 and 24% for fertilizer, and 7 and 15% for manure.

Bernstad and la Cour Jansen (2012) reviewed LCAs for food waste management, mainly with respect to climate change. They reveal a large variability of the results and that the use of compost and digestate is profitable from an environmental point of view in some works, but negligible in other ones. The variability of the results is explained by the MFE value, the environmental impact of substituted fertilizer and carbon storage. The authors advise to consider nitrogen emissions from fertilizers in accordance with international recommendations (as ILCD) for impact assessment. But variability and lack of knowledge are again underlined. Only one reference with FR and avoided emissions is cited (Møller et al. 2009).

While most publications deal with waste treatment scenarios, Martinez Blanco et al. (2009) compare mineral fertilization to the use of compost from municipal organic waste for tomato crops. In this case, the use of compost avoids landfilling and landfill impacts are subtracted to the system: this substitution drives the environmental impacts and sets compost as best solution. A similar work, yielding in the same conclusions has been done for compost from wine shoot and sewage sludge (Ruggieri et al. 2009).

4.4. Animal manures

About twenty articles dedicated to cattle and pig productions have been found. Manure and slurry spreading is commonly represented. FR use impacts are usually negligible in comparison to emissions from livestock building and animal manure storage (Beauchemin et al. 2010; O'Brien et al. 2011) (and also for poultry production (Leinonen et al. 2012)). Animal manure storage and spreading are also often merged in a single step (Sonesson 2005; Thomassen et al. 2009).

First works on livestock LCA (Cederberg and Mattsson 2000; Cederberg and Flysjo 2004; Sonesson 2005) used a Swedish model for nitrate leaching (Aronsson and Torstensson 2003). Recent works (Fantin et al. 2012; Jan et al. 2012) follow EcoInvent guidelines (Nemecek and Kägi 2007; Nemececk and Schnetzer 2012) for all emissions. When EcoInvent is not used, emissions are usually computed by national references and models (Anton et al. 2005; Antón et al. 2005; Cooper et al. 2011; Leinonen et al. 2012; Uchida and Hayashi 2012). But nitrous oxide and methane emissions are determined in most of cases by IPCC guidelines (Cederberg and Mattsson 2000; Beauchemin et al. 2010; Hörtenhuber et al. 2010; Rotz et al. 2010; O'Brien et al. 2011; Yan et al. 2011; Fantin et al. 2012; Mc Geough et al. 2012; O'Brien et al. 2012; Bonesmo et al. 2013). The use of IPCC guidelines is also found for crop production studies (Mattsson and Wallen 2003; Cooper et al. 2011; Kimming et al. 2011; Nemecek et al. 2011a; Nemecek et al. 2011b; Hakala et al. 2012). Langevin et al. (2010) work on nitrogen emissions from slurry spreading. From a literature review, they show that pedoclimatic conditions imply a variability of LCA results that can be larger than the variability resulting from spreading technics.

Nemecek and coauthors (Nemecek et al. 2011b) underline the interest of animal manure use as fertilizer with regard to resource depletion (fossil and mineral) and soil quality. This benefit is tempered by nutrient leaching due to management complexity of the organic fertilization.

4.5. Digestates

Recently, several environmental studies of anaerobic digestion plants with agricultural use of the digestate have been published. Here, again, emissions are often computed according to EcoInvent guidelines (Jury et al. 2010; De Vries et al. 2012; Poeschl et al. 2012b; Poeschl et al. 2012a). Jury et al. (2010) used an allocation approach instead of substitution to represent digestate use. A monetary value of the avoided mineral fertilizer was used. Hamelin et al. (2011) compared slurry spreading to anaerobic digestion and digestate spreading. The MFE value followed Danish legislation. Nitrous oxide emissions were calculated according to IPCC guidelines, and other nitrogen emissions were determined with a Danish model. Carbon storage was represented according to (Petersen et al. 2002). This work incorporates crop yield variations according to fertilizer type (mineralization process of the anaerobic digestion step; the nitrogen of digestate is more available for plants than nitrogen from slurry; an increase of 9 kg of wheat per kg of nitrogen was considered). Crop yield variations are represented by avoided wheat production. However, the assessments are mainly driven by avoided fertilizer, with the yield increase effect being negligible.

4.6. Biochars

Recent works focused on agricultural use of biochar (Kameyama et al. 2010; Roberts et al. 2010; Hammond et al. 2011; Ahmed et al. 2012; Mattila et al. 2012; Cao and Pawlowski 2013; Sparrevik et al. 2013). Carbon storage is usually the driver of the study and biochar use appears as an interesting solution. Cao and Pawlowski (2013) underline also the benefit on climate change and the energetic balance because of avoided mineral fertilization (They assume that biochar soil-enrichment implies a decrease of 10% of mineral nitrogen, phosphorus and potassium fertilizer use because of better nutrient bioavailability).

5. Conclusion

Agricultural use of residues is a common way for waste valorization and the fertilizing function is often represented in LCA of waste treatment systems. The use of residues as fertilizer induces usually significant impacts on the ecosystems due to heavy metals and on climate change and atmospheric pollution because of nitrogen compounds emissions. The benefit from the avoided mineral fertilizer production can counter balance the impacts from spreading emissions, but, unfortunately, this substitution is often misdescribed or only partially documented. Because MFE is a key parameter for LCA of agricultural use of residues, it should be clearly presented in the studies.

Field emissions of FR differ from mineral fertilizer emissions because of management practices and nitrogen forms. In LCA works, the variety of the system limit (no emissions, FR emission only or FR and mineral fertilizer balance) implies a variability of the results, which should be integrated in the interpretation of the results.

An LCA study dealing with agricultural use of residues should be carried out notably with:

- the references, the rules and/or the models and their parameters used to determine field emissions,
- the value used as MFE, supplemented with references and sensitivity analysis,
- a description of the system limit, which has to include the whole substituted system (mineral fertilizer emission from the production to the field emission).

Some aspects are not represented in LCA. Pathogens and health consequences are not assessed in LCA, which has to be highlighted for human waste and animal manure uses. LCA works start to deal with this (Motoshita et al. 2010), but methods are not operational. Even if methods have been developed (Milà i Canals et al. 2007; Garrigues et al. 2012), the effects of the FR organic matter on soil quality is not taken into account. Recent publications deal with carbon storage and the consequences on climate change (this can be observed in publications dedicated to biochar, for example). This should be generalized in the next years.

6. Acknowledgments

This work is a part of a collective scientific expert assessment dedicated to agricultural use of residues (esc-MAFOR), which is led by the French National Institute of Agronomic Research (INRA), the French National Centre for Scientific Research (CNRS) and the French National Research Institute of Science and Technology for Environment and Agriculture (IRSTEA). The authors would like to thank M. Pradel for the valuable exchanges about this review.

ABSTRACT

Langlois et al. (2012; 2014a) proposed characterization factors (CF) for fish biotic resource extraction impact assessment at the species level. This paper is an improvement of this approach. In the present work, the CF depends on the Maximum Sustainability Yield (MSY), weighted by the ratio of the current total fishing effort to the fishing effort at the MSY value. Because this ratio often cannot be computed from current databases, it is here obtained from the ratio of total catches to MSY and roots of the parabola linking catches to fishing effort. The new version of the CF is proposed for 125 fish stocks. This work allows assessment of fisheries in the LCA formalism. It contributes to a better representation of the depletion of biotic resources.

Keywords: Biotic resource depletion, Fisheries, Maximum sustainable yield, Characterization factor

1. Introduction

Food production is a major sector for environmental burden due to increase of foodstuff demand and food production intensification. The sea is more and more exploited for human food, and environmental assessment approaches have to take into account this use. Seafood products, coming from direct fishery activities or from aquaculture, where a part of the feeding comes from fish catches, induce a large consumption of biotic resources for human activities. An environmental assessment of these systems by Life Cycle Assessment (LCA) cannot be performed without a focus on this impact.

Langlois et al. (2014b) review the use of the sea in LCA and propose related impact pathways dedicated to the biodiversity damage potential, the ecosystem services damage potential, climate change, and the biotic resource damage potential. Recently, Emanuelsson et al. (2014) proposed new characterization factors (CFs) for fish resource depletion based on the lost potential yield (LPY). The LPY represents the average of lost catches owing to ongoing overfishing and is assessed by simplified biomass projections covering different fishing mortality scenarios. This useful approach provides CFs for 31 European fish species, but several parameters are needed: CFs are computed from (1) current biomass and fish mortality, and (2) target biomass and target fish mortality to Maximum Sustainability Yield (MSY).

The biotic resource damage potential is studied in Langlois et al. (2012; 2014a) for fishing activities at both species, for a given stock, and ecosystem levels. Proposed CF values have been used by Avadí et al. (2014). For the species level, CFs are built based on MSY and catches to deal with the biotic resource states. The present work is an improvement of CF determination at the species level.

2. Methods

2.1. Maximum Sustainability Yield.

The relation between catches and fishing effort is commonly modelled by a parabola, where the MSY is equal to the catches at the inflexion point (see Figure 1). Fish stocks are classically assessed with MSY: the highest fish catch that can be sustained in the long term (Graham 1935; Schaefer 1991). Fishery exploitation of a given stock at time t (C_t) can be increased up to a maximum level by increasing the fishing effort (E_t), because the catches are compensated by an equivalent fish production. Above the MSY and its corresponding E_{MSY}, renewal of the resource (reproduction and body growth) cannot keep pace with the removal caused by fishing and natural mortality. The MSY can be estimated either with a variety of stock-assessment methods or empirically. The most useful database for this is the RAM Legacy Stock Assessment Database (Ricard et al. 2012).

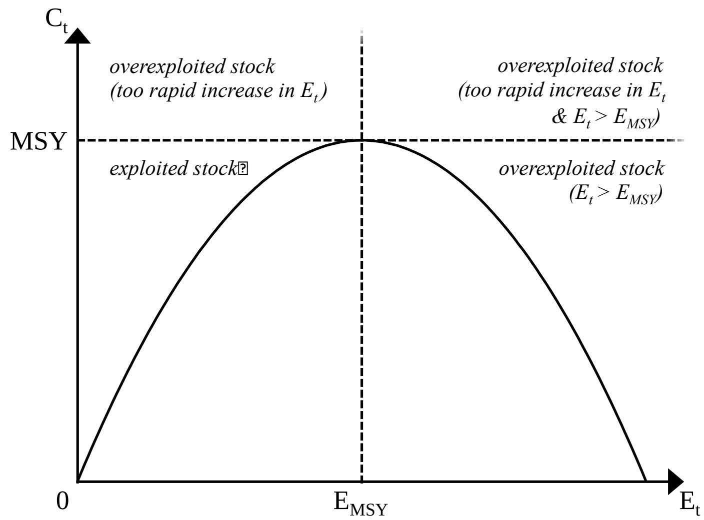

Figure 1. Fish catch (C_t) as a function of fishing effort (E_t) at the steady state

2.2. Characterization factors previously proposed

In Langlois et al. (2012; 2014a), CFs are computed as follows

$$\mathrm{CF} = \begin{cases} \frac{1}{\mathrm{MSY}} & \text{if exploited} \\ \frac{1}{\mathrm{MSY}} \times \frac{\mathrm{MSY}}{\bar{C}_t} = \frac{1}{\bar{C}_t} & \text{elseif} \end{cases} \quad \text{Eq. 1}$$

where $\bar{C}_t$ represents mean fish catches over five years prior to impact assessment to approximate the equilibrium value (if average catches are higher than the MSY due to non-equilibrium situation, $\bar{C}_t$ is set equal to MSY). For an exploited stock, CF allows to place landings in front of renewability of the stock. When the stock is overexploited, the ratio of MSY to $\bar{C}_t$ is added. The ratio varies from 1 to infinity for catch rates ranging from MSY to zero (i.e. when the stock is overexploited close to MSY or when it is severely depleted, respectively). The ratio allows introducing the seriousness of the overexploitation based on catches only, which are common data (unfortunately, fishing efforts are often unavailable data). See Langlois et al. (2014a) for the determination of the stock status (i.e. overexploited or not).

2.3. Improvement of the characterization factors

In the present work, to determine the CF, MSY is changed in accordance with the ratio $\frac{E_t}{E_{\mathrm{MSY}}}$, which describes the extent of exploitation or overexploitation. Let the relation presented in Figure 1 be

$$\bar{C}_t = -a_1 E_t^2 + a_2 E_t \quad \text{Eq. 2}$$

The derivative is the following:

$$\frac{d\bar{C}_t}{dE_t} = -2a_1 E_t + a_2 \quad \text{Eq. 3}$$

$$\left.\frac{d\bar{C}_t}{dE_t}\right|_{E_t = E_{\mathrm{MSY}}} = 0 = -2a_1 E_{\mathrm{MSY}} + a_2 \quad \text{Eq. 4}$$

With (2) and (4), we have

$$\bar{C}_t = -a_1 E_t^2 + 2a_1 E_{\mathrm{MSY}} E_t \quad \text{Eq. 5}$$

$$\mathrm{MSY} = -a_1 E_{\mathrm{MSY}}^2 + 2a_1 E_{\mathrm{MSY}} E_{\mathrm{MSY}} \quad \text{Eq. 6}$$

$$\frac{\bar{C}_t}{\mathrm{MSY}} = -\left(\frac{E_t}{E_{\mathrm{MSY}}}\right)^2 + 2\frac{E_t}{E_{\mathrm{MSY}}} \quad \text{Eq. 7}$$

The polynomial (7) allows finding the ratio of fishing effort to fishing effort for the MSY as a function of the ratio of catches to MSY. The roots are the following:

$$r_1 = 1 + \sqrt{1 - \frac{\bar{C}_t}{\mathrm{MSY}}}, r_2 = 1 - \sqrt{1 - \frac{\bar{C}_t}{\mathrm{MSY}}} \quad \text{Eq. 8}$$

and are used in the CF to weigh MSY

$$\mathrm{CF} = \begin{cases} \dfrac{1}{\mathrm{MSY}\left(1+\sqrt{1-\frac{\bar{C}_t}{\mathrm{MSY}}}\right)} & \text{if exploited} \\ \dfrac{1}{\mathrm{MSY}\left(1-\sqrt{1-\frac{\bar{C}_t}{\mathrm{MSY}}}\right)} & \text{elseif} \end{cases} \quad \text{Eq. 9}$$

This weight varies theoretically from 2 (unexploited resource) to 0 (totally depleted resource) and introduces a relative position for the stocks according to the fishing effort only with catches and MSY values.

3. Results

The RAM Legacy database includes biological reference points for over 361 stocks, of which 138 have MSY values and 313 have catches data. The number of stocks with both values is 125. Table 1 gives CF values for overexploited (55) and exploited (70) stocks, where both catches and MSY are available in the RAM legacy database. Figure 2, left part, shows the CF weight factors according to the relative finishing effort both for previous (1 for exploited, $\frac{\mathrm{MSY}}{\bar{C}_t}$ for overexploited stock) and current CFs $\left(1 \pm \sqrt{1 - \frac{\bar{C}_t}{\mathrm{MSY}}}\right)$. Figure 2, right part, shows the total biotic resource depletion impacts (i.e. $\bar{C}_t \times \mathrm{MSY}$) for both previous and current work.

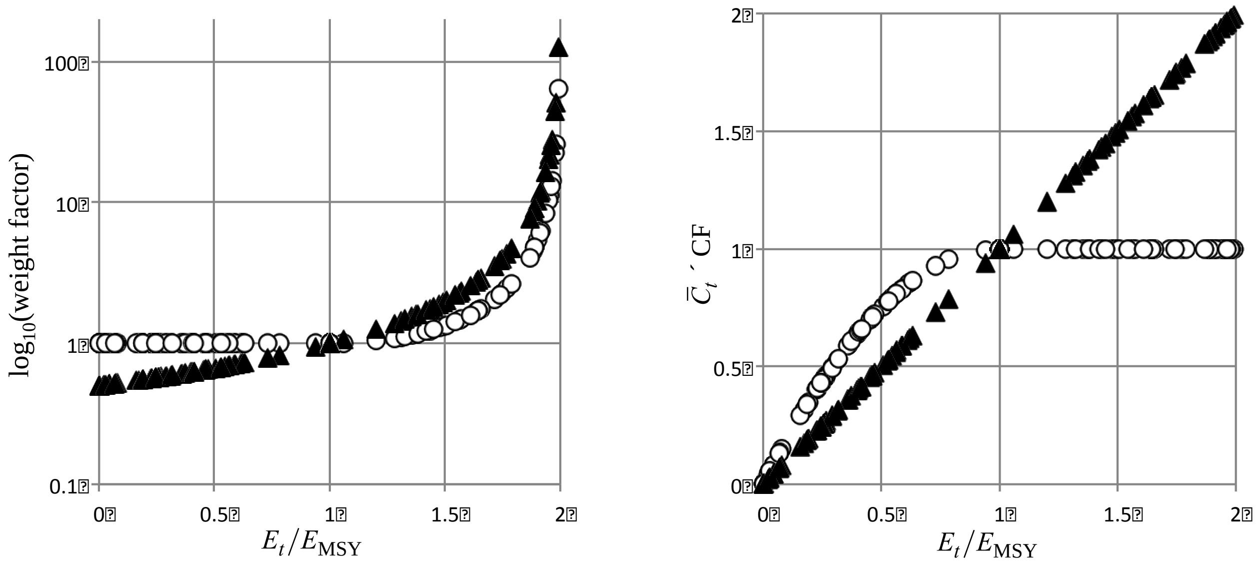

Figure 2. Weight factors (left part) and total impact (right part) according to relative fishing effort. White circle: approach proposed in Langlois et al. (2014a); black triangle: this study.

4. Discussion

This work is an improvement of the previous CF calculations in two respects:

- The CF value increases now continuously according to the total fishing effort for exploited species. The CF for a species where the current total catches is close to the MSY (i.e. close to overexploitation) is now higher than the CF for a species where catches are low, as it is shown in Figure 2, left part, when the relative fishing effort is lower than 1.
- The total impact (total catches by CF) increases continuously from low exploited species to depleted resources, whereas in the previous equations, the total impact was identical for all overexploited species (Figure 2, right part, when the relative fishing effort exceeds 1).

As already expressed in Langlois et al. (2014a), the use of MSY and steady state assumption present some limitations. The transition periods for a given stock are not properly taken into account, being it the result of a drastic increase in effort leading to overexploitation, or to a fast decrease in effort, resulting from the implementation of a low quota aimed at the rapid restoration of the stock biomass. In order to limit this inconvenient and to approximate the equilibrium state, a five-year catches average has been used.

5. Conclusion

While many impacts are now consensual in LCA and standard frameworks are starting to be available (JRC-EIS 2011), no guidelines exist for biotic impact assessment (Emanuelsson et al. 2014). This work proposes CFs at midpoint level for fishing activities, where the use of the biotic resource is taken into account in front of the resource recovery capacity (expressed by the MSY). This work allows assessment of fisheries in the LCA formalism. It contributes to a better representation of the depletion of biotic resources.

6. Acknowledgments

Greenhouse Gas Emissions of the U.S. Diet: Aligning Nutritional Recommendations with Environmental Concerns

ABSTRACT

Dietary choices – the overall food consumption patterns displayed by a population – can, and do, influence greenhouse gas emissions (GHGE) of the food system. Here, we consider the GHGE associated with production of the current U.S. diet, and various dietary recommendations. USDA's loss adjusted food availability dataset is used to represent current consumption. GHG emission factors were compiled from published LCA sources. Production of the current U.S. diet has GHGE of 5.0 kg CO_2eq capita^{-1}day^{-1}, 28% of which is due to food losses; a diet based on USDA's *Dietary Guidelines* has similar or greater GHGE as this current diet. Lacto-ovo vegetarian, vegan, and Harvard's Healthy Eating Plate guidelines show 33%, 53%, and 33% lower GHGE, respectively, than their USDA omnivore counterpart. Official USDA food plans at four cost levels show increasing emissions with rising food costs, but decreasing emissions per unit cost. This paper suggests aligning environmental and health objectives through dietary recommendations policy.

Keywords: sustainable diet, carbon footprint, diet shift, consumption, cost-based food plan

1. Introduction

Opportunities to reduce the greenhouse gas emissions (GHGE) associated with food and agriculture exist throughout the food production chain, but researchers warn that technological improvements in agriculture alone – enhanced yields, resource use efficiencies, etc.– will likely be insufficient to keep pace with population growth and rising demand for meat and dairy (Garnett 2011). Behavioral choices, including shifts in diet and minimizing food waste, particularly in developed countries, can have large influences. With transportation, housing and food (in that order) as the largest contributors to the carbon footprint of the typical U.S. household, often the most economically effective abatement options for consumers are dietary changes (Jones and Kammen 2011). In addition, more than 40% of food waste in industrialized countries happens at the retail and consumer levels (Gustavsson et al. 2011). In this study, we explore in detail the GHGE associated with current and recommended diets in the U.S.

Changes in both the quantity and quality of the American diet may hold potential to affect the carbon footprint of food production. The current obesity epidemic, in the U.S. as well as other developed nations, garners broad academic, political and media attention; the most recent statistics claim that 69% of U.S. adults are overweight and 36% are obese (CDC 2013). Food overconsumption and obesity contribute not only to human health dangers, but also translate directly and indirectly into increased agricultural demand, excess resource utilization, and concomitant environmental impacts (Blair and Sobal 2006; Cafaro et al. 2006). Not only are Americans over-consuming, they are not eating properly: repeated assessments find that Americans do not meet the Federal dietary recommendations (Krebs-Smith et al. 2010; Wells and Buzby 2008). Dietary choices influence the environmental cost of food consumption (Carlsson-Kanyama and Gonzalez 2009; Marlow et al. 2009), and research from Germany (Meier and Christen 2013) and Austria (Fazeni and Steinmuller 2011) suggests that a shift from current consumption patterns to German Nutrition Society dietary recommendations can result in reduced environmental impacts from the agri-food sector. Dietary choices are complex and influenced by a myriad of factors; dietary recommendations presented by governments are but one avenue to influence policy and consumer choices to move toward a more nutritionally healthy diet. However, if multiple objectives (e.g., health and sustainability) are not aligned in recommendations, undesirable outcomes are possible. Here, we explore the implications on food related GHGE of U.S. dietary recommendations and policy-related food patterns.

2. Methods

2.1. U.S. food consumption and losses

The Loss Adjusted Food Availability (LAFA) data series (USDA ERS 2012) serves as a useful proxy for per capita food consumption in the U.S. The food availability series measures the use of basic food commodities (e.g., wheat, beef, fruit, vegetables) by tracking their "disappearance" in the U.S. marketplace. For most commodities, the available supply is the sum of production, imports and beginning stocks, minus non-food use (feed and seed, industrial uses), exports, and ending stocks for a given calendar year. In the Loss Adjusted data series, the food availability data for over 200 commodities are modified by percent loss assumptions at the primary level, retail/institution level, and consumer level. Retail losses include dented cans, unpurchased holiday foods, spoilage, and the culling of blemished or misshaped foods. Consumer losses include spoilage, cooking shrinkage, and plate waste. Nonedible food losses (bones, peels, pits, etc.) are accounted for separately in the data series and not included in the results presented here. We use LAFA data from 2010 in this study to represent current food consumption patterns in the U.S., shown in Table 1. Percent losses for individual foods were assumed to be unchanged in considering a shift to dietary recommendations, thus allowing an assessment of how food losses might be affected by a dietary shift. Further detail and report of per capita availability and loss estimates for various foods are presented in (Heller and Keoleian 2014).

2.2. Dietary recommendations and food plans

The 2010 *Dietary Guidelines for Americans* contains food pattern recommendations (Appendix 7, 8 and 9 of (USDA 2010)) that provide recommended average daily intakes of different food groups (assumed to be in nutrient dense forms and lean or low-fat) for a range of Calorie levels, depending on individual caloric intake needs. The *Dietary Guidelines* also provide estimated caloric needs by age, gender and physical activity level (Appendix 6 of (USDA 2010)). Weighting these estimated caloric needs with U.S. age and gender demographics from 2010 (U.S. Census Bureau 2011) suggests that the weighted average caloric need for a moderately active U.S. population is 2093 Calories[1] (1867 Calories and 2361 Calories for sedentary and active, respectively). For the purpose of this paper, we explore recommended food patterns at two caloric levels (see Table 1): the current caloric intake (according to the LAFA series) of 2534 Calories, representing an iso-caloric diet shift, and the often used reference point of 2000 Calories, representing a weighted average target intake for the average U.S. citizen, assuming moderate activity. We also evaluate lacto-ovo vegetarian and vegan food pattern recommendations at 2000 Calories, as defined by the *Dietary Guidelines* (USDA 2010).

The Healthy Eating Plate (HEP) diet is a food pattern designed to represent the Alternative Healthy Eating Index (AHEI) developed by nutrition experts at the Harvard School of Public Health. AHEI is based on foods and nutrients predictive of chronic disease risk, and has demonstrated a stronger association with chronic disease risk, particularly coronary heart disease and diabetes, than USDA's Healthy Eating Index (which quantifies adherence to *Dietary Guidelines*) in prospective cohort studies (Chiuve et al. 2012). The HEP is characterized by high quality grains (whole vs. refined), healthy proteins (fish, poultry, beans and nuts vs. red meat and processed meat), greater intake of poly unsaturated fatty acids (healthy oils), reduced intake of sugar-sweetened beverages, and reduced dairy (Harvard School of Public Health 2014). The HEP food pattern at 2000 Calories examined here is defined in Table 1 and is from (Willett 2014).

USDA also maintains official food plans designed to meet required dietary standards and specified cost levels, which are used for various policy implementation purposes. The Thrifty Food Plan (Carlson et al. 2007b) serves as a national standard for a nutritious diet at a minimal cost and is used as the basis for maximum food assistance allotments. Bankruptcy courts often use the value of the Low-Cost Food Plan (Carlson et al. 2007a) to determine the portion of a bankrupt person's income to allocate to necessary food expenses; the U.S. Department of Defense uses the value of the Liberal Food Plan to determine the Basic Allowance for Subsistence rates for all service members; many divorce courts use the values of the USDA Food Plans to set alimony payments, and they are also used to set child support guidelines and foster care payments.

These food plans reflect the consumption patterns and eating habits of U.S. citizens as determined by the

[1] 1 Calorie = 1 food calorie = 1 kilogram calorie = 4,186.8 Joules

2001-2002 National Health and Nutrition Examination Survey (NHANES); the U.S. population is divided into quartiles of food spending by combining NHANES food intake data with the 2001-2002 Food Price Database (Carlson et al. 2007a). The Thrifty Food Plan corresponds with the first quartile of food expenditure, the Low-Cost plan with the second quartile, the Moderate-Cost Plan with the third quartile, and the Liberal Food Plan with the upper quartile. A mathematical optimization model is used to identify food market baskets representing a diet as close as possible to actual food consumption patterns within a given quartile group while also meeting USDA dietary standards and the cost limits for that quartile. Within each Food Plan, diets for 15 age-gender groups are identified; for simplicity's purposes, we consider here only the male and female diets in the 19-50 year old group. Purchasing costs at the four quartile levels are updated monthly (USDA 2014); costs from June 2013 (assigned by USDA to represent the annual average) are used here in order to present GHGE per dollar for the four food plans. Note that updated Food Plans reflecting the (most recent) 2010 Dietary Guidelines have not yet been published; the Food Plans reported in (Carlson et al. 2007a; Carlson et al. 2007b) are based on the 2005 Dietary Guidelines for Americans.

[j] Healthy Eating Plate food pattern from Walter Willett, personal communication (Willett 2014).
[k] The vegan "dairy group" is composed of calcium-fortified beverages and foods from plant sources. Soy milk is used as a GHGE proxy for the entire group.
[l] GHGE factors for food groups were calculated as described in (Heller and Keoleian 2014), Supporting Information.

2.3. Food GHGE data

While numerous LCA-based studies of food production have been published, there currently is not a comprehensive and authoritative database of food environmental impact. Thus, we have chosen a meta-analysis approach of published LCA data to arrive at representative GHGE factors for the diversity of foods considered in this study. Results are drawn from a variety of sources (referenced in (Heller and Keoleian 2014), Supporting Information (SI)), compiled by food type, and averaged across comparable food type. These sources include studies representing a variety of countries of origin, climatic conditions, transportation distances, and production methods and therefore are intended to provide a reasonable range of expected values rather than a definitive result for each food type. U.S. based data is limited, and thus this meta-analysis includes data from other developed countries. The average GHGE values for the ~100 foods considered in this study, along with minimum and maximum GHGE values from the meta-analysis, are given in (Heller and Keoleian 2014), SI. In some cases where insufficient data on individual foods exist and where small differences in GHGE are expected between foods (such as, e.g., added sugars and sweeteners), available examples are used to represent the entire food category.

The emission factors for broad food categories and subcategories shown in Table 1 are averages of representative foods, weighted by current consumption patterns in the U.S. as dictated by the LAFA dataset. Conversions to food pattern equivalents units are based on grams per food pattern equivalents contained in the LAFA dataset (USDA ERS 2012).

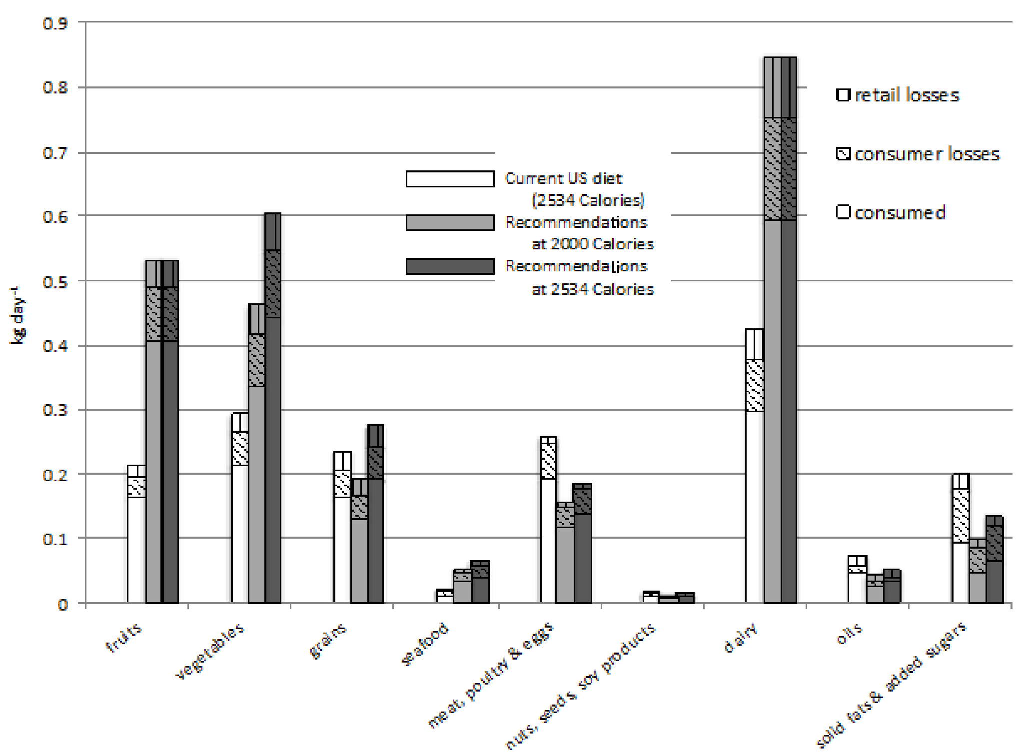

Figure 1. Per capita quantities consumed and losses by food types for the current US diet (white bars), a recommended diet at 2000 Calories (light grey bars) and a recommended diet at 2534 Calories (dark grey bars).

3. Results

Figure 1 summarizes the average daily per capita diet in the U.S. as well as food patterns corresponding with the USDA dietary recommendations. To shift their diet to meet recommendations, the average U.S. citizen would need to significantly increase fruit, vegetable and dairy intake while decreasing intakes of meats, oils and solid fats and added sugars. Figure 1 also shows the retail- and consumer-level food losses, as specified by the LAFA dataset, and expected food losses with a recommended diet, assuming the same loss percentages for individual food types. The total weights of food consumed and wasted are reported in Table 2. In Figure 2, the same diets are shown but with individual food weights multiplied by GHGE factors, providing a distribution of GHGE associated with producing the U.S. diet. Not surprisingly, meats and dairy dominate the carbon footprints of both current and recommended diets. As can be seen in Table 2, the total diet-related GHGE is greater for dietary recommendations at the same caloric intake compared with the current diet, whereas a shift to recommendations accompanied by a 20% decrease in caloric intake shows the same GHGE as the current diet. This appears to be primarily due to the balance between decreased meat and increased dairy in the recommended diets. The total weight of food losses associated with a recommended diet at 2534 and 2000 Calories is nearly 50% and 30% greater than the current diet, respectively, whereas GHGE associated with those food losses only increase 20% and 7%, respectively. The weight of food losses increases primarily due to increased consumption of fruits, vegetables and dairy – all foods with relatively high loss percentages but low GHGE factors; decreases in meat consumption also contribute to the disproportional increase in food loss GHGE.

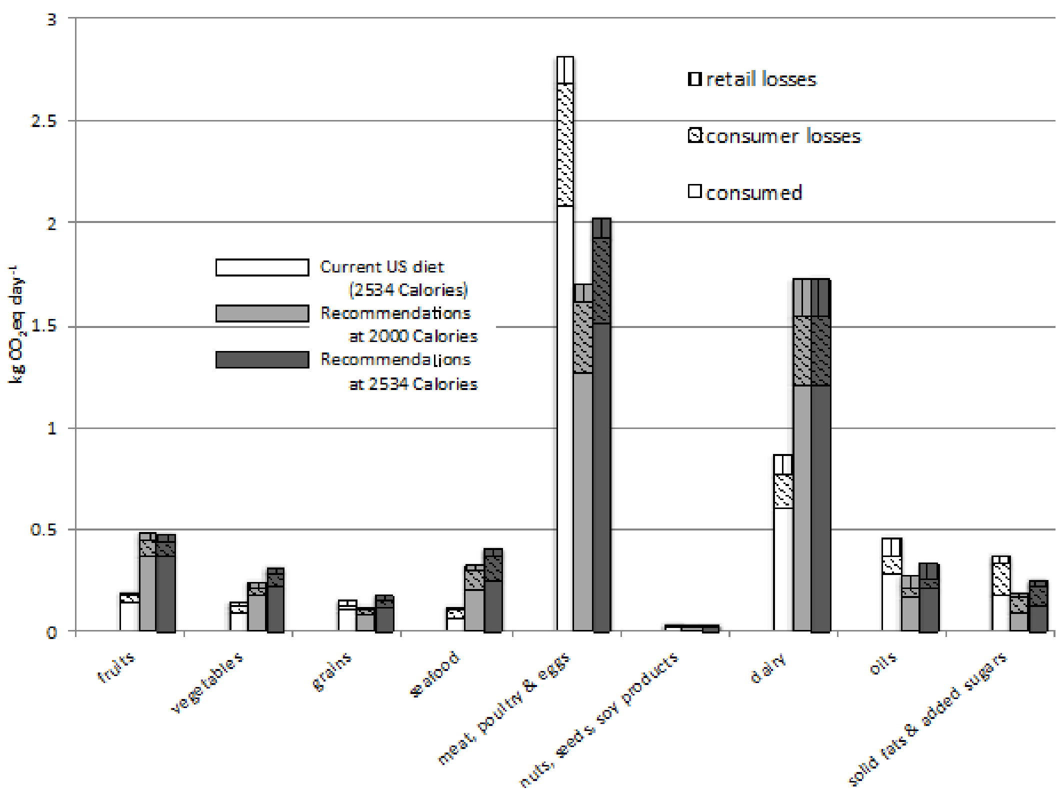

Figure 2. Per capita greenhouse gas emissions associated with producing consumed food and losses by food types for the current US diet (white bars), a recommended diet at 2000 Calories (light grey bars) and a recommended diet at 2534 Calories (dark grey bars).

Table 2. Total per capita weights and GHGE associated with consumed food and estimated food losses of the diets shown in Figures 1 and 2.

	weight (kg day^{-1})				GHGE (kg CO_2 eq day^{-1})			
	consumed	Retail losses	Consumer losses	Total losses	consumed	Retail losses	Consumer losses	Total losses
Current US diet (2534 Cal.)	1.19	0.17	0.36	0.53	3.60	0.40	1.0	1.4
US dietary recommendations at 2000 Cal.	1.70	0.24	0.46	0.69	3.57	0.45	1.1	1.5
US dietary recommendations at 2534 Cal.	1.91	0.27	0.53	0.79	4.02	0.51	1.2	1.7

Figure 3 compares the GHGE associated with food patterns for four recommended diets all at 2000 Calories: the USDA recommended diet shown in Figures 1 & 2, lacto-ovo vegetarian and vegan adaptations of this diet (also offered by USDA), and a food pattern representing the HEP recommendations made by Harvard School of Public Health. As expected, limiting or eliminating animal products in the vegetarian and vegan diet significantly reduces GHGE. Interestingly, the HEP diet, which recommends reduced (but not eliminated) levels of animal proteins and dairy, demonstrates GHGE equivalent to the lacto-ovo vegetarian diet.

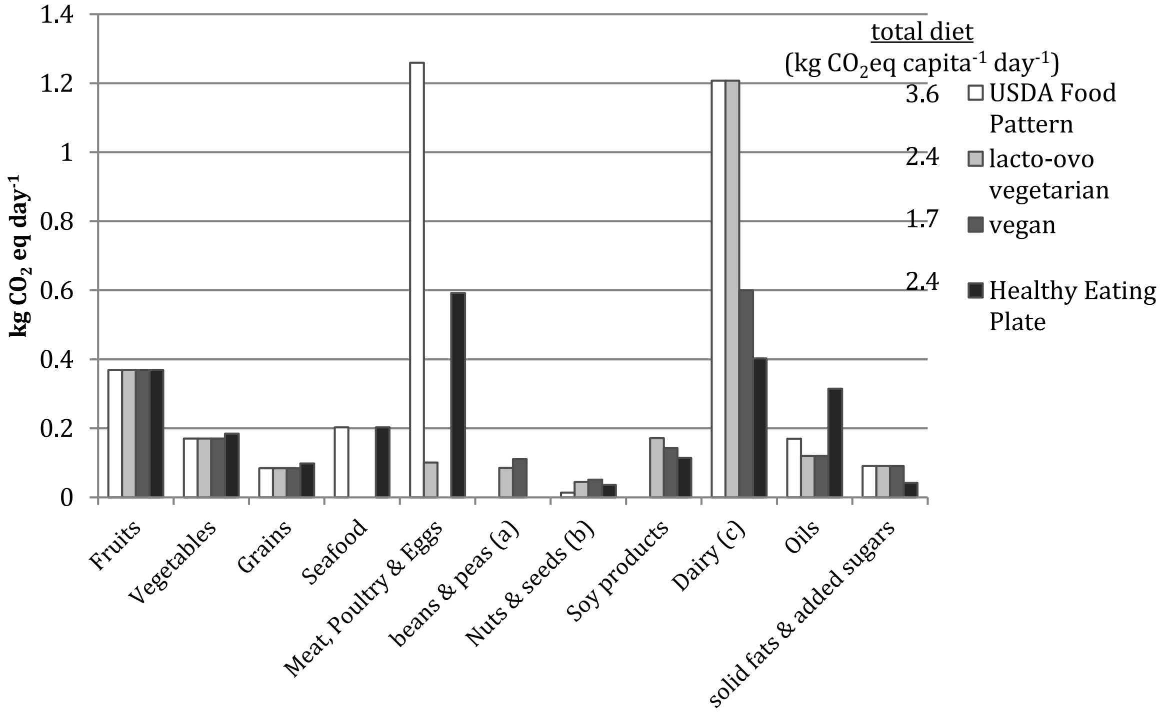

Figure 3. Comparison of the per capita greenhouse gas emissions associated with various 2000 Calorie recommended food patterns. Diets are as described in Table 1. Notes: (a) this category represents beans and peas added to the vegetarian and vegan diet *in addition* to those included in "vegetables". (b) nuts, seeds & soy products are combined into the same category in the USDA food pattern, presented here as a bar only in "nuts & seeds". (c) "dairy" category in the vegan diet contains calcium-fortified beverages and foods from plant sources.

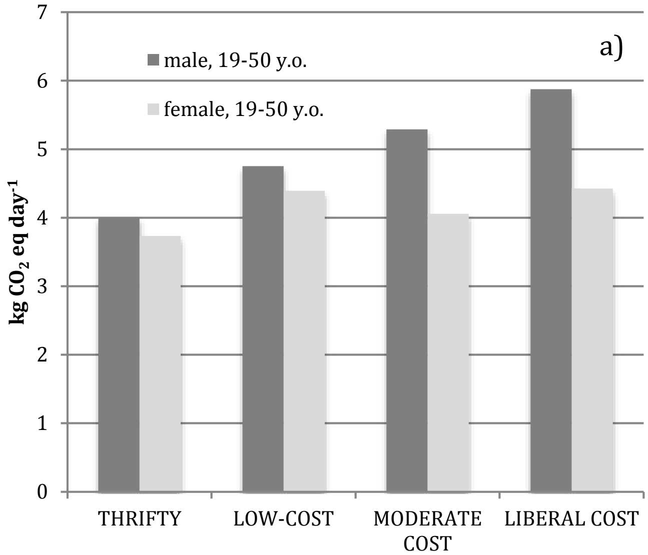
Figure 4 offers a high-level summary of the GHGE associated with USDA cost-based food plans. These food plans are based on the food expenditures of surveyed U.S. citizens. Food expenditure distributions for each of 15 age and gender categories are divided into quartiles; the average share of food consumption in each quartile is used to represent the group. An optimization is then performed to arrive at a food plan (collection of food items) that meets nutritional requirements, does not exceed the expenditure cut-off for the group, and minimizes change in consumption from the average food consumption for the group. Figure 4 shows that the food-plan-associated GHGE for 19-50 year old men and women rise with food expenditures, but apparently at a slower rate than the increasing cost, as the GHGE per $ cost decreases. Table 3 gives the distribution of both food expenditures and GHGE across broad food categories for all four food plans. Interestingly, the dominant cause of the increase in GHGE from the Thrifty to the Low-cost food plan is due to the introduction of soft drinks and sodas: these beverages are absent from the Thrifty food plan for 19-50 year olds. Additional trends are more difficult to identify: increasing red meat consumption with increased cost plays a role, often buffered by decreasing poultry consumption. Vegetable consumption tends to move away from starchy vegetables like potatoes to dark green and other vegetables with increasing costs. Surprisingly, legumes (beans, lentils, peas), which might be considered low cost protein sources, actually increase with expenditure in these food plans.



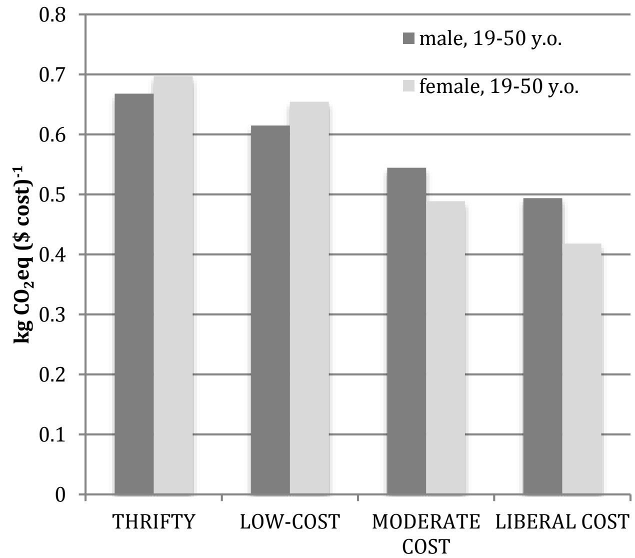


Figure 4. Comparison of GHGE associated with USDA food plans developed at meal cost quartiles, shown for diets developed for 19-50 year old males and females.

Table 3. Expenditure (cost) and GHGE shares across food categories for Thrifty, Low-cost, Moderate-cost and Liberal cost food plans. Food plans for 19-50 year old males and females are shown. Expenditure shares from (Carlson et al. 2007a; Carlson et al. 2007b).

[a]"Meat" include beef, pork, veal, lamb, poultry, fish, sausages and luncheon meats, nuts, nut butters and seeds, and eggs and egg mixtures.
[b]"Other foods" include table fats and oils, gravies, sauces and condiments, coffee and tea, soft drinks and sodas, sugars sweets and candies, ready-to-serve, condensed and dry soups, and frozen or refrigerated meals.

4. Discussion

Better understanding the environmental implications of dietary food patterns is a critical step toward a more sustainable food system. Here, we provide an approach to estimating the GHGE associated with the current U.S. diet. The LAFA dataset on which our estimate is based is a top down approach, starting with *disappearance* of (primarily) agricultural commodities and, through a series of loss estimates, arriving at a proxy for per capita consumption. Some impacts of food processing and distribution are missed in this approach, and we acknowledge that the GHGE factors used for individual foods are limited in their specificity and geographic accuracy. While our estimate for GHGE associated with the average U.S. diet of 5.0 kg CO_2eq capita^{-1} day^{-1} (consumption plus losses) is within the range of other national average diet carbon footprints reported in the literature (see Table 3 in (Heller et al. 2013)), reported economic input-output LCA based estimates for the U.S. diet are higher (8.4 kg CO_2eq. capita^{-1}day^{-1} from (Weber and Matthews 2008) and 8.5 kg CO_2eq. capita^{-1}day^{-1} from (Jones and Kammen 2011)).

Despite the limitations, the approach presented here is valuable in comparing the relative effects of dietary shifts. A USDA recommended dietary pattern at the same caloric intake as the current diet is associated with 12% greater GHGE. While a 20% reduction in caloric intake at a constant dietary pattern would result in a 20% decrease in GHGE, a 20% reduction in caloric intake combined with a shift to dietary recommendations results in no change in GHGE.

Food losses represent a significant impact for the U.S. food system. By our estimates, the GHGE associated with retail- and consumer-level losses totaled 160 MMT CO_2 eq. in 2010, roughly equivalent to the emissions of 33 million average passenger vehicles (Heller and Keoleian 2014). Interestingly, this is also roughly equivalent to the GHGE difference between the omnivore recommended USDA food pattern and the lacto-ovo vegetarian food pattern (Figure 3). A population-wide shift to vegetarianism is highly unlikely in the U.S., but comparisons with the HEP guidelines suggest that similar reductions are possible without completely giving up meat. Reduced dairy consumption is a primary driver of the carbon footprint differences seen with the HEP food pattern. While the scientific debate over the health implications of dairy in our diet (e.g., (Ludwig and Willett 2013)) are beyond the scope of this paper, clearly the trade-offs between the health and environmental impacts of dairy deserves further attention, and is a focus of our future work. Of course, in order to infer actual change in climate impact from the dietary shifts considered in this paper, a consequential LCA analysis is needed, as market-mediated and other indirect effects are likely significant. Still, the attributional approach presented here suggests the potential for reduction in food system GHGE through changes in diet.

Analysis of the USDA cost-based food plans offers an initial glimpse at consideration of a triple bottom line objective for dietary recommendations. It should be noted that these food plans are based on a different approach to defining current U.S. consumption patterns than the diet presented in Figures 1 and 2, and therefore may not be directly comparable. The influence of current consumption patterns on these food plans should also not be underestimated: they do not represent an optimal low-cost nutritious diet, but instead a nutritious diet within a given cost constraint that *minimally deviates from current consumption*. That said, the results in Figure 4 further demonstrate the effect that dietary composition can have on GHGE of food plans that are (roughly) nutritionally equivalent. In addition, it raises questions as to what the ideal optimization objective might be when including environmental concerns in nutritional policy and recommendations: minimizing overall environmental impact? Impact per unit cost? Impact per unit nutritional benefit? Such questions echo the perennial challenge of functional unit definition in food LCA, and are at the heart of the additional work needed to permit meaningful incorporation of environmental indicators into nutritional policy.

5. Conclusion

The GHGE associated with production of the food consumed by the U.S. population is significant: 8% of total U.S. GHGE in 2010, based on our estimates (Heller and Keoleian 2014). Yet, the results presented here suggest that these emissions could be reduced by upwards of 30%, not by eliminating all animal products from the diet, but by shifting to a healthy diet based on foods and nutrients that are predictive of lowered chronic disease risk. According to our analysis, a diet based on the food patterns recommended by the *Dietary Guidelines for Americans 2010* would have the same or greater GHGE as the current U.S. diet. Absent of additional interventions, greater food losses can be expected with a shift to dietary recommendations, but the relative GHGE impact of those losses are diminished. While policy-level food plans designed to supply ample nutrition at limited cost show increasing GHGE with increasing cost, they also demonstrate the highest emissions per unit of food cost at the lowest expenditure food plan, suggesting that further optimization of the health/ environment/ affordability triple bottom line is possible. Policy-level discourse regarding sustainable food consumption and the inclusion of environmental factors in nutritional guidelines has emerged in various European countries as well as in Australia (Lang and Barling 2013), but such conversation is at a nascent stage in the U.S. This study provides much needed quantitative evidence to the emerging U.S. sustainable diet debate, and suggests the need to align environmental and health objectives of the U.S. food system through dietary recommendations.

Acknowledgements The authors wish to thank Walter Willett and Teresa Toiyee Fung of The Harvard School of Public Health and Jennifer Baum of Simmons College for assistance in defining a food pattern that adheres to the Healthy Eating Plate guidelines.

Using LCA to Identify Options for Greenhouse Gas Emission Reductions in Australian Wheat Farming

ABSTRACT

Agriculture can be a contributor to a nation's total greenhouse gas emissions. Nitrapyrin (2-chloro-6-trichloromethylpyridine) is a nitrification inhibitor used globally to improve the efficacy of applied ammoniacal nitrogen fertilizers. By stabilizing nitrogen in the ammoniacal form, it results in more of the applied nitrogen available to plants thereby reducingN_2O and nitrate emissions from the farm. We used LCA to determine if the potential benefit from the use of nitrapyrin exceeded the burdens to create and transport it, and to discover additional opportunities to reduce emissions from high rainfall zone wheat farming in Australia. Use of nitrapyrin could reduce global warming potential (GWP) by 20% and marine eutrophication by 16%, with burdens created by its supply of only 0.5% and 0.01%, respectively. Production of nitric acid for urea ammonium nitrate fertilizer impacts GWP as much or more than the field emissions. Reducing emissions from nitric acid production may provide a similar (15%), independent and additive, benefit in GWP.

Keywords: nitrapyrin, greenhouse gas emissions, nitric acid, wheat, high rainfall zone

1. Introduction

Climate change, driven by emissions of "greenhouse gases" (GHG) such as CO_2, CH_4 and N_2O, is a critical global issue, but was particularly of concern in Australia. About 93% of electricity in Australia is generated from fossil resources, primarily coal (International Energy Agency, 2012), which generates greenhouse gas emissions and is a challenge to change over the short term. There was great interest and research on various approaches to help Australia meet targets for GHG reduction set out by the Kyoto protocol; one of them was to increase use of nitrification inhibitors to reduce nitrous oxide (N_2O) emissions from agriculture (Dalal *et al*., 2003; Bhatia *et al*., 2010).

Nitrapyrin (2-chloro-6-trichloromethylpyridine) is a nitrification inhibitor produced in Pittsburg, California, by Dow AgroSciences, a business unit of The Dow Chemical Company (Dow), and is used globally in agriculture as a way to improve the efficiency and efficacy of applied fertilizers (Dow, 2012). Nitrification is a natural biological process that converts ammonia (from fertilizers) in soils to nitrate. The nitrate form of nitrogen is highly susceptible to losses from the soil root zone as N_2O emissions to air and nitrate emissions to ground and surface waters. The pathways of emissions are shown in Figure 1; nitrapyrin inhibits the nitrification process and thus reduces these emissions (Wolt, 2000; Chen *et al*., 2010). Reduction in N_2O emissions from fertilizer by use of nitrapyrin has been demonstrated in many studies (Wolt, 2004; Akiyama, Yan and Yagi, 2010).

The goal of our work was to determine if the potential benefit from the use of nitrapyrin exceeded the burdens to create and transport it, to understand other potential impacts, and to discover additional opportunities to reduce GHG emissions from wheat farming. Life Cycle Assessment (LCA) is a useful methodology for examining the total environmental impact of a product or service. LCA takes a holistic view, examining environmental impacts over the complete "cradle to grave" product life cycle. Results from LCA address the complete environmental impacts of a product, and are hence more meaningful than those obtained for a single process or step in the life cycle. A life cycle perspective helps to ensure that environmental burdens are not unintentionally transferred from one life cycle stage to another and helps to prevent unintended environmental consequences.

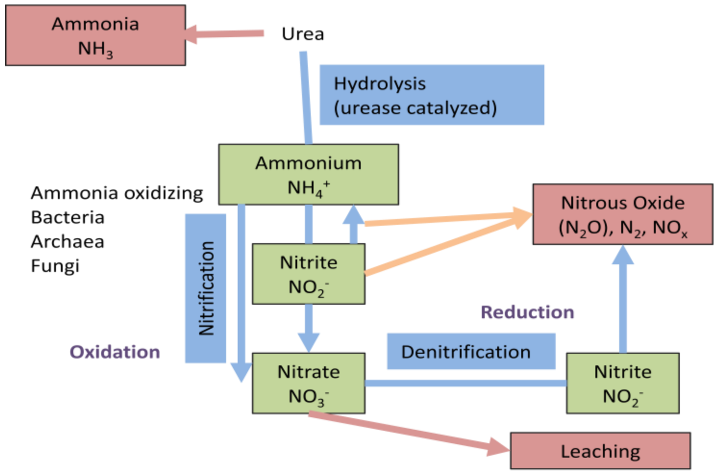

Figure 1. Routes to key emissions from use of fertilizers (re-drawn from a 2012 presentation by Chen and Suter)

Two studies were particularly useful in understanding the inputs to and emissions from wheat farming in Australia. Chen et al. (2010) reports the impact of use of nitrification chemicals on nitrogen speciation and emissions from laboratory experiments. It provided a basis for the unit ratio of nitrapyrin to applied N, applied N rate, and for the impact of nitrapyrin on N_2O emissions. Biswas *et al*. (2010) had extensive data and analysis of inputs and emissions from HRZ (high rainfall zone) wheat in rotation farming. Although there was no nitrogen fertilizer used due to the rotation with sheep farming, the other inputs were quite relevant to this project. The report also included field data for N_2O emissions. HRZ farming is distinct from wheat farming in, for example, Western Australia, which has been the subject of previous publications related to LCAs (Biswas *et al*, 2008; Biswas *et al*., 2010).

2. Methods

LCA is framed by ISO standards 14040 and 14044 (ISO, 2006a; ISO, 2006b), which provide comprehensive guidelines for conducting an LCA study. Good insights on the uses and limitations of LCA are described in many publications (EU-JRC, 2010; Curran, 2006; Curran, 2012). Previous use of LCA at Dow is also described in publications (DiMuro *et al*., 2014; Helling and Russell, 2006; Helling *et al*, 2012).

SimaPro 7.3.3 from Pré Consultants was the life cycle assessment software used in this study. Dow and other data were used directly to create process models in SimaPro. The primary sources of information for nitrapyrin production were Dow technical experts and Dow manufacturing databases. Dow confidential statements of formulation were used for the composition of the delivered product (also referred to by the tradename "eN-trench™"). Ecoinvent v2.2, was used within SimaPro to model utility process operations, transportation, packaging, and other material inputs. For materials produced or operations conducted in Australia, such as fertilizers, a version of the Ecoinvent data based adapted for Australian conditions (primarily for the sources of heat and power) was used (v 2012.5) (Life Cycle Strategies, 2012). Life cycle impact assessment (LCIA) was performed using valuation systems available in Ecoinvent, primarily selected from ReCiPe (Hischier *et al*., 2009; Goedkoop *et al*., 2010), using "midpoint" metrics and with no normalization to a target or weighting of different impact categories. The reported results include the impact categories of global warming potential (GWP), cumulative energy demand, water withdrawals, acidification potential (AP), freshwater and marine eutrophication potential (EP), photochemical oxidant creation potential (POCP) (smog), and ozone depletion potential (ODP).

The function of nitrapyrin is to reduce losses of fertilizer nitrogen by nitrification pathways, thereby preventing losses of the nitrogen fertilizer in the crop. Nitrapyrin is marketed and sold on the basis of a treated hectare, so the functional unit was one hectare of high rainfall zone (HRZ) wheat farming in Australia, with and without applied nitrapyrin. Calculation of potential impacts per ton of wheat production was done as part of the sensitivity analysis.

This was a cradle-to-grave study, so the boundaries extended upstream to materials in the earth and continues to materials returned to the earth (air, water, or soil). The primary chemical reaction in the process is the chlorination of alpha-picoline to make 6-chloro-2-trichoromethylpyrine ("α-6-tet"), the active ingredient in nitrapyrin. A high-level view of the overall system is shown in Figure 2. The figure shows the flow of the primary mass of the product; there are mass and energy inputs to each of these blocks and potentially emissions and by-products from each block. In the figure, TG stands for "technical grade" and AU is the country code for Australia. Capital equipment was excluded from the study, except for farm equipment, for which data were available in Biswas *et al.* (2010). Transportation was included for all significant mass flows or any transport over long distances. TG production, formulation, and packaging are all done in multi-product plants, for which the consumption of utilities and emissions (which are tracked in Dow per facility) were allocated equally by mass to all the production. Raw material consumption was known in detail specifically for each material; no material inputs were excluded, although minor inputs totaling <1% of the formulated products were lumped together as "chemicals, organic".

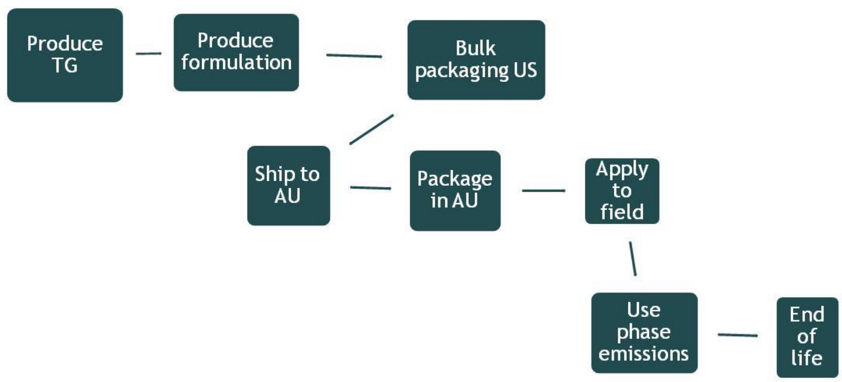

Figure 2. High-level process map for supply and use of nitrapyrin

The data sources and assumptions related to the direct emissions from applied chemicals were important for this project. Direct fossil CO_2 emissions from use of farm chemicals came from two sources: Urea and nitrapyrin, with urea being more significant by a factor of about 50. We assumed that all of the CO in the applied urea was converted to CO_2, as per IPCC guidelines, and also that all of the carbon in the applied nitrapyrin was released as CO_2 (this is expected to be a conservative estimate). N_2O emissions for the no-nitrapyrin case were taken from IPCC (2006) models applied to wheat, with the key inputs (besides the urea-ammonium nitrate (UAN) molecular weight, elemental composition, and application rate) being:

- Nitrogen fraction of crop residues, 0.0064
- Crop dry matter fraction, 0.85
- Mass ratio of residues to crop, 2.3, which was assumed to all be left on the field

The resulting N_2O emissions from fertilizer use and crop residues are 3.95 kg/ha. N_2O emissions were also calculated from the other nitrogen containing components in the formulation, and were less than 0.1% of those from the urea.

There is a range in the reported benefit of using nitrapyrin, as it depends on soil moisture, temperature and other factors (Dalal, *et al*., 2003). Wolt (2004) found an average reduction in field GHG emissions (N_2O and CH_4) of 51% in fourteen studies covering a range of crops, locations and applied fertilizer type; Chen *et al*. (2010) found a reduction in N_2O emissions of 65-98% in laboratory work covering a wide range of soil temperature and moisture levels. We believe Chen's work to be of high quality, more recent, and particularly relevant for Australia. To be conservative, we selected the 65% minimum reduction in N_2O emissions from this work.

3. Results

Results for the selected impact categories are shown in Figure 3 for the cradle-to-grave life cycle of one hectare of high rainfall zone wheat production, with (the bar on the right of each set) and without use of nitrapyrin. For all the impact categories, the results have been normalized by the maximum value of the two, which is for the hectare treated with nitrapyrin for all impacts except GWP and marine eutrophication. The specific maximum values for each impact category are (per hectare):

- Climate change (GWP): 3,100 kg CO_2 eq
- Cumulative energy demand: 18,100 MJ
- Water withdrawals (ReCiPe): 17.8 m^3
- Terrestrial acidification (acidification potential, or AP): 9.53 kg SO_2 eq
- Freshwater eutrophication (eutrophication potential, or EP_f: 0.373 kg P eq
- Marine eutrophication (eutrophication potential, or EP_m): 55.2 kg N eq
- Photochemical oxidant formation (photo oxidant creation potential, or POCP): 5.39 kg NMVOC (non-methane volatile organic carbon)
- Ozone depletion (ozone depletion potential, ODP): 4.6E-05 kg CFC-11 eq

There are three primary observations from the figure:

- For most impact categories there is no significant difference between the with and without nitrapyrin cases
- Use of nitrapyrin clearly reduced GWP and marine (nitrogen-based) eutrophication
- Use of nitrapyrin may increase ozone depletion potential.

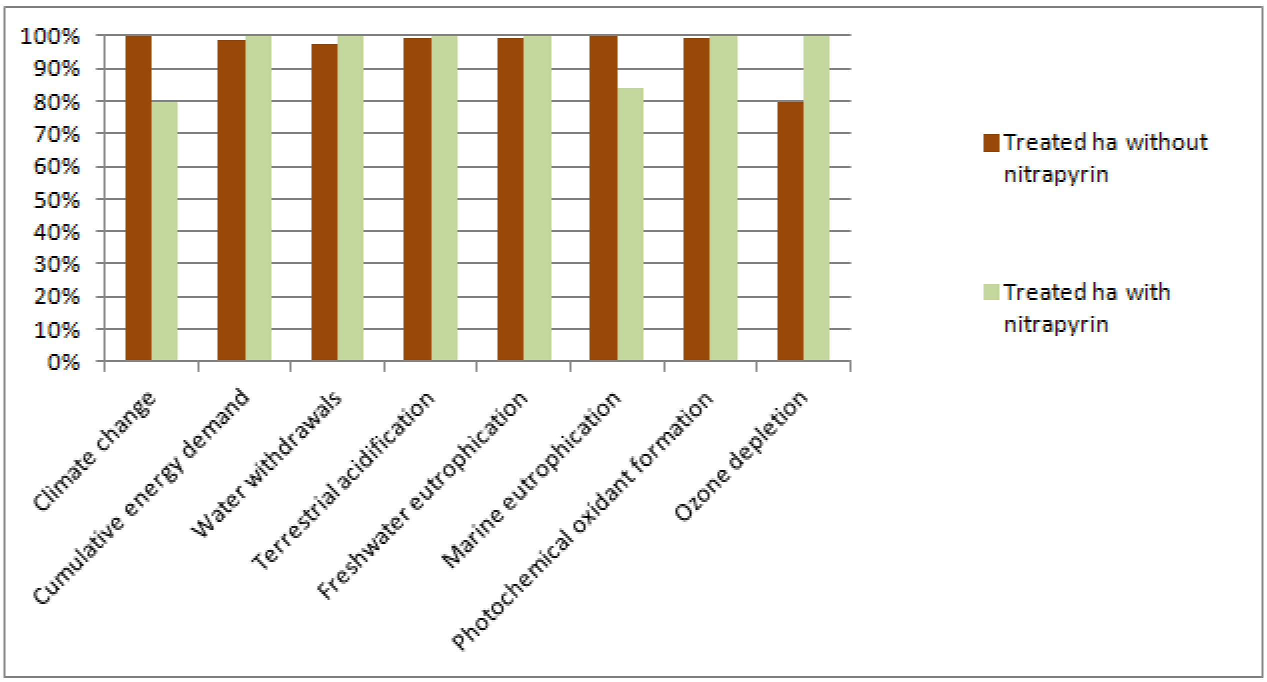

Figure 3. Comparison of potential impacts per hectare of HRZ wheat farming in Australia

The contributions of the different inputs to the full list of metrics considered are shown in Figure 4. For most metrics, the largest contributors are UAN production and single super phosphate production. Direct field emissions are significant for GWP and EP_m. Production of alachlor (a surrogate model for the use of clethodim on-farm) is the largest contributor to ODP. Production of nitrapyrin is a significant contributor only to ODP.

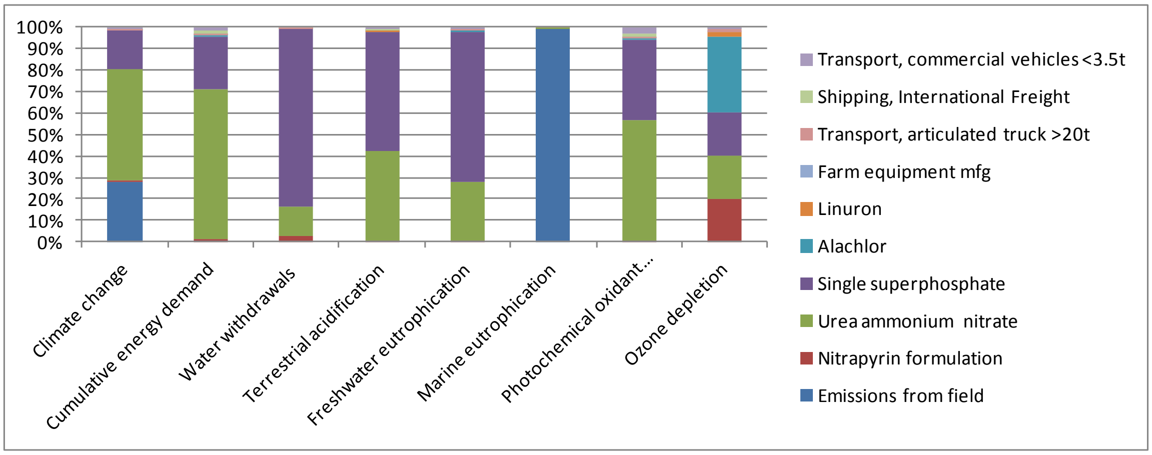

Figure 4. Contributions to potential impacts per treated HRZ hectare

4. Discussion

Use of nitrapyrin, which reduced modeled field emissions of N_2O by 65%, resulted in a GWP reduction of about 20%. The GWP of a treated hectare is 2470 kg CO_2eq/ha, which is 630 kg/ha less than the value for the hectare without nitrapyrin, 3100 kg CO_2eq/ha. About 22% of the GWP comes from field emissions of N_2O and only 0.5% comes from the nitrapyrin (11 kg CO_2eq/ha). The GWP benefit of nitrapyrin (648 kg CO_2eq/ha) is almost 60 times the GWP burden from manufacturing it. The largest contributor to GWP is the production of the UAN fertilizer, which contributes 52% of the GWP. The upstream burden of UAN production is more than twice as large as the impact from the N_2O emitted in the use of the product. There is also a significant contribution of 18% from phosphate fertilizer production and 6.5% from field emissions of CO_2 due to decomposition of the urea in the UAN. The production burden of UAN is still larger than the sum of the N_2O and CO_2 impacts from the use of the product in HRZ wheat farming. CO_2 emissions in UAN production are related to energy use, but N_2O is also a production reaction by-product, for which the emissions can be controlled by using different vent gas treatment technologies. The US EPA has compiled an excellent overview of the state of the art for N_2O abatement from nitric acid production (US EPA, 2010). Appendix C of the EPA report includes data on N_2O emissions (lb/ton) before and after implementation of technology changes at 45 plants in developing geographies. The average emissions of N_2O from the improved plants were 1.3 kg/MT, an 85% reduction from the emissions in the model for nitric acid production in the Australasian LCI dataset (which was unchanged from the European Ecoinvent value); the best technology could be 97% lower. We adapted the Australasian LCI model for nitric acid production by changing only N_2O emissions, neglecting any other inputs required to achieve this performance. Use of more current N_2O emissions technology in nitric acid production could lower the GWP of HRZ wheat farming by 16%, assuming that current nitric acid production in Australia is similar to that described in Ecoinvent. No other potential impacts were changed. This GWP impact is similar to that from using nitrapyrin, but is completely additive: using both more current nitric acid processes and nitrapyrin could combine to reduce GWP by 38%.

The decrease in marine eutrophication (N-load) by 16% with the use of nitrapyrin as shown in Figure 3 was directly due to the impact from the work by Wolt (2004), with the burdens created by supply of nitrapyrin being only 0.01% of the total. Although marine eutrophication is a significant issue for US agriculture, it may not be a significant issue for Australian agriculture (Geosciences Australia, 2013). The relevance of the reduction in marine eutrophication by use of nitrapyrin will depend on the region where it is used.

Figure 3 also showed increased ozone depletion potential with use of nitrapyrin in HRZ wheat farming. This is due estimated CCl_4 emissions from the chlorine production process at the plant of K2 PURE SOLUTIONS NOCAL LP in Pittsburg, California. This is a new facility (not owned or operated by Dow) and will need to publically report CCl_4 emissions, but data are not yet available for this facility (US EPA, 2012). When these data are available, it will be possible to determine if this potentially higher burden for nitrapyrin is real or not. The major contribution to ODP, production of alachlor, also has a high degree of uncertainty. ODP calculations are sensitive to small emissions of materials with high characterization factors. The use of alachlor as a surrogate for clethodim herbicide based on its structural similarity is reasonable for potential impacts such as GWP or cumulative energy demand, but is likely less so for ODP. The differences in ODP are likely not significant.

During the course of this project, there were also field studies in Managatang, Victoria, to measure the impact on yield of otherwise identically treated areas of wheat production, with and without use of nitrapyrin. A representative comparison using 2.5 L of eNtrench, 50 kg diammonium phosphate (DAP) and 40 L of urea ammonia nitrate increased the yield of wheat from 2.90 to 3.16 MT/ha, or about 9%. The quality of the wheat was similar for both treatments (11.7% protein without nitrapyrin; 11.8% protein with nitrapyrin). The yields, fertilizer inputs, and corresponding emissions were used to create models on a "per MT" basis. For most impact categories there was a small decrease between the cases with and without nitrapyrin, due to the 9% improvement in yield, although differences of this magnitude in LCA are often not considered significant. Use of nitrapyrin reduced GWP 29% and marine (nitrogen-based) eutrophication by 23%. Due to the lower input of fertilizer in the results per MT wheat in Managatang, many of the potential impacts were smaller in magnitude than those per typical treated hectare. This is demonstrated for GWP which was 3,100 kg CO_2eq/ha for the untreated typical hectare compared to 390 CO_2eq/ha for the reported field trial. Fertilizer production contributed 43% and field emissions contributed 44% of the GWP for the field trial without eNtrench; for the typical hectare these were 55% and 41%, respectively. Later field trials in Australia have shown that typically 5-7% increase in yield can be seen when nitrapyrin is used and all other factors are conducive to maximize the yield impact.

5. Conclusion

The potential benefits with respect to global warming potential (GWP) and marine eutrophication through the use of nitrapyrin in high rainfall zone (HRZ) wheat farming in Australia far exceed the burdens of these potential impacts created by its supply. Use of nitrapyrin could reduce global warming potential (GWP) by 20% and marine eutrophication by 16%, with burdens created by its supply of only 0.5% and 0.01%, respectively. There is no significant difference in the broad range of other potential impacts considered between a farmed hectare with and without use of nitrapyrin, with the possible exception of the ozone depletion potential. Production of nitric acid for urea ammonium nitrate fertilizer impacts GWP as much or more than the emissions from the field on its use. Reducing emissions from nitric acid production may provide a similar benefit in GWP as the use of nitrapyrin, and the potential benefits are independent and additive.

ABSTRACT

Although the human health effects of pesticides have decreased, chronic health problems are still significant in many developing countries and emerging economies. In this project we examined the various exposure pathways of pesticide application over the whole life cycle of potatoes grown in Colombia. Exposure pathways included e.g. workers' exposure during pesticide preparation and application and consumer exposure by ingestion of the pesticide-treated crops. A dynamic model was developed for pesticide crop uptake and evaluated with measurements performed within a field trial in the region of Boyacá, Colombia. Pesticide concentrations were measured periodically in soil and potato samples from the beginning of tuber formation until harvest. The model was able to predict the magnitude and temporal profile of the experimentally derived pesticide concentrations well, with all measurements falling within the 90% confidence interval. Pesticides residues in potatoes were rather low and below health-based threshold values in the case investigated. However, the study was performed in an unusually dry year with smaller amounts of fungicides applied than in other years. Therefore, to study exposure and risk in the region under normal circumstances, an enquiry about pesticide use was conducted among 79 farmers of the region and the model applied to the application pattern of pesticides reported by the farmers. Results show that substitution of a few active ingredients could lower consumer exposure significantly. With regard to workers' health, dermal exposure was found to be enhanced in only several cases. Several measures are suggested to lower workers' exposure. Finally, human intake of pesticides was quantified and compared throughout the life cycle of potatoes. Cumulated intake fractions of consumers' ingestion and farmers' dermal exposure were comparable, but individual doses for farmers were much higher and above no-effect-levels. This highlights that individual risk assessment studies are needed in addition to LCA, which typically cumulates intake.

Keywords: pesticides, toxicity, plant-uptake model, farmers' exposure

1. Introduction

Pesticides can help to avoid harvest losses and increase yields, but may come at the expense of health effects if not correctly applied. Although the human health effects of pesticides have decreased significantly in industrialized countries, misuse of pesticides in developing countries is still problematic. Possible factors contributing to these effects include the application of old products with high persistence and toxicity and missing or insufficient protection of workers during pesticide application and use. Consumers, farmers and authorities are interested in understanding and ultimately mitigating the life-cycle environmental and health impacts related to the use of pesticides.

The goal of this project was to examine the various exposure pathways of pesticide application over the whole life cycle of potatoes grown in Colombia. Potatoes were chosen for this study as it is the vegetable that is consumed most (e.g. per capita consumption in Columbia of 42 kg/capita/y), involves small-scale farming and is the crop with high pesticide use in Colombia.

2. Methods

We collected data, performed experimental studies and developed models to quantify the magnitude of exposure to pesticides from the preparation of pesticide solution, the application on the field, as well as post-harvest consumer exposure due to ingestion of potatoes.

2.1. Crop uptake model and field measurements

A dynamic model for uptake of pesticides in potatoes was developed and evaluated with measurements. The model takes into account the time between pesticide application and harvest, the time between harvest and consumption, the amount of spray deposition on soil surface, mobility and degradation of pesticide in soil, diffusive uptake and persistence due to crop growth and metabolism in plant material, and loss due to food processing like cleaning, washing, storing, and cooking. Intake fractions were calculated according to Equation 1.

$$iF_{consumers} = PF \cdot C_{potato} \cdot Y \cdot n / M \qquad \text{Eq. 1}$$

Where iF is the intake fraction, PF the processing factor (loss of pesticide by processing, e.g. washing or cooking), C_{potato} the concentration in the potatoes, Y the yield, n the number of people exposed, and M the mass of pesticide applied.

A field trial was performed on a farm in the region of Boyaca. This trial included periodical measurements of pesticide concentrations in soil and in the potato samples from the beginning of tuber formation until harvest. Application patterns (times, amounts and types of pesticides applied) were recorded.

For a complete documentation of the model and the results of the field experiments see Juraske et al. (2011).

2.2. Farmers' exposure

Dermal and inhalation exposure experiments of pesticides in potato cultivation systems in Colombia were carried out. Farmers' exposure during preparation and knapsack-sprayer application of pesticide was quantified with tracer experiments and the whole-body dosimetry methodology (Lesmes-Fabian et al. 2012). Intake fractions of the farmer were calculated according to Equation 2.

$$iF_{farmer} = M_{dermal} / M \qquad \text{Eq. 2}$$

Where iF is the intake fraction, M_{dermal} the mass of pesticide deposited on the skin of the farmer applying the pesticides, and M the total mass of pesticide applied.

2.3. Survey

To understand and calculate exposure in the region, a survey was conducted. Pesticide application data was collected through interviews with 79 farmers in the region of Boyacá, covering a total cultivation area of 82 ha. This data was then combined with the models developed to estimate exposure.

3. Results

The survey showed that 22 different active ingredients were used with an average of 9.8 kg/ha. 90% of total mass applied due to only 4 pesticides (carbofuran, carbosulfan, mancozeb, and methamidophos). Figure 1 shows the distribution by mass of these pesticides.

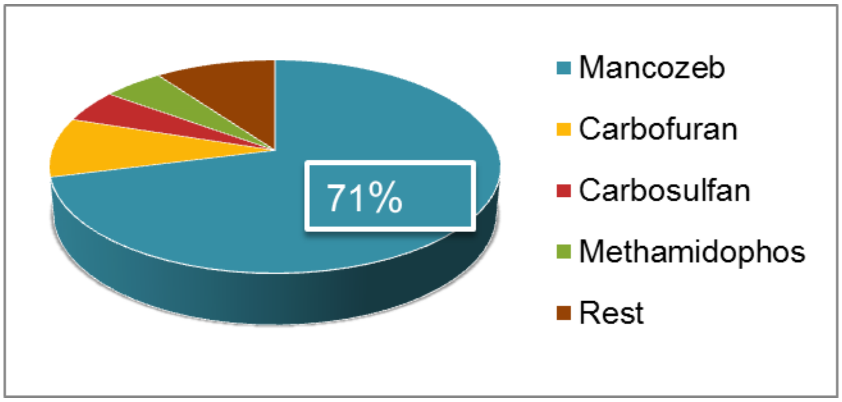

Figure 1: Share of pesticide masses applied in the study area

Modeled data for crop uptake was in good accordance with experimental data (Juraske et al. 2011). Cumulative intake fractions of consumers through ingestion of potatoes were $iF_{consumers} = 10^{-4}$ for cooked potatoes consumed directly after harvest (no cleaning/washing), $iF_{consumers} = 10^{-6}$ for cooked potatoes consumed 3 months after harvest (no cleaning/washing) and $iF_{consumers} = 10^{-5} - 10^{-7}$ for cooked potatoes that were previously cleaned and washed. Pesticides residues in potatoes were rather low and below health-based threshold values in the case investigated. However, the study was performed in an unusually dry year with smaller amounts of fungicides applied than in other years.

Table 1: Exemplary results of applied doses mean concentrations (n=3) and coefficient of variation of pesticides detected in soil (A) and pesticides applied but not detected in soil (B) in one field trial (Juraske et al. 2011). Samples taken at average tuber depth (12 cm).

(A)

	DDT	DDD	DDE	Carbofuran	Chlorpyrifos	m-parathion
Dose (kg ha^{-1})	-	-	-	-	0.435	-
Conc. (mg kg^{-1})	0.29	0.13	0.25	0.5	2.11	0.18
CV (%)	19	26	27	25	32	76

(B)

	chlorothalonil	cymoxanil	glyphosate	mancozeb	metamidophos	paraquat
Dose (kg ha^{-1})	0.54	0.08	0.14	0.66	0.55	0.08
Conc. (mg kg^{-1})	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.

To study exposure and risk in the region under normal circumstances, an enquiry about pesticide use was conducted among 79 farmers of the region and the model applied to the application pattern of pesticides reported by the farmers. Questions were related to:

- Household description
- Potato field description
- Pesticide and fertilization management
- Occupational hygiene (use of personal protective equipment)
- Health problems related to the use of pesticides

Results show that substitution of a few active ingredients could lower consumer exposure significantly. However, in spite of some cases in which too much pesticide was applied too late before harvest, concentrations in potatoes were mostly low at harvest (below maximum residue levels MRLs). By contrast, farmers' exposure during application was significant, particularly dermal exposure. Dermal exposure depended on type of work clothing, cleaning of the application equipment, and application frequency. Although cumulated intake fractions of consumers' ingestion and farmers' dermal exposure were comparable, individual doses for farmers were much higher and above no-effect-levels. This highlights that individual risk assessment studies are needed in addition to LCA, which typically cumulates intake across all people exposed.

4. Conclusion

This study investigates various pathways for human health effects from pesticide exposure and, hence, focuses only on one impact category. While this was fine for the scope of the analysis in this case, also other impact categories than human toxicity need to be addressed when performing a complete LCA study.

The system showed to be rather resilient in terms of uptake of pesticide in the potatoes. Only in very few cases elevated residues were found, while for the majority of applications no health impacts from potato consumption are to be expected. By contrast, pesticide exposure of farmers from the application of pesticides was elevated and health impacts have been reported. The level of human health risk was especially for the pesticides like metamidophos. Exposure and health effects could be lowered by substituting the most toxic active ingredients, avoiding unnecessary application of pesticides, wearing appropriate protection clothing made of thick fabric and covering the whole body and cleaning all spill residues on the sprayer tank before starting the application.

The results of this study illustrate the importance of considering farmers/workers' exposure, which is often neglected in common LCA studies. However, it also shows the shortcomings of the LCA approach. In spite of the differences in individual exposure, LCA would have come to the conclusion that exposure of consumers and the farmers are comparable, as typically LCA does not consider individual but cumulative exposure. One farmer takes in the same amount of pesticide as a multitude of consumers together via potato consumption, resulting in similar intake fractions according to equations 1 and 2. However, the farmer is much more likely to exhibit health effects, as his individual dose of pesticide is much higher. This shows that risk assessment studies are always needed in addition to LCA, in order not to miss important effects.

LCA is only relative – Experiences from the quantification of overall dispersions around aquaculture LCI results

Patrik Henriksson*, Jeroen Guinée

CML, Institute of Environmental Sciences, Leiden University
* Corresponding author. E-mail: *henriksson@cml.leidenuniv.nl*

ABSTRACT

As part of an evaluation of European seafood imports from Asia, overall dispersions were determined for a wide range of processes. Once propagated into LCI results using Monte Carlo (MC) simulations, large absolute uncertainties around results made conclusions difficult to reach. In response, the results were reevaluated, only considering relative uncertainties related to different hypotheses. This approach allowed for dispersions related to more than one of the products under study to be assumed the same, producing correlated samples. These results could, in turn, be tested using paired T-tests which allow for greater statistical power. Greater statistical power means that the resolution of comparisons is improved and the risk of reaching flawed conclusions reduced. Among other bias related to absolute results, the present research presents many contending arguments for only comparing LCI and LCA results in relative terms.

Keywords: LCI, uncertainty, dispersion, Monte Carlo, significance, statistical test

1. Introduction

Quantifying uncertainties related to life cycle inventory (LCI) results has long been desired in the field of life cycle assessment (LCA). To date, however, most estimates of uncertainties have been derived using a pedigree approach (Weidema and Wesnaes 1996), based upon expert judgment (Röös et al. 2010), or focused on a few key parameters (Middelaar et al. 2013), resulting in manageable ranges. In the few studies where parameters have been more extensively defined (e.g. Gregory et al. 2013), comparisons of products or services are often inconclusive. This is due to the large dispersions related to LCI results. Meanwhile, results are commonly communicated as point values, with little to no indication of the confidence behind any conclusive outcomes. Supporting LCI outcomes with information on its uncertainty and statistical testing is therefore needed.

The first step towards implementing statistical tests to LCI results is to identify all relevant sources of dispersion. In the present research, the *overall dispersions* defined in Henriksson et al. (2013) were adopted. Overall dispersions are the sum of inherent uncertainties (inaccuracies in measurements which may be reduced by additional research), spread (variability resulting from averaging) and unrepresentativeness (mismatch between the representativeness and application of data) (Henriksson et al. 2013). Secondly, data need to be collected and assembled following a representative sampling technique. However, as data collection commonly is the most resource demanding stage of any LCA, and LCA is data intensive, most studies source their data opportunistically. This results in data often representing very small sample sizes (n), surveys carried out using snowball sampling, geographically limited areas, temporally limited timespans or otherwise biased samples. Thirdly, a propagation method is needed to aggregate the unit process dataset into LCI results. In the field of LCA, Monte Carlo (MC) simulations with random virtual sampling is the most common propagation method (Lloyd and Ries 2007). While MC simulations of large datasets require relatively extensive computing, advances in hardware and software today allow for a great number of iterations to be produced from extensive LCI databases within a reasonable time using a standard personal computer.

When all sources of dispersion are taken into account, the resulting *absolute uncertainties* often become very large, making it difficult to draw conclusions in comparative studies (Henriksson et al. 2014). Common when comparing LCI results, however, is that many of the sources of dispersion are positively correlated with each other (Hong et al. 2010). In LCI studies this may refer to dispersions related to emission models (e.g. CH_4 estimates from diesel combustion), emissions from land-use change, or other processes which are shared amongst the production systems compared. Therefore, in comparative studies, only *relative uncertainties* are of importance and all shared dispersions can be assigned the same random samples. E.g. if an LCA evaluates two toasters, the uncertainties related to electricity generation can be assumed identical and only the uncertainty related to the amount of electricity used and the production of the toasters should be considered. Thus, only dispersions unique to either of the products under study, the relative uncertainties, are considered.

The types of statistical tests that can be implemented to test LCI results depend upon the characteristics of the data. Parametric statistics, for example, allow for more statistical power but assume equal variances and a type of probability distribution (Table 1). The probability distribution assumed by the most commonly used statistical tests (e.g. the T-test) is the normal distribution, but other test exist and distributions can also be transformed (e.g. from a lognormal to a normal distribution). In the meantime, non-parametric tests which do not require data to conform to a specific probability distribution offer more robustness, but an increased risk of committing a type II error (see Table 1). Implementing the wrong type of test can consequently result in flawed conclusions. For example, a novel biofuel might be deemed as equally polluting as diesel, while it in fact has significantly lower emissions. If only relative uncertainties are considered, the outcomes of each individual MC run for the product systems compared are correlated with each other (Wilcoxon 1945; Zimmerman and Zumbo 1993). This is referred to as correlated samples and implies that a paired statistical test should be implemented, where only the difference between product A and product B (A-B) is considered for each MC run. Paired statistical tests offers increased statistical power and are often used for e.g. testing groups of patients before and after a drug is administered (Zimmerman and Zumbo 1993).

Table 1: Common statistical terms used throughout this manuscript

Parametric statistics	Statistics of data of an assumed type of probability distribution; offers more statistical power and less chance of type II errors
Type II error	Failure to reject a false null-hypothesis
Statistical power	The probability of rejecting the null-hypothesis when the alternative hypothesis is true
Non-parametric statistics	Statistics of data with no characteristic structure; offers more robustness and less chance of type I errors
Type I errors	An incorrect rejection of the null-hypothesis
Statistical robustness	The ability to evaluate data of no characteristic structure, data affected by outliers, or data where variances are not equal

In the present research we evaluated the advantages of only considering relative uncertainties when comparing LCIs and challenged the use of absolute values. In order to do so, we worked on an inventory dataset describing Asian aquaculture. The data were collected as part of the SEAT project (www.seatglobal.eu) for several important aquaculture systems in Asia. In the present study, however, we only used the example of carbon dioxide emissions from the production of one tonne of tilapia fillets from two different Chinese farming systems, conventional and integrated with pigs, as an example. Our hypothesis was that "*fish integrated with pigs would have lower emissions than conventional systems as part of their feed is provided by the pig manure*".

2. Methods

Primary data collection started in 2010-2011, building upon a random sample of 200 fish farms (Murray et al. 2013). Based upon the outcomes of this sample, additional primary data were collected in 2012-2013 on supporting processes, including feed mills, hatcheries, processing plants, etc. The primary dataset was also supported by an extensive review of secondary data, detailing many of the supporting services (e.g. electricity production, transportation, etc.). For these data, aggregation of dispersion parameters was conducted using the spreadsheet supplied as Online resource to Henriksson et al. (2013) (also available at cml.leiden.edu/software/software-quanlci.html). For all other supporting processes the ecoinvent v2.2 database was consulted, relying upon default inherent uncertainties and the pedigree approach presented by Frischknecht et al. (2007). A full review of the data used and modelling choices adopted is available in Henriksson et al. (2014). Modeling and propagation was conducted in the CMLCA software v5.2 (available at cmlca.eu). For each farming system alternative 1 000 iterations were conducted. Probability density functions were evaluated in EasyFit v5.5 (mathwave.com), using the Anderson-Darling test to determine the distribution of data. Statistical tests were conducted using Wilcoxon matched-pair signed-rank test in SPSS v.21.

3. Results

The outcomes from the correlated and the non-correlated sampling were largely identical, apart from some random sampling differences. Between the two, integrated farms performed slightly better than the conventional farms (Table 1). The relative differences between the two data ranges (conventional-integrated) were not normally distributed.

Table 2: LCI results for carbon dioxide emissions from the production of one tonne of tilapia in either of two different Chinese tilapia farming systems.

	Conventional	Integrated
Average	3027	2684
Median	2805	2530
Standard deviation	1226	953

When compared on a MC run basis, two products with equal emissions would each be expected to yield the higher emissions 50% of the time. Meanwhile, the integrated farms came out as having higher emissions than conventional farms only 43% of the runs when absolute results were regarded, and 39% when relative results were regarded. The difference in the dependently sampled results could also be determined as highly significant ($p<0.001$) using the non-parametric Wilcoxon matched-pair signed-rank test. When visualized for a small selection of MC runs (Figure 1), the correlation between the samples in the dependent sampling becomes evident. Where only relative uncertainties are considered (dependent sampling) the samples generally come out closer to each other than when absolute uncertainties are considered (independent sampling). This as the results rely upon the same LCI matrix, where e.g. the assumed emissions from electricity generation and transportation in China remain the same for both production chains in each MC run.

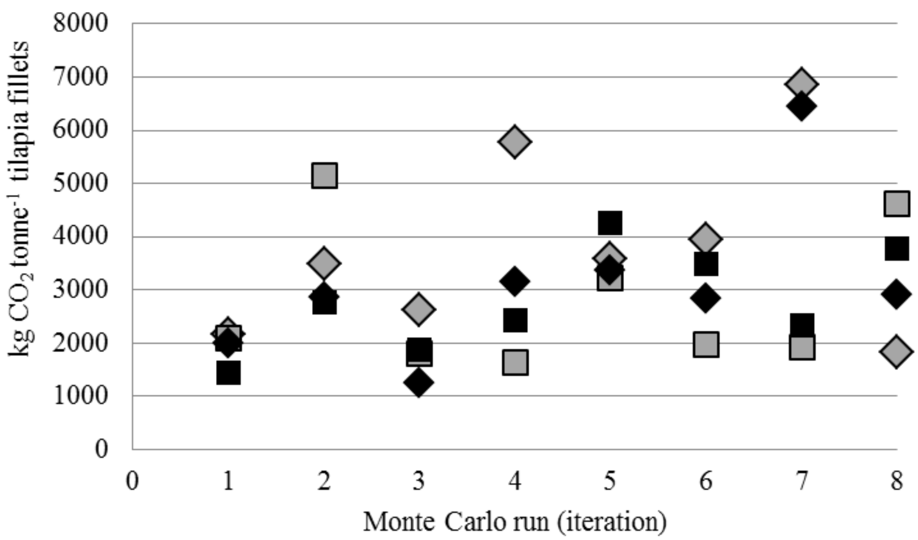

Figure 1: Illustrative example of a selection of outcomes using correlated (black) and non-correlated (gray) sampling for carbon dioxide emissions from conventional (diamonds) and integrated (squares) tilapia farming in China.

4. Discussion

Given the definition of the overall dispersions evaluated here, the ranges of results give an indication of the *absolute uncertainties* underlying results. Meanwhile, if two production chains which experience many shared sources of dispersions are to be compared, only relative uncertainties need to be considered. Only considering relative uncertainties improve the resolution of comparisons and also allow for the implementation of more powerful paired statistical tests. The field of LCA should therefore amend the practices of most other sciences, where results are only compared to an alternative or control (benchmark), working towards a predefined hypothesis.

Although often used in LCA studies instead of great or large, the word significant in the scientific realm implies that a statistical test has been performed. Meanwhile, only a handful of LCA studies have so far implemented statistical testing to support their conclusions (Canter et al. 2002) and the role of statistical tests in the field of LCA is still vaguely defined. Embracing statistical concepts would, however, contribute towards more solid LCA practices. Essential for this will be the understanding that statistical tests are only ever as strong as the sampling framework they build upon. Sampling frameworks therefore need to promote random unbiased samples, where any remaining bias is communicated so that it can be corrected for. Moreover, the probability density function of LCI outcomes should be characterized and transformed when needed, in order to allow for parametric tests. Otherwise there is a risk that type II errors are committed.

If the approach proposed here is adopted, modeling options may also need to be considered. For example, if a generic process for “Combustion of diesel in generator” is used, rather than defining its emissions as part of each process using a generator, dependent sampling becomes possible. Similarly for waste flows, where e.g. a waste processes may be created for each kg of nitrogen applied to agricultural fields. While the uncertainties for these more generic processes might be larger, they are less relevant from a relative point-of-view. Dependent sampling is also beneficial when uncertainties around characterization factors are considered. In some cases, such as freshwater ecotoxicity, uncertainties may range an order of magnitude (Henderson et al. 2011). In such cases, adopting dependent sampling could greatly improve the resolution of comparative studies.

Further efforts are needed to develop the ideas presented here. For example, the strong influence of sample size in most statistical tests. When results are resampled, as in MC simulations, the sample size can be changed at the click of a button. This means that a null-hypothesis might not be rejected (no significant difference) at 100 iterations, but at 1 000 iterations. This rather arbitrary feature has even been addressed by implementing sequential stopping boundaries, where MC tests will stop once a sufficient number of runs have been produced to achieve a certain significance level (Fay et al. 2007). Future research should therefore explore how to deal with such resampling risks in the field of LCA (Gandy 2009) and evaluate statistical tests building upon the cumulative distribution function, such as the Kolmogorov–Smirnov test.

5. Conclusion

LCAs presenting results as point values may be flawed when concluding that one product is better than another while no significant difference exists (type I error), or to conclude that two results are indifferent from each other while they actually significantly differ (type II error) when dispersions are quantified as yet. Either of these false outcomes may result in flawed decisions, and only by quantifying the dispersions around LCI results can statistical tests be implemented and the confidence behind conclusions communicated. In doing so, dependent sampling only regarding relative uncertainties offers many advantages. This, however, requires studies to work towards a hypothesis, in order to avoid multiple comparison problems. Multiple comparison problems refer to the elevated chance of finding significant trends by chance if a large number of comparisons are made. Amending these recommendations will allow LCA to become a much more scientifically robust tool, rather than an exploratory framework. Conclusively, we argue that LCI and LCA results should only ever be seen as relative, and discourage comparisons of absolute results across studies.

ABSTRACT

Freshwater is a scarce resource in many parts of the world. Besides the quantitative restriction, a potential contamination of water resources ranks high on the agenda of environmental concerns in many regions. The objective of this paper is to describe methods for impact-weighted grey water footprints (WFs), derived from grey water-use (WU) estimates. Furthermore, total WU (blue surface- and groundwater, green evapotranspiration water from precipitation and virtual grey dilution water) and WFs (impact-weighted blue and grey water footprints) are calculated based on life cycle assessment (LCA) principles for two Austrian milk production systems (PS). We identified two approaches for impact-weighted grey water results: (1) a regional catchment area-based approach and (2) a local approach. It is shown for the milk PS that differences in management result in different virtual grey WU with high importance for the overall water demand. Analogously management- and precipitation-related impact-weighted grey WFs completely dominate the overall WF results.

Keywords: water-use, water footprint, nitrate emissions, grey water, impact-weighting

1. Introduction

Freshwater is a scarce resource in many parts of the world. Besides the quantitative restriction, a potential contamination of water resources ranks high on the agenda of environmental concerns in many regions. In recent years, scientific studies have started to analyze factors influencing water-use (WU), the resulting impact on water-resources and water quality induced by diverse production systems and management strategies for comparable food products. Earlier studies on amounts of "virtual water" (see e.g. Allan et al. 2003) or on different types of so-called "water footprints" (WFs; see e.g. Hoekstra et al. 2011) implemented methodologies with lower resolution to analyze and illustrate hydrological aspects in a broader context: the concepts were primarily developed to show effects of WU in all stages of supply chains for nations, companies or products and to illustrate virtual global water flow.

Previous studies focused on food production's water consumption only, but did not or not fully account for the effects of production on water quality. From these it was often concluded that high-output production results in a lower water demand per unit of product output. Contrarily, a few recent studies using refined methodology demonstrate effects of different production systems on water aspects with a focus on water quality and grey water (i.e. virtual water demand to dilute the main emitted pollutant in a specific water body) on a product level: For example, Ercin et al. (2012) compared soy production from different countries and diverse production methods and found that shifting from non-organic to organic farming may reduce the grey water related to soybean cultivation by 98%. Franke and Mathews (2013) found that organic farming practices for Indian cotton showed a five times smaller grey water demand than for conventional production, while having comparable land productivities as in conventional farming. However, these concepts are based on WU at an inventory level, but the water demand is not weighted by its impact on a water system which could influence a regional or local WF result. In contrast to a global warming potential (carbon footprint), which provides a measure for an impact on global warming with globally equal impact factors for the different greenhouse gases, impacts of WU vary spatially and temporally and because of the related methodological difficulties, they are hardly incorporated in WF studies. Opposed to the unweighted WU, a few impact assessment methods were created in recent years, e.g. the water stress index (WSI; Pfister et al. 2009). The latter was developed for blue water (ground- and surface-water used) only and characterizes the impact relevance of regional water consumption (for midpoint modelling). Regionally varying stress indicators are used, ranging from 0 (no water stress) to 1 (extreme water stress) for more than 11'000 globally differentiated watersheds in order to calculate product water footprints.

The objectives of this paper are: (1) to propose a method that is based on life cycle assessment (LCA) principles and LCA data and fully accounts for all kinds of WU (blue, green and grey water) and also for impact-weighted WFs (red and impact-weighted grey water); (2) to describe characterization methods which address impact-weighted grey WFs. (3) Furthermore, to demonstrate the implementation of this method, WU results (for blue, green and grey water) and WFs (red and impact-weighted grey water) are calculated per kg milk for two typical different Austrian milk PS.

2. Methods

2.1. Proposed method, scope and system boundaries

This contribution presents a method for water-use (WU) and water footprint (WF) estimates for agricultural products, which is based on LCA principles and accounts for all relevant life cycle-related inputs for the inventory level. This includes: (1) blue water, i.e. surface or groundwater used during production processes (e.g. in housing or for irrigation); (2) green precipitation water which is evapotranspirated by plants and soil; (3) grey water, i.e. the amount of water needed to dilute contaminants in affected freshwater. For the impact-weighted water footprints, the proposed method covers the so-called red WF, i.e. an impact-weighted blue WF, (see e.g. Pfister et al. 2009) and introduces an impact-weighting for grey water, which has not been covered in previous contributions (see e.g. Launiainen et al. 2014, Chenoweth et al. 2013). Deriving red water through a weighting step for blue water is meant to taking into account the regional stress on freshwater resources that is related to a WU. In analogy, grey WU results are impact-weighted in order to represent the water quality stress: any contamination of water not only leads to an increase in the grey WU of a product, but exerts a particular impact if an affected water body's quality is already impaired, increasing the amount of water needed to dilute the contaminant to acceptable contents. The NO_3-contamination of groundwater related to agricultural production may serve as an example for this: The NO_3-content in water bodies is mainly affected by the amount of precipitation water and flowing water for groundwater and surface water bodies, respectively. Additionally, it is influenced by the amount of NO_3-N emitted into the water systems, depending on the cultivation management and on further NO_3-loads e.g. from deposition. The proposed impact-weighting does not only account for the specific grey water demand of an assessed product, but also includes the effect of regional NO_3-loads on groundwater. The impact-weighting factor depends on the groundwater NO_3-content, which is assumed to be influenced by long-term cultivation management and related NO_3-loads. For the local approach, constant long-term conditions are assumed, which are reflected in the current state of the respective water bodies.

Green water, which is included at the inventory level (WU method), is not considered for the impact-weighted level (WF method) any more. This green water is not comparable to blue water, as it is assumed not to contribute to water scarcity from a water management perspective, and its impact is related to the indicator land use (Ridoutt and Pfister 2010). Contrarily, other authors argue that green water is also limited, can be substituted by blue water and may affect blue water availability (Jefferies et al. 2012, Berger and Finkbeiner 2012, in: Chenoweth et al. 2013); consequently, we include green water on the inventory level.

Figure 1 illustrates water types according to different methods and results included in this paper for WU (inventory level) and for WFs (impact level), i.e. red water according to Pfister et al. (2009) and an impact-weighted grey water footprint affected by the background concentration of the substance to be considered (here: nitrate).

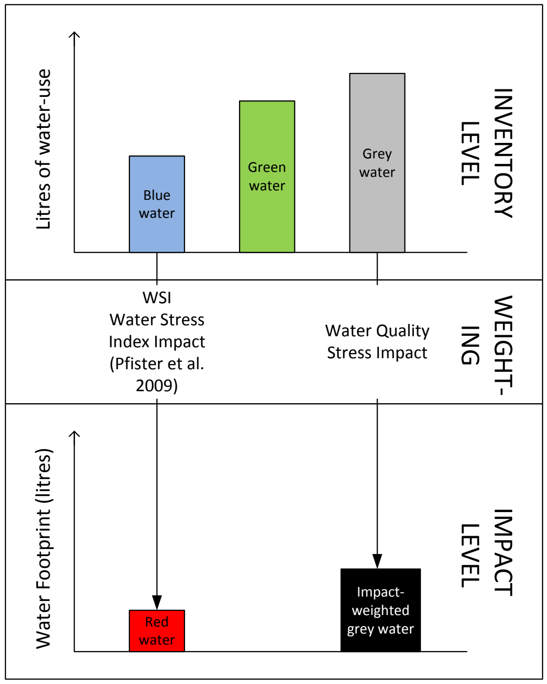

Figure 1: Water types covered in our method for water-use estimates and a product water footprint.

The concept of WU is based on Hoekstra et al. (2011) concerning blue, green and grey water but uses other data sources and calculation procedures for quantification. Table 1 gives an overview of the calculation procedures and of some of the algorithms provided in this paper for WU and WF calculations at different stages in the life cycle for the case of milk production. System boundaries were defined to include the most important processes requiring water, such as the supply of input factors relevant for the production of feedstuffs, evapotranspiration of plant feedstuffs, water directly used for livestock husbandry and for milk processing in the dairy (Table 1). Generally, WU (water demand) is calculated as the product of activity data (e.g. amounts of mineral nitrogen fertilizers to produce one unit of feedstuff) and water demand factors per unit (e.g. liters (L) of blue water needed per kg nitrogen fertilizer produced). While some WU estimates such as for blue drinking and cleaning water used in housing represent gross water demands, the red WF results describe further weighted net losses of water from a local system (e.g. irrigation water lost by evapotranspiration or water contained in products leaving the local system). Grey water is generally not lost from a local system, but is a virtual water demand which is accounted for in the water balance to include effects of water pollution on water demands.

Table 1: Different water types and algorithms provided for water-use and water footprints for different elements of a milk production system.

2.2. Blue water use for irrigation – methodological aspects and input data

For cultivation of feedstuffs, regionally varying amounts of blue water have to be used for irrigation ($Blue_{irrigation}$) to compensate for a lack of precipitation. Equation 1 [Eq.1] quantitatively describes this WU (liters of blue water for irrigation per kg milk).

$$Blue_{irrigation} = \sum_{i=1}^{n} Feed_{i,r,m} * I_{i,r,m} = \sum_{i}^{n} Feed_{i,r,m} * irr_{i,r,m} * ET_{i,r,m} \qquad \text{Eq.1}$$

where $Feed_{i,r,m}$ is the amount of different feedstuffs i from specific regions r, produced with management practices m to yield one unit (kg) of milk, multiplied with the feedstuffs' specific irrigation water demands $I_{i,r,m}$ (specific for feedstuffs/crops i, for regions r and for management practices m; in L kg^{-1} DM). $ET_{i,r,m}$ describes the evapotranspiration water demand (in L) for selected Austrian feedstuffs i as derived from the EPIC model (Schmid 2011, Asamer et al. 2011; see Table 2). The term $\%irr_{i,r,m}$ represents the proportion of irrigation water from overall water for ET plus recharge water amounts for crop i in region r for management practices m. Due to mostly sufficient precipitation for evapotranspiration, blue water is commonly not used for irrigation feedstuff production in Austria, where only a small proportion of cropland is irrigated. Most feed producers do not have the infrastructure for irrigation. Consequently, a proportion ($\%irr_{i,r,m}$) of only 1 % and 2 % of overall evapotranspiration water $ET_{i,r,m}$ was estimated for Austrian grain and corn production, respectively. Siebert and Döll (2010) show a comparable percentage of blue water from overall virtual water for crops from other regions which mainly export crops to Austria. Hence, we assumed the same values for $\%irr_{i,r,m}$ for imported cereal grains, maize and soybeans.

We used mass allocation for co-products, e.g. 1 kg of soybean cake shows an equal evapotranspiration water demand as toasted soybeans or extracted soybean meal (see Table 2).

Table 2: Water required for evapotranspiration for selected concentrate feedstuffs (liters per kg DM).

Feedstuff	$ET_{i,r,m=Austria}$ m = Organic / Conventional	Feedstuff	$ET_{i,r,m=Austria}$ m = Organic / Conventional
Triticale & wheat	471.5 / 480.8	Lucerne meal	502.0 / 528.7
Barley	467.4 / 490.9	Wheat bran	471.5 / 480.8
Maize (corn)	505.7 / 544.9	Soybean cake	477.5 / 495.1
Peas	455.2 / 448.6	Extracted soybean meal	477.5 / 495.1

2.3. Irrigation-related red water footprint

For characterizing the irrigation-related water footprint, we applied the Water Stress Index WSI (Pfister et al. 2009) to our inventory results $Blue_{irrigation}$ for the feedstuffs $Feed_{i,r,m}$. We assumed that all feedstuffs for the milk production were cultivated in Austria or in the neighboring countries (Hungary, Slovakia, Slovenia) and Croatia or Romania, which all belong to the water catchment basin of the Danube. Hence we multiplied all blue water results from the inventory level with a WSI-factor (WSI_r) of 0.0689 for this water catchment basin according to Pfister et al. (2009). As an exemption, imported soybeans for extracted soybean meal are assumed to be imported mainly from Brazil, Argentina and USA; on average, we assumed a WSI-factor of 0.012 for imported soybeans (Pfister et al. 2009). See equation 2 to for the detailed calculation:

$$Red_{irrigation} = Blue_{irrigation} * WSI_r = \sum_{i=1}^{n} Feed_{i,r,m} * I_{i,r,m} * WSI_r \qquad \text{Eq.2}$$

2.4. Green water (precipitation) use – methodological aspects and input data

Green water was estimated at the inventory level as the difference between the overall water demand for evapotranspiration as derived from the EPIC model and the amount of irrigation water. Equation 3 describes this green water demand from precipitation which results from evapotranspiration and is usually removed from local water cycles. With the proposed method green water is accounted for at the inventory level; it is also limited and can be substituted by blue water. Additionally, we estimated a yield-related loss of green water from reduced precipitation in the case of preceding clearing of tropical forests (based on data from Avissar and Werth 2005). This loss of green water from a regional water cycle is relevant for a part of soybeans from South America.

$$Green_{evapotranspiration} = \sum_{i=1}^{n} Feed_{i,r,m} * \left(ET_{i,r,m} - I_{i,r,m}\right) = \sum_{i=1}^{n} Feed_{i,r,m} * \left(ET_{i,r,m} * (1 - \%irr_{i,r,m})\right) \quad \text{Eq.3}$$

2.5. From grey water-use to the impact-weighted grey water footprint

The concept of grey water related to crop cultivation is based on Hoekstra et al. (2011) but was refined: First we confirmed nitrate to be the most relevant substance in terms of limiting ground water quality for most of Austria (Austrian Environment Agency 2007). Furthermore, we changed the constant 10 % nitrogen (N) assumed by Hoekstra et al. (2011) to be leached as nitrate to proportions for average conventional production, which were found in a meta-analysis covering 127 studies (Kolbe 2002). As a result of the meta-analysis, 26.6 % and 11.0 % of applied N for conventional management were calculated to be lost as nitrate from arable land and permanent grassland, respectively. The parameter $\%leaching_{i,r,m}$ in equation 4 represents the proportion of lost NO_3-N in connection to $N_{applied\ i,r,m}$, i.e. the amount of N applied per kg of feed from fertilizers including available N from biological N-fixation and deposition of gaseous N-losses from livestock husbandry (see Hörtenhuber et al. 2010 and Hörtenhuber et al. 2011 for activity data on N loads and N applied as well as N-emissions for selected feedstuffs). As the term ($N_{applied\ i,r,m}$ * $\%leaching_{i,r,m}$) is given in kg NO_3-N, it has to be converted into NO_3 (nitrate) by division (0.2259).

In contrast to previous literature sources, this contribution does not include a "regional background concentration" of nitrate in affected water bodies for calculation of grey water. Hence, for "$Grey_{leaching}$" per kg milk, i.e. the amount of virtual grey water which is needed to dilute pollutants in fresh water, we used a maximum tolerable limit for drinking water quality ($C_{max\ NO3}$) of 45 mg (0.000045 kg) NO_3 L^{-1}.

$$Grey_{leaching} = \sum_{i=1}^{n} Feed_{i,r,m} * \left(\frac{\frac{N_{applied\ i,r,m} * \%leaching_{i,r,m}}{0.2259}}{\max\_nitrate_{drinking-water}}\right) \quad \text{Eq.4}$$

Figure 2 describes all parameters and processes covered in the proposed method for estimation of WU at the inventory level (green, blue and grey water; the latter based on NO_3-N) for the cultivation of feedstuffs.

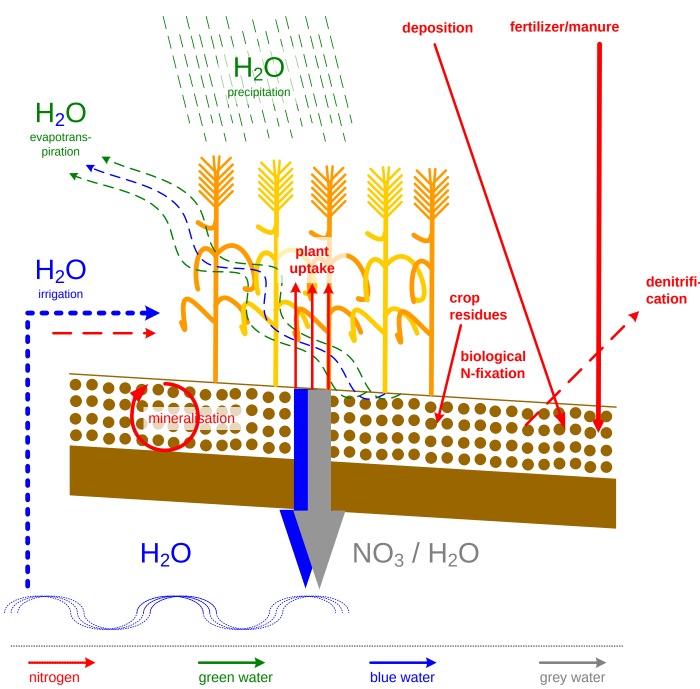

Figure 2: Parameters covered in the proposed method for estimation of water-use concerning cultivation of feedstuffs.

Relatively small amounts of virtual grey dilution water result from potentially leached N related to energy consumption that is primarily emitted as NO_X-N, NH_3-N or N_2O-N from cultivation of feedstuffs, animal husbandry, transports or dairy processing, and is termed $Grey_{energy\text{-}use}$ herein. The amount of leached N is based on the source of energy, i.e. on its specific N emission. According to an IPCC (2006) default value, we assumed 30 % of all gaseous N-emissions from energy supply and usage to be lost to water bodies via deposition on natural land, on settlements without water treatment in sewage plants or on agricultural land, followed by leaching.

As this energy-related grey water is no key source for the overall water demand, a simplified calculation may be used: we converted total energy needed for feed processing, housing, milking, milk-cooling and processes in the dairies, etc. (see Table 1) into diesel-equivalents and calculated the associated CO_2-eq emissions. Based on Hausberger (2000), assumptions concerning NO_X-N, NH_3-N or N_2O-N emissions and the 30 % leached N (IPCC 2006), we calculated 77.3 L of grey dilution water per 1 kg of CO_2-eq from fossil fuels.

The impact-weighted grey water footprint is calculated from a combination of the cultivation-related $Grey_{leaching}$ water demand and the less relevant $Grey_{energy\text{-}use}$ water demand plus a weighting factor to account for a regionally variable "water quality stress".

Two different approaches may be used to derive an impact-weighted grey WF ("Imp.Grey" in equations 5 and 6):

(1) In a regional (catchment based) approach, the ratio between the regional concentration of the substance that defines the grey water (here: nitrate; $\boldsymbol{C}_{regional\ \mathrm{NO3}}$ in mg NO_3 L^{-1}) and its maximum tolerable concentration in drinking water ($\boldsymbol{C}_{max\ \mathrm{NO3}}$, 45 mg L^{-1}) characterize the regional "water quality stress" and is used as an impact factor.

$$Imp.Grey_{leaching-approach(1)} = \left(Grey_{leaching} + Grey_{energy-use}\right) * \left(\frac{\boldsymbol{C}_{\mathrm{regional}\,NO3}}{\boldsymbol{C}_{\mathrm{max}\,NO3}}\right) \qquad \text{Eq.5}$$

(2) For a local approach, the impact-weighted grey WF is derived by using the ratio of grey water needed for dilution of emitted nitrate and the water actually available for dilution as an impact factor. The water available for dilution results from water recharge amounts as a function of local annual precipitation plus irrigation minus evapotranspiration (each per kg of crop).

$$Imp.Grey_{leaching-approach(2)} = \left(Grey_{leaching} + Grey_{energy-use}\right) * \left(\frac{\mathrm{Grey}_{\mathrm{leaching}} + Grey_{energy-use}}{\frac{\left(\sum_{i=1}^{n} Feed_{i,r,m} * (pre_r + I_{i,r,m} - ET_{i,r,m})\right)}{\sum_{i=1}^{n} Feed_{i,r,m}}}\right) \qquad \text{Eq.6}$$

where pre_r is defined as the local precipitation ($Green_{evapotranspiration}$ water plus green water for ground- and surface water recharge) in L per kg harvested yield.

For approach (1) the average impact factors for derivation of the impact-weighted grey WF are 0.336 and 0.334 for the two production systems (PS) "PS A" and "PS L", respectively (see subsection 2.7 for further details on the PS). The associated average values for $C_{regional\ \mathrm{NO3}}$ in drinking water are approximately 10 mg for grassland areas and 25 mg for arable land (BMLFUW/UBA 2006, 2010). For approach (2), we obtain an average impact factor of 1.1928 for PS A with differing recharge water amounts for on-farm areas and land used to produce bought-in concentrates. For PS L we calculated an average impact factor of 1.5268.

2.6. Further sources for blue and red water demand

In addition to blue (and red) water used for irrigation, livestock husbandry requires some blue water consumed by the animals and for cleaning purposes. The drinking water demand of dairy cows and heifers was calculated based on their diets (Wiedner 2010). Average default values from literature (KTBL 2008) were assumed for the required quantity of cleaning and flushing water. Furthermore, some blue water is needed for cleaning purposes in feed processing plants, for cleaning of transport facilities and especially in the dairies

(Nielsen 2003, Theilen and Goldbach 2000). For the red WF, i.e. the impact-weighted blue water demand as described above (subsection 2.1), see the Water Stress Index WSI (Pfister et al. 2009) and subsection 2.3 for further details.

2.7. Input data for Austrian milk production systems and their upstream supply chains

Amounts of feed used to produce one kg of energy-corrected milk were taken from Hörtenhuber et al. (2010) for an alpine and a lowland milk production system (PS “A” and PS “L”). The assessment includes on-farm land and land areas indirectly claimed via bought-in concentrates. Including the effects of the rearing phase and accounting for the by-product beef from cull cows, dairy cows need 0.87 and 0.62 kg DM roughage, mostly from permanent grassland, per kg of energy-corrected milk for PS A and PS L, respectively; an additional 0.16 and 0.18 kg DM of concentrates are fed per kg of milk in PS A and PS L, respectively. The concentrate mixtures are mainly based on barley, wheat and corn as well as some supplementary protein from rapeseed cake, extracted soybean meal and distillers dried grains with solubles; for further details see Hörtenhuber et al. (2010).

Concerning inputs into milk PS as well as their upstream supply chains and calculation procedures described in subsection 2.5, a total of 12.9 L (34 % from fertilizer production) and 13.2 L (20 % from fertilizer production) of $Grey_{energy\text{-}use}$ dilution water demand were calculated for PS A and PS L, respectively. These result from energy consumed for cultivation and processing of feedstuffs, from the production of mineral fertilizers and pesticides, including gaseous N-losses from the fertilizer production (see Table 1), for livestock husbandry and upstream transports.

3. Results

The average sum of unweighted WUs for PS A and PS L is around 700 L per kg milk, with an average grey WU of 314 L/kg (45% of total WUs). In detail, we found 266 and 361 L of grey dilution water per kg milk for PS A and PS L, respectively. Green WU for cultivation of feed was 384 and 304 L/kg of milk for PS A and PS L, respectively; green water lost from the regional cycle due to deforestation added up to 16 (PS A) and 17 (PS L) L/kg. Blue water for irrigation (grains and corn) was identified to be 4 L per kg milk for both PS A and PS L. In total, blue WU estimates for housing, for production of mineral fertilizers and for dairy processing purposes resulted in 13 L/kg (similarly for both PS A and PS L; about each 5 L for housing and the dairy, the other 3 L for production of mineral fertilizers and pesticides). Equally, additional 13 L per kg milk were found for both PS A and PS L for grey water from livestock husbandry’s or transports’ energy demand-related deposited and leached N-emissions. The latter 13 L are accounted for in the category “Grey water for crops and roughage cultivation” in Figure 3, as they are assumed to be deposited mainly on the agricultural land.

The blue and green WU is usually connected to the production efficiency and is therefore higher for the alpine (+25 %) than for the lowland PS, whereas the latter shows greater grey WU (+33 %), especially due to higher nitrate emissions related to the greater proportion of arable land used (see Figure 3). Comparably, the impact-weighted grey WF is also smaller for PS A than for PS L; the difference between the two PS is 32% following approach (1), which reflects a regional perspective, and 72% if estimated by approach (2), which represents the local scale.

In contrast to the impact-weighted grey WF, red water is of very little relevance for Austrian dairy production, because only small amounts of blue water are required, which partially do not leave the local systems and are not scarce in the regions addressed (Pfister et al. 2009). Consequently, red water (less than 1 L per kg milk) is hardly visible in Figure 3.

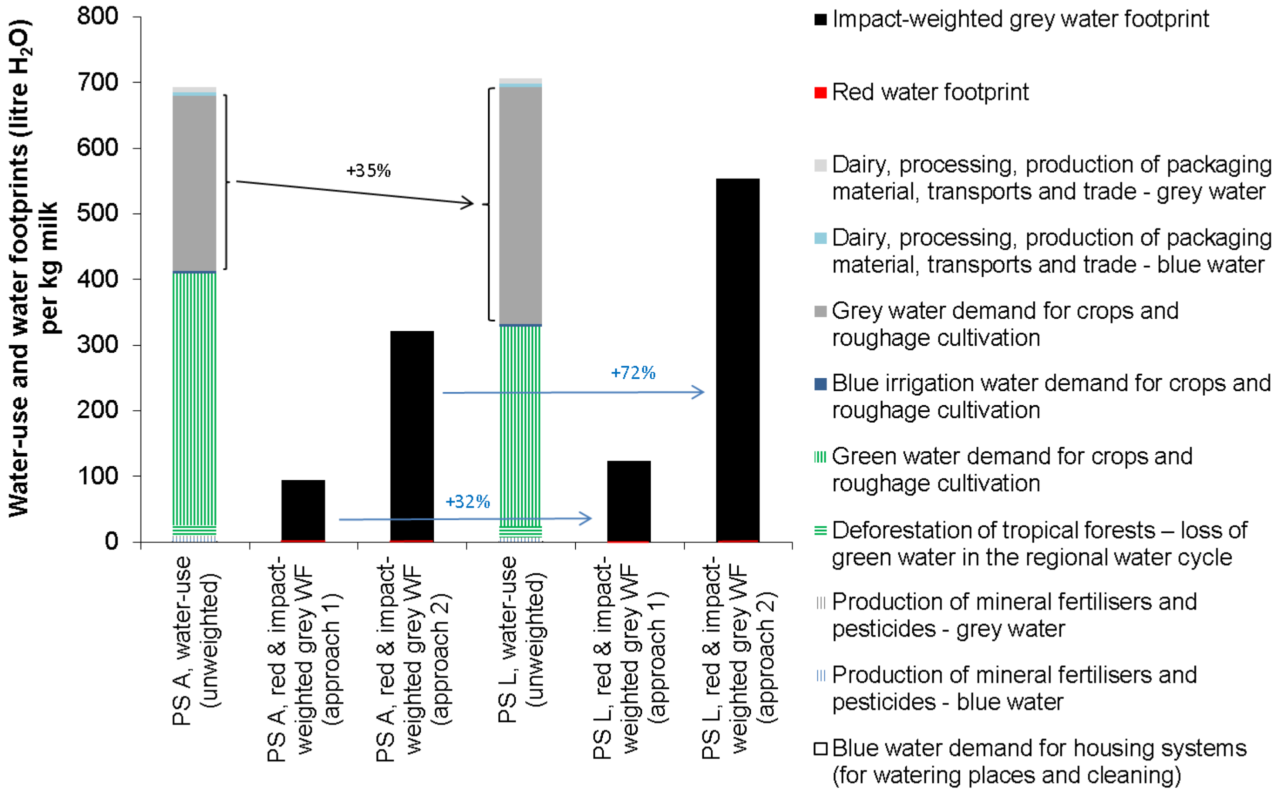

Figure 3: Water-use (blue, green and grey water) and the impact-weighted grey water footprint as well as red water for two dairy production systems in Austria (alpine PS A and lowland PS L).

4. Discussion

Both impact-weighting approaches (1) and (2) seem to be practicable for the impact-weighted grey WFs of typical crops. For specific crops (e.g. with a high proportion of N lost as NO_3) or for a small-structured agricultural area with crop rotations (within one catchment area), we propose to use the less detailed regional approach (1). As a consequence of the less specific influences, approach (1) results in less diverging WF results than approach (2). In approach (2) the impact factor is derived from processes in the upper soil layer of a cultivated area only, but does not account for the dilution effect of water transfer from areas with less or no N fertilization such as forests. Deviating therefrom, the impact factor is derived from a concentration of the relevant substance in affected water sheds in approach (1), which therefore better represents the regional situation, particularly in terms of agricultural impacts (e.g. nitrate losses).

Some conceptual aspects are currently discussed in the relevant literature (see Chenoweth et al. 2013): (i) Should different types of water be added up for a final quantification? While blue and green water represent physically used amounts of water, grey water is a virtual water-use, which is not accompanied by a physical water consumption. Consequently, we did not compare total WU per kg of liquid milk, but compared single sources for water demand. (ii) Green water is naturally supplied by precipitation and thus it is questionable whether it is to be accounted for in a WF, which is assumed to consist only of human-driven water demands in some concepts. Contrarily, we assume green water to have an important impact on available amounts of blue water (in downstream water bodies) and also an impact on grey water, as it dilutes nutrient or pollutant loads. As a consequence, the proposed method accounts for green water at the inventory WU level and estimates an impact-weighted grey WF. This grey WF is influenced by the green water-use, mainly through its function for recharging water bodies. (iii) Most water footprints which implement grey water derive its demand from nitrogen losses, although in many areas other substances may be most limiting for the water quality. Therefore, attention must be given to a proper estimation of the grey water use and to the identification of the substance most critical to water quality, which ultimately defines the grey water demand.

Grey water is not considered in typical multiple-indicator LCA studies, as they usually cover nutrient (nitrogen and phosphorus) loads in an eutrophication potential and partially also pollutant loads (mainly pesticides) in toxicity indicators. To avoid double counting, these studies use at the most blue or red water as an indicator of resource use – if at all. Contrarily, grey water estimates may provide an important information in studies which do not integrate eutrophication potential estimations or toxicity indicators, which not only aim at scientific analysis, but also at the communication of environmental concerns. Regarding the understanding and interpretation of qualitative and quantitative aspects of water resources, the concepts of virtual water and water footprints already provided some knowledge (see Chenoweth et al. 2013). However, in contrast to an eutrophication or a toxicity potential, the impact-weighted grey WF described in this paper even shows an advantage from a scientific perspective: this indicator includes a regionally or locally variable impact of emissions by addressing the background concentration of the substance concerned, such as nitrate, phosphorus or different pesticides.

The method suggested herein basically follows life cycle assessment principles (see guidelines for life cycle assessments: e.g. ISO 2006, BSI 2011) which makes it coherent to other LCA criteria and allows for an integration into a wider assessment, whenever the use of water resources is of interest.

5. Conclusion

We propose an integral consideration of quantitative and qualitative aspects related to water resources in so-called "water footprints", following principles of life cycle assessment. Blue, green and grey water-use shall be assessed at the inventory level and shall be amended by considering red water and an impact-weighted grey water footprint. The latter is defined within the proposed method to characterize the impact of a grey water demand in accordance with an existing method for red water.

For the overall water-use of the two production systems presented herein, an inclusion of grey water leads to a disadvantage for the more intensive PS L as compared to PS A. Similarly, the consideration of the regional and local impact for a WF according to the suggested approaches (1) and (2) leads to a disadvantage for the more intensive PS L due to a substantially higher virtual impact-weighted grey WF.

However, for crops and crop rotations with an inherent risk for water pollution we propose to use the less detailed impact-weighting approach (1), which should be based on measured data, focuses on the regional level and better reflects conditions for small-structured agriculture and the impact of nitrate leaching on regional water quality.

ABSTRACT

Emissions of CO_2 due to land use and land-use change (LULUC) are being quantified, but their allocation to products is complicated by indirect (iLUC) effects. Arguing that it is increases in net agricultural commodity imports that drive iLUC, we propose to link LULUC emissions from domestic agricultural production to iLUC emissions caused by international agricultural commodity trade. LULUC due to expanding infrastructure areas is discounted. The method is demonstrated with results for selected example nations (e.g. Brazil, China, Indonesia, USA). The method also permits allocating emissions specifically to product groups within the country of consumption. This is demonstrated for product groups within the example countries. Results are found to vary widely between nations and between product groups within a nation. The method is an attempt to provide a computational basis for a more equitable approach to LUC-related GHG-accounting between "LULUC-emitting/exporting nations" and "LULUC-importing nations".

Keywords: land use change, greenhouse gas emissions, LULUC, iLUC

1. Introduction

Increasing demand for food energy and protein adds to the environmental impacts of food and feed production, the latter indirectly through animal production. Impacts include both land use (LU) emissions on extant agricultural areas through intensification and land use change (LUC) related emissions from newly converted areas (such as primary and secondary forests and savannahs; Hörtenhuber et al. 2013, Fargione et al. 2008). LUC and to a lesser extent LU are among the major contributors to global CO_2 emissions, especially in the tropical regions of South-America, Asia and Africa. Emissions from LUC are reported to have contributed approximately 20% of total global CO_2-emissions during the last two decades of the twentieth century (Denman et al. 2007). For the decade from 2000 to 2010 the proportion of CO_2 emissions originating from LUC substantially decreased but still contributed to about 12% (Poruschi et al. 2010) or 10% (Harris et al. 2012) of global CO_2 emissions. The multitude of unanswered scientific questions regarding the complex interactions between LUC's environmental, socio-economic and societal aspects (e.g. in Foley et al. 2005, UNEP 2014) cannot be properly addressed in this paper. This paper focuses on how LULUC-related greenhouse gas emissions can be allocated to the (worldwide) trade and national "consumption" of agricultural commodities.

A previously published method by the authors (Hörtenhuber et al. 2013) attempted to quantify primarily dLUC greenhouse gas (GHG) emissions from known and definable regions of origin. In contrast to the environmental effects of direct land-use-change (dLUC), GHG emissions from indirect land-use-change (iLUC) effects are an evolving issue that has wide-ranging policy implications (e.g. Finkbeiner 2013, Fritsche et al. 2010). Although region-specific dLUC emission results can be useful, they fail to account for the effects of international agricultural commodity trading. Many countries that are global top exporters of food and feedstuffs actually cause domestic LULUC emissions on behalf of the countries buying their exports. We hypothesize that countries with increasing net agricultural exports will tend to emit more CO_2 from LULUC as well, because they are forced to increase production through conversion of previously unused land (LUC) and intensification of cultivation on existing land (causing LU emissions due to soil carbon losses). This potential correlation is of course subject to other factors – for example, a growing domestic population will exacerbate LULUC emissions, while any decrease in domestic demand will weaken export effects.

Consequently, the objective of this work is to provide a deterministic top-down method which accounts for the effects of iLUC linked to international agricultural commodity trade on country-specific LULUC emissions.

2. Methods

In this section we present in more detail the concept underlying the proposed method, some of its key assumptions, and the simple computational steps involved.

2.1. Country-specific shares of agriculture-related LULUC emissions

When accounting for environmental impacts of LU and LUC, agricultural products with increasing production volume exert stronger pressure on land supplies than products with decreasing production volumes. Therefore increasing production should be assigned a larger share of impacts. Conceptually, agricultural exports can be linked to international indirect LUC (iLUC) effects: If domestic production becomes more export-oriented, domestic supply will decrease and the unmet domestic demand will lead to increased commodity imports if economically feasible. The approach presented here thus assumes the existence of a (hypothetical) global pool for iLUC emissions.

Aside from the global iLUC emissions pool, the method presented takes a country-specific approach, since trends in agricultural production, imports and exports differ by region (as well as by product type). A country-specific method can be expected to better mirror large regional LULUC variations than a one-size-fits-all approach that assigns equal LULUC emissions on an area basis (see e.g. Williams et al. 2010, Vellinga et al. 2013), regardless of regional differences. If regional LULUC data and regional agricultural statistics are available within a country, the approach could easily be adapted to a higher spatial resolution as well.

Countries with increasing agricultural exports will feed a proportional share of their LULUC emissions into this pool, thereby reducing their burden of LULUC emissions, and countries with increasing net imports will import a proportional share of the global iLUC pool emissions. It is important to note that this takes a dynamic rather than static view: the temporal changes in exports and imports (increases and decreases) determine the flows of iLUC emissions, and not the absolute export and import data. Also, since the iLUC pool is fed by "exported" LULUC emissions, it actually includes LU-related emissions in addition to LUC-related emissions. Thus the effects of intensified agricultural production on LU emissions are also exported and imported into and out of the pool. We have nevertheless chosen to use the term "iLUC pool" here since it is well established in the international discussion.

To allow for aggregation of the wide variety of agricultural commodities produced by a given country and traded internationally, we convert commodity masses as given in the FAO statistics (FAO 2012) to their energy-content equivalent (lower heating value, LHV), based on data from Fehrenbach et al. (2008), and Beilicke (2010). Furthermore, all calculations in this study refer only to CO_2 emissions; other GHGs such as methane and nitrous oxide are not included in this method, since they typically contribute little to LULUC emissions change (Olivier and Janssens-Maenhout 2011).

As a starting point we use for each country the CO_2 emissions L_k (Olivier and Janssens-Maenhout 2011) that are caused by LULUC:

$$\sum_k L_k = L_{glo} \qquad \text{Eq. 1}$$

where
L_{glo}…annual LULUC emissions, worldwide (excluding those countries for which no suitable data are available), Tg a^{-1}
L_k… annual LULUC emissions from country k, Tg a^{-1}

Each country's LULUC emissions have to be reduced by those LULUC emissions that are caused by the expansion of infrastructure areas (including built-up areas; Krausmann et al. 2013) rather than by the expansion of agricultural areas (FAO 2013). Given the focus on agricultural production, we split the infrastructure LULUC emissions and the agricultural LULUC emissions in proportion to their country-wide area increases.

$$AG_k = L_k - INF_k \qquad \text{Eq. 2}$$

where
AG_k … annual agriculturally-related LULUC CO_2 emissions from country k, Tg a^{-1}

INF_k … annual infrastructure-related LULUC CO_2 emissions from country k, Tg a^{-1}

In the model presented here, agriculture-related LULUC emissions are in principle allocated to the emitting country. As described above, a correction is made to account for iLUC-causing increases of net imports into a country:

$$NL_k = AG_k + NI_k \qquad \text{Eq. 3}$$

where
NL_k...net annual agriculturally-related LULUC emissions for country k, Tg a^{-1}
NI_k...net import emissions due to net import increases into country k, Tg a^{-1}

The following equations illustrate how the net import emissions are calculated.

We first calculate the global iLUC pool and then distribute the iLUC pool's emissions to countries proportional to their net import increases during a selected accounting period.
The global iLUC pool is fed into by all export-increase related LULUC emissions EX_k:

$$iLUC_{glo} = \sum_k EX_k \qquad \text{Eq. 4}$$

EX_k in turn are defined as the share of a country's agriculture-LULUC emissions that is proportional to a country's export increases:

$$EX_k = AG_k * e_k \qquad \text{Eq. 5}$$

where
EX_k...LULUC emissions due to agricultural commodity export increases of country k, Tg a^{-1}
e_k…energy-content (LHV) based export-increase allocation factor (dimensionless).

The allocation factor e_k relates a country's agricultural export increases to its domestic agricultural production increase, both calculated as annual averages and expressed in energy equivalents (LHV):

$$e_k = \frac{\Delta E_k}{\Delta D_k} \qquad \text{Eq. 6}$$

where
ΔE_k…average annual export increases of all agricultural commodities expressed as LHV, TJ a^{-1}
ΔD_k…average annual domestic production of all agricultural commodities expressed as LHV, TJ a^{-1}

The average annual export increase ΔE_k and the average annual domestic production increase ΔD_k are both calculated in the same way: The annual LHV equivalents of exports and production of all products for a given country are averaged over an initial three-year period and over a final three-year period – from 1998 to 2000 and from 2007 to 2009, respectively – and then the initial three-year average is subtracted from the final three-year average to obtain the increase over the ten years of the accounting period (from 1999 to 2008). This ten-year increase is then divided by ten to obtain an average annual increase over the ten years of the accounting period (from 1999 to 2008).

Now that the global iLUC emissions pool has been established, its emissions are distributed among all countries in proportion to their individual net import increases ni_k:

$$NI_k = iLUC_{glo} * ni_k \qquad \text{Eq. 7}$$

where
ni_k…net import-increase allocation factor (LHV-based and dimensionless)

The net import allocation factor ni_k is defined as the difference between a country's share of global import increases and a country's share of global export increases:

$$ni_k = \frac{\Delta I_k}{\sum_k \Delta I_k} - \frac{\Delta E_k}{\sum_k \Delta E_k} \qquad \text{Eq. 8}$$

where
ΔI_k…average annual import increase of all agricultural commodities expressed as LHV, TJ a^{-1}
$\Sigma_k \Delta I_k$…global sum of average annual import increases of all agricultural commodities expressed as LHV, TJ a^{-1}
ΔE_k…average annual export increase of all agricultural commodities expressed as LHV, TJ a^{-1}
$\Sigma_k \Delta E_k$…global sum of average annual export increases of all agricultural commodities expressed as LHV, TJ a^{-1}.

2.2. Product group-specific shares of agriculture-related LULUC emissions

Net LULUC Emissions can also be calculated specifically for a product group p that is consumed in a country k. Emissions will vary for a given product group p depending on the producing country. Otherwise the approach follows largely that for countries.

For aggregating the diverse array of agricultural commodities (i.e., imports, exports, domestic production, and domestic demand), we use the energy content of each product group, expressed in units of lower heating value (LHV). The following product groups are considered here: alcoholic beverages, cereals (excluding for beer), fruits (excluding for wine), oil crops, pulses, spices, starchy roots, sugar and sweeteners, sugar crops, tree nuts, vegetable oils, vegetables, animal fats, eggs, meat, milk (excluding butter), offals, stimulants; no data are available in FAO (2012) for the groups "tobacco and rubber" and "miscellaneous".

Each product group in a country is assigned a share of the country-wide agricultural LULUC AG_k in proportion to its LHV-based share of the total agricultural production:

$$AG_{k,p} = AG_k * a_{k,p} \qquad \text{Eq. 9}$$

where
$AG_{k,p}$...LULUC emissions of agricultural product group p in country k, Tg a^{-1}
$a_{k,p}$ …energy (LHV)-based product allocation factor (dimensionless).

The product allocation factor $a_{k,p}$ relates a product group's production increases in country k to that country's total domestic agricultural production increase, both calculated as annual averages and expressed in energy equivalents (LHV):

$$a_{k,p} = \frac{\Delta P_{k,p}}{\sum_p \Delta P_{k,p}} \qquad \text{Eq. 10}$$

where
$\Delta P_{k,p}$…average annual production increase of product group p in country k, expressed as LHV, TJ a^{-1}

As was done with countrywide emissions, product-specific LULUC emissions $AG_{k,p}$ are adjusted with additional iLUC emissions from the global iLUC pool $NI_{k,p}$ in proportion to their net import increases $ni_{k,p}$. The expression for net LULUC emissions is similar to that for country as a whole:

$$NL_{k,p} = AG_{k,p} + NI_{k,p} \qquad \text{Eq. 11}$$

where
$NL_{k,p}$...net annual agriculturally-related LULUC emissions for product group p in country k, Tg a^{-1}
$NI_{k,p}$...net import emissions due to net import increases of product group p into country k, Tg a^{-1}.

The net import emissions for product group p in country k are calculated as:

$$NI_{k,p} = iLUC_{glo} * ni_{k,p} \qquad \text{Eq. 12}$$

where
$ni_{k,p}$…net import-increase allocation factor for product group p in country k (LHV-based and dimensionless)

The net import allocation factor $ni_{k,p}$ is defined as the difference between a country- and product-specific share of global import increases minus the corresponding global export increases:

$$ni_{k,p} = \frac{\Delta I_{k,p}}{\Sigma_k(\Sigma_p \Delta I_{k,p})} - \frac{\Delta E_{k,p}}{\Sigma_k(\Sigma_p \Delta E_{k,p})} \qquad \text{Eq. 13}$$

where
$\Delta I_{k,p}$…average annual import increase of product group p in country k expressed as LHV, TJ a^{-1}
$\Sigma_k(\Sigma_p \Delta I_k)$…global sum of average annual import increases of product group p expressed as LHV, TJ a^{-1}
ΔE_k…average annual export increase of product group p in country k expressed as LHV, TJ a^{-1}
$\Sigma_k(\Sigma_p \Delta E_k)$…global sum of average annual export increases of product group p expressed as LHV, TJ a^{-1}.

As a last optional step of the method, mass-specific net LULUC emissions $nl_{k,p}$ that are associated with domestic consumption of product group p in country k can be calculated from the average consumption:

$$nl_{k,p} = NL_{k,p} / C_{k,p} \qquad \text{Eq. 14}$$

where
$nl_{k,p}$ …average mass-specific net annual LULUC emissions for consumption of product group p in country k, Tg Tg^{-1} (kg kg^{-1})
$C_{k,p}$ …average consumption of product group p in country k, Tg a^{-1}

All values are averaged over the last three years of the accounting period (2007 to 2009).

3. Results
