AgBalance is a life-cycle assessment method for value chains focusing on primary agricultural production that integrates environmental, social and economic cost indicators. It is based on mandatory and optional parts of the ISO 14040 and 14044 standards for life cycle assessment. Furthermore, the developments of different working groups such as UNEP/SETAC for social LCA, the SA 8000 and ISO 26000SR standards were considered in the development of the methods. The results from the individual impact categories were aggregated as outlined (Saling 2002). The method received independent assurance of functionality and coherence from DNV Business Assurance, TÜV Süd and the National Sanitation Foundation (NSF).

Specific impacts of agriculture on the environment (biodiversity, soil health and land use etc.), the economy (total costs and profitability etc.), as well as to social (health and safety, gender equality, working conditions, training, fair trade etc.) aspects are assessed. In total up to 200 metrics are considered to evaluate up to 70 indicators in the three dimensions environment, society and economy. AgBalance offers the flexibility to assess production systems with different regional scope, from the farm level up to regional or even national level. Specific algorithms have been developed that can be operated with different databases, such as specific farm data as well as statistical, sectorial data or survey data. Preferably, publicly available data are used in order to give the system a high level of data transparency. AgBalance further allows for scenario analysis demonstrating interdependent variations of impact results as a function of changes to input parameters.

The set of AgBalance biodiversity indicators follows the "driving force – state – response" model which is proposed by OECD to structure the complex relationships between agriculture and biodiversity (OECD 2003). It is closely related to the "pressure – state – response" concept which can be regarded as largely accepted. Accordingly, the "pressure" component compiles factors which affect negatively biodiversity resulting in a decline of the state of biodiversity (what is reflected in a negative numerical factor on the state). The "state" indicator quantifies the status quo of biodiversity. Generally, organisms which are scientifically or politically accepted are selected for this purpose. "Response" indicators reflect activities which are able to promote or conserve biodiversity.

The indicators are linked with each other by calculation factors which are generated with indicator – specific algorithms. Quantitative ranges which are allowed for each indicator are specified in table 2. The selection of factors between 0.5 and 1.5 is based on bird data of different ecological groups (farmland birds, woodland birds, water and wetland birds, seabirds, butterflies) which show trend curves in this range and indicate herewith numerical realism of calculation factors (Bird indicators, BTO 2014). Maps showing bird populations in Europe as basis for the evaluation can be found at European Environmental Agency EEA under data and maps (EEA).

Table 2. Biodiversity indicators of AgBalance according to the pressure-state-response concept

Indicator	**Calculation factor**
Pressure indicators:	
Low cropping diversity	0.5 – 1
Nitrogen surplus	0.5 – 1
Ecotoxicity potential of pesticides	0.5 – 1
High farming intensity	0.5 – 1
Outcrossing potential	0.5 – 1
State indicator:	
IUCN assessment	(0,7)
Response indicators:	
High cropping diversity	1 – 1.5
Agri-environment schemes	1 – 1.5
Protected areas	1 – 1.5
Low farming intensity	1 – 1.5

2.1 Pressure indicators

“Low cropping diversity” is per se a reduction of agro-biodiversity and provides relatively poor plant-based resources to many animals (FAO 2004). In general, “agro-biodiversity” is more than the pure number of crops: according to FAO, “agrobiodiversity encompasses the variety and variability of animals, plants and micro-organisms that are necessary for sustaining key functions of the agro-ecosystems”. The multitude of crops – i.e. the number of crop species, crop varieties, the number of crop rotation programs on a farm or in a region – are an important element of sustained management of biological resources. In AgBalance, the number of crop plants in a rotation was selected as indicator since the advanced standardization and reduction of complexity of crop rotation programs which is often seen as element of farming intensification has a double negative impact on biodiversity: firstly, it is per se a reduction of agro-biodiversity, and it secondly reduces the diversity of food sources for wild and domesticated animals. Accordingly, under-average numbers of crops in crop rotation programs are selected as pressure indicators in AgBalance. Cropping diversity enhancement is a target of European agricultural regulations with respect to biodiversity protection (summary paper IEEP 2014).

“**Nitrogen surplus”** reduces mostly plant diversity and, based on that, in addition diversity of animals. It is important to make clear that nitrogen is not per se negatively assessed in AgBalance: nitrogen fertilizer – it may be natural or synthetic – is essential for plants. In the context of sustainability, the surplus of nitrogen is critical of several reasons. In the biodiversity indicator set, it is not the potential risk for surface water or groundwater which may be primarily a risk for human health at excessive concentrations. For biodiversity, nitrogen surplus was selected as indicator since it deeply influences plant societies in agricultural landscapes; it often causes the reduction of flowering plants and stimulates grasses. This reduction of primary biodiversity has often indirect negative consequences for pollinating or plant-feeding animals, i.e. the higher levels of the food chain. Therefore, an algorithm for nitrogen surplus is chosen as an indicator for low biodiversity in AgBalance. Appropriate nutrient balances are elements of SAFA (FAO 2012) and IRENA (EEA 2005) indicator systems.

“Ecotoxicity potential of pesticides” is an influencing factor on organisms which are exposed to these compounds. Pesticides – or “plant protection products” – are biologically active compounds which are used by farmers to control weeds (herbicides), fungal diseases (fungicides) or animal pests (insecticides or acaricides). The compounds may have a risk potential, i.e. for unwanted side-effects on such organisms which are not the target of the application by the farmer. Although, registrations which are the precondition for any pesticide application require often a specific risk management by farmers, these products can be handled safely. For instance, buffer zones to surface water to protect aquatic organisms, the risk potential of definite products were selected in AgBalance as in indicator. Data for short-term (acute) and long-term (chronic) eco-toxicity of plant protection products on earthworms, honey bees, rodents, birds, water fleas and fish are therefore available from pesticide toxicity databases. This selection of test organisms follows the European regulations (regulation EC No 1107/2009). Very detailed data on these products can be reviewed and extracted from the European Commission and can be used as well for other regions (EU pesticides database).

"High farming intensity" is a descriptive summarizing parameter; there is scientific evidence that high yields are generally negatively correlated with reduced biodiversity (Geiger et al 2010). This indicator may be challenged since it raises some questions. Empirically, there is the trend that "intensive agriculture" and biodiversity reduction often go hand in hand, while farming practices with reduced productivity – like many organic farming practices, extensive or traditional farming practices – in general promote biodiversity. But, some questions remain open. Is lower productivity in one area (for instance, in Europe) translocating problems to other continents from which agricultural goods need to be imported? This indirect land use or in a more negative sense indirect land use change is often discussed and might be addressed more properly in consequential LCA. However, there is so far no common agreement how to do it. On the other hand a question is, if the negative effect which high productivity often has can be compensated by the generation of more diverse landscapes with hedges, trees and zones which are dedicated to biodiversity protection. Although these questions can be regarded as open, it was decided for the AgBalance indicator set to follow the empiric evidence for a negative correlation between farming intensity and biodiversity. The farming intensity is only one effect to assess the biodiversity; other positive effects from modern farming systems can balance them as well in a positive way.

"Outcrossing potential" means the potential of a crop for fertile reproduction with native wild plants and herewith the genetic infiltration of original biocenoses. Although it may be a numerical increase of biodiversity in natural habitats when outcrossing occurs, there may be competition between indigenous biodiversity and such elements of biodiversity which is introduced by humans. The outcrossing potential according to this indicator is crop specific: there are crops with high outcrossing potential due to parameters like pollen transfer potential, number of wild plants of the same biological taxon in the region (which facilitates inbreeding), seed persistence in soil. Accordingly, a ranking of crops is made which reflects in summary the outcrossing potential of a crop species. Outcrossing potential is in particular an element of political decision making and often controversial public debates in the context of genetically modified organisms (summary paper EFSA 2014).

2.2 State indicator

"Farmland bird populations" are often used as indicators of species diversity (or biodiversity in general) since birds are on top of food chains and require for successful reproduction a diversity of biotic resources (like breeding habitats or different food sources).

In AgBalance, the status of biodiversity in a particular region is assessed by the number of species available that feature on the IUCN Red List for that region (IUCN 2008). The state indicator is calculated from the number of Red List species, according to a non-linear function. The function has the following range: the biodiversity state ranges from 1 (optimal) to 0 (worst); the slope is higher for smaller number of species, i.e., the differences are higher between regions with a smaller number of endangered species than those with higher number of endangered species. For Germany, the 632 Red List species were assigned a biodiversity state of 0.7. This definition is based on the published national biodiversity index of Germany. Other regions are assigned values by interpolation with zero Red List species corresponding to a biodiversity state indicator of 1, and 4000 Red List species to an indicator value of 0.1.

2.3 Response indicators

"High cropping diversity" is per se an increase of agro-biodiversity and provides diverse resources to animals in higher levels of the food chain. "High cropping diversity", i.e. over-average number of crops in crop rotation programs as response indicator, responds to "Low cropping diversity" as pressure indicator (see above).

Cropping diversity is accordingly a bi-directional indicator in AgBalance, since high crop numbers are positively rated, low numbers negatively.

"**Agri-environment schemes"** are subsidies can be applied by farmers to increase elements of biodiversity. Although ARSes may be critically judged (Berendse et al 2004), they are regarded as a response indicator due to the positive effects on biodiversity which they have in total on biodiversity (European Commission 2014). AR-Ses are implemented on a local level, therefore, different measures may be funded which promote biodiversity: it may be extensive farming to promote definite birds species or the sowing of flower strips from which pollinating insects benefit. Two factors are considered in this AgBalance indicator algorithm: the level of funding which the farmer receives, and the acreage for which this funding is dedicated. Both figures and regional information as well can be used and quantified as additional indicators for the change of biodiversity after applying different subsidies.

"Protected areas" are a classical tool of nature conservation to increase elements of biodiversity. In general, there are many different categories of nature conservation territories which contribute to the increase of biodiversity**.** Farmland is often part of such protected areas, for instance in Natura 2000 territories which clearly contribute to the enhancement of biodiversity (European Commission 2014). Therefore, the local range of protected land is selected as an AgBalance indicator.

"Low farming intensity" practices describe in summarizing form the trend that low yields often promote elements of biodiversity (European commission 2014, Geiger et al. 2010). In AgBalance, farming intensity is (like cropping diversity) a bi-directional indicator: low farming intensity practices often contribute to biodiversity conservation, while high farming intensity has the opposite result (see above under pressure indicators). High nature value practices which contribute to biodiversity are mostly associated with lower productivity than conventional farming (BFN 2014).

The above mentioned indicators fulfill the requirement for indicators in the sense that they are influencing factors, which can be regarded as publicly and scientifically accepted. But, this does not allow the quantitative assessment of the biodiversity range which is relevant in anthropogenic landscapes. The concept of using bird population trend curves is applied in AgBalance as a data-based approximation for this quantification. In European countries (and globally) it is shown that the range of 0.5-1.5 gives a realistic dimension (Global wild bird index 2010; Bird indicators 2013; BLE 2007). Based on these data, the biodiversity indicators are connected by factors within a range between 0.5-1.0 for driving force indicators, 1.0-1.5 with response indicators, and a state indicator which is normally <1, for Europe it is 0.7 unless national data are available. This factor depends on the region and former losses of biodiversity to a defined status. A desired trend according to this concept is the positive shift of the state indicator; ideally the state indicator should reach 1.

Competition between agricultural landscapes and natural areas is an important factor in the context of global biodiversity development. It is specified in the "environmental pillar" section, as part of the indicator "land use". It is not an element of the set of biodiversity indicators described here, but a standard element of each study since "land use indicators" are obligatorily used.

Each AgBalance study requires the assessment of all indicators in all three pillars – ecology, economy, social. Herewith, it is avoided that a targeted selection of indicators results in an unbalanced or biased assessment. A study result cannot be exclusively driven only by biodiversity or social or soil indicators or any other selected set of indicators even when the study question refers to elements of sustainability. All single results are displayed and shown separately in the study report. Finally they will be aggregated to an overall result.

3. Results and Discussion

For the showcase study on winter oilseed rape production in the Northern German state Mecklenburg-West Pomerania, the main data sources were from the German "reference farm network", the German annual agricultural report and interviews conducted on five farms, each with 100 – 500 ha of agricultural area planted with winter oilseed rape. The general study's scope was the sustainability performance of winter oilseed-rape production in the study region in 2008 in comparison to production ten years before. The customer benefit was defined as the 'production of 1 ton of oilseed rape, cradle to field border, in Mecklenburg-Vorpommern, Germany, product water content below 9%, data from 2008 and 1998.

Biodiversity indicators are shown in table 3. The indicator results of the two alternatives 1998 and 2008 can be compared with numerical results and have been calculated from single impact categories. The indicators

"Ecotoxicity potential", "Nitrogen surplus" and "Protected areas" show quite good improvements in the 10 years period, the others are constant but not negative. Only the Biodiversity state indicator was reduced which can be linked to other agricultural or industrial processes and the reduction of species in that region. Although the absolute number of pesticides which were used in the standard application schemes increased (5 in 1998 comparing to 9 in 2008), the ecotoxicity potential showed a positive trend due to more favorable ecotoxicity profiles of the new products.

Table 3. Overview on biodiversity impact categories for 1998-2008 comparison for the winter oilseed rape production

		2008 Standard	1998 Standard
Biodiversity	Biodiversity state indicator	0,69	0,70
	Agri-environmental schemes	1,00	1,00
	Protected areas	1,28	1,09
	Crop rotation	1,00	1,00
	Ecotox potential	0,91	0,88
	Farming intensity	0,60	0,60
	Intermixing potential	0,65	0,65
	Nitrogen Surplus	0,75	0,69
	Result biodiversity	0,24	0,18

The protected area coverage evaluates the coverage of Natura2000 and FFH areas in the study region (in this case, the federal state) against a given target value, as well as the fraction of area enrolled in agri-environmental schemes.

The results of the evaluation of the Biodiversity Potential can be linked afterwards with results from other environmental indicators to come to conclusions which are easy to understand, consider the whole life cycle and are holistically done. With the final results, further decision-making can be initiated and can be used for further improvements of the agricultural processes.

The highest aggregated assessment of all sustainability indicators showed a substantial improvement of sustainability score throughout all dimensions ("Economy", "Environment" and "Society") when comparing the good agricultural practice "Standard 1998" to "Standard 2008" practice. It is evident that ecological indicators contributed significantly to this difference since they exhibit clear differences between 1998 and 2008. In Figure 1 it is shown, in which environmental indicators, the alternatives differ and where improvements happened during the time period of 10 years. As more outside an alternative is located for the specific indicators, as more this alternative have benefits in the defined categories. The figure shows that in 2008 compared to 1998 all indicators have been improved; just the soil indicator showed the same result.

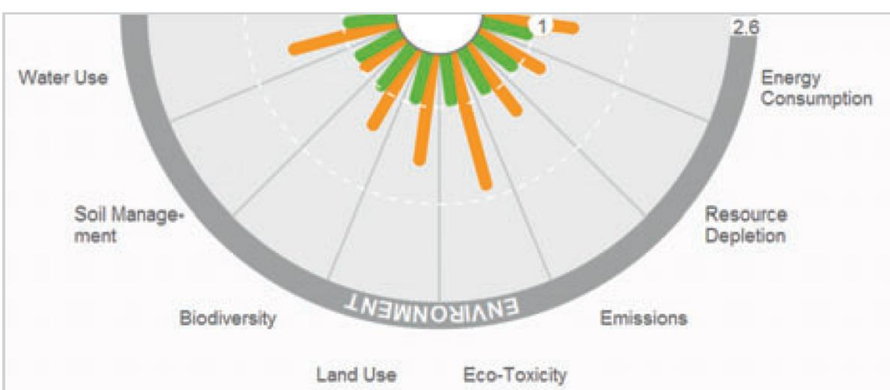

Fig. 1 Assessment results of biodiversity in total in the context of the other indicator sets of the environmental pillar (Green petals reflect the values for 1998, orange petals represent 2008).

The overall results can be shown in a similar way, covering all types of indicators to get a good overview, were improvements have been made over the last 10 years and where further activities or changes needed to have a more sustainable solution. Figure 2 shows all the impacts and allows specialists together with farmers the development of strategies for higher sustainability in the sector. In all main categories, the 2008 technology is more sustainable compared to 1998. It can be shown with the AgBalance methodology and can be quantified, that the sustainability in the defined type of agriculture was improved over the last 10 years. A common opinion in the society that the biodiversity was reduced if the situation today is compared to the situation 10 years ago, can be refuted.

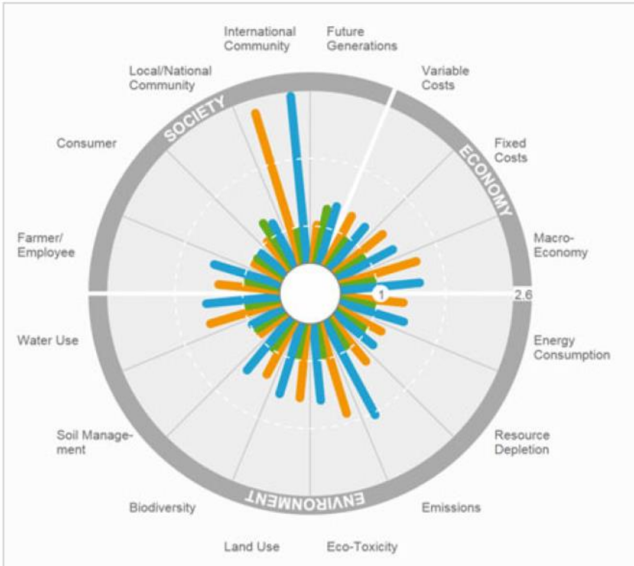

Fig. 2 Assessment results of all indicators in total (Blue petals reflects the values for modified fertilizer regime, based on Good Agricultural Practice in 2008, Green petals reflect the values for 1998, orange petals represent 2008).

4. Conclusion

The indicator set which is used to assess biodiversity in AgBalance has definite properties which become particularly visible with the showcase study. The concept implements that agriculture is not „good“ or „bad“ for biodiversity in general, instead, specific agricultural measures may promote or reduce biodiversity. A “state indicator” is a valid tool to make assumptions about biodiversity in general, based on drawing extrapolations from organisms of a select group to describe the state of biodiversity in total at a definite time and at a definite place. The amount of detailed information on various aspects of the sustainability performance of the production system together with scenario analysis makes AgBalance a powerful tool to derive recommendations for optimized crop production protocols.

Several examples show, that this kind of information is very helpful for farmers and other members of the whole supply chain, to develop more sustainable processes and to support a more sustainable agriculture. The quantification of sustainability indicators show very clearly optimization potentials and can be used for further improvement of processes. It can support the positioning of farmers in the society and increase the acceptance of products in the market following general principles of sustainability as a market trend. In particular the biodiversity facts of an agricultural process are in the focus of different stakeholders and needs to be improved to reach the goals of generating higher state indicators of a certain time period. The methods shown in this article are bale to measure and assess these effects and giving clear directions for the improvement of biodiversity.

ABSTRACT

In 2009 two French laws were passed on the provision of reliable and complete environmental information on "product plus packaging" to consumers. The AGRIBALYSE programme has produced an LCI database of agricultural products at farm gate to: i) support environmental labelling and ii) provide benchmarks for improving agricultural production systems. AGRIBALYSE analysed a wide range of animal Product Groups and Contrasted Production Systems. LCIs were calculated using a single methodological frame (Koch and Salou, 2014). The Functional Unit for the study was kg (life weight, Fat and Protein Corrected Milk, egg). The indicators Global Warming Potential, non-renewable fossil energy demand, acidification, eutrophication and land occupation were analysed. This paper presents a synthesis of AGRIBALYSE results with a focus on pig production systems. In the last part of this paper we expressed our results using an economic allocation method to better compare them to literature references.

Keywords: Livestock production, Life Cycle Assessment, LCI database, Review

1. Introduction

In 2009 two French laws were passed on the provision of reliable and complete environmental information on "product plus packaging" to consumers. The Life Cycle Assessment (LCA) method was chosen to assess environmental impacts of goods. ADEME, the French Environment and Energy Management Agency, was mandated to set up a Life Cycle Inventory (LCI) database to support this policy. The AGRIBALYSE program (Colomb et al., 2014) started in 2010, involving: i) ADEME as project coordinator; ii) Agroscope (Switzerland) for plant production and INRA for animal production as project co-leaders; iii) CIRAD, ACTA and 10 technical agricultural institutes as project partners. The aim of AGRIBALYSE was to provide LCIs of French agricultural products at farm gate to: i) support environmental labelling and ii) provide benchmarks for improving agricultural production systems. To ensure consistency between the various products of the database, a general methodological framework for the programme was defined (Koch and Salou, 2014). It was decided that the methodologies used and the deliverables must be consistent with ILCD recommendations (JRC and EIS, 2010). The database contains LCIs for 28 crop and 18 animal products, for many products several LCIs exist, reflecting different production systems. In total 113 LCIs are available in a unit process format (www.ademe.fr/agribalyse-en).

In this paper, we first present the AGRIBALYSE database results for animal products. The second part of the article focuses on the environmental impacts of pig production systems. The third part compares AGRIBALYSE results to literature results for animal product LCAs.

2. Methods

2.1. Choice of systems studied

Within AGRIBALYSE, the choice of systems studied was based on an analysis of agricultural products most consumed in France (BIO IS, 2010). Studied systems were chosen according to two main criteria: i) systems representative of French production, to match the first objective of AGRIBALYSE; ii) contrasted or innovative systems, to match the second objective. For animal production, 44 systems, distributed within18 product categories, have been studied (Koch and Salou, 2014).

2.2. Methodology for LCA

The Functional Units (FUs) retained were kg of live weight, kg of Fat and Protein Corrected Milk (FPCM) and kg of egg. Inventories were calculated from “cradle to farm gate”, so transformation processes were not included. Emissions and resource use for animal productions were calculated according to Koch and Salou (2014). The models used to calculate direct emissions from livestock production are presented in Table 1.

Livestock production systems are often multifunctional and thus a production system frequently produces two or more co-products. Consequently, a method to assign environmental impacts to co-products is needed. ISO 14044 (2006) gives recommendations concerning co-product handling: i) avoid allocation; when allocation is unavoidable, allocate the impacts according to ii) a physical criterion that reflects the underlying relationships between the co-products, or iii) the economic value of each co-product. To match these recommendations, AGRIBALYSE developed a two step “biophysical” approach to handle livestock co-products (Koch and Salou, 2014). In the first step, allocation is avoided by dividing the production system in several unit processes. Each of these corresponds to a characteristic physiological stage of the animal. When a stage yields a single product, all impacts are attributed to this product. Thus for several stages, allocation is avoided. For stages yielding several products, allocation is based on the metabolic energy required to produce each co-product. The metabolic functions considered are: maintenance, activity, growth, lactation, gestation and wool production.

Table 1. Models used in the AGRIBALYSE program to calculate emissions and resource use directly linked to livestock production. CO_2: carbon dioxide; VOC: volatile organic compound; SO_X: sulphur oxide; NO_X: mononitrogen oxides.

Substance emitted / Resource consumed	Source of emissions / consumer of resource	Literature reference for model used
Ammonia (NH_3)	Animal excretion (building/storage)	
	- calculation of nitrogen excreted	CORPEN 1999a, 1999b, 2001, 2003 and 2006
	- emission factors	EMEP/EEA 2009 Tier 2
Combustion gas	CO_2	ecoinvent v2 (Nemecek and Kägi 2007), using an LCI “combustion of diesel/kerosene” data set
	Other air pollutants (metals, VOC, SO_X, NO_X…)	
Methane (CH_4)	Animal excretion (building/storage/grassland/outdoor run)	IPCC 2006 Tier 2
	Emissions from enteric fermentation: cattle and sheep	IPCC 2006 Tier 2
	Emissions from enteric fermentation: other animals	IPCC 2006 Tier 1
Nitrate (NO_3)	Outdoor runs	Basset-Mens et al (2007)
Nitric oxide (NO)	Buildings and storage	EMEP/EEA 2009 Tier 1
Dinitrogen oxide (N_2O)	Buildings and storage	IPCC 2006 Tier 2
Land transformation	All types of production	ecoinvent v2 (Frischknecht et al. 2007)
Phosphorus , nitrogen, total suspended solids (TSS)	Aquaculture	Papatryphon et al. (2005)

Several impact indicators have been retained for AGRIBALYSE (Koch and Salou, 2014), following ILCD recommendations. Indicators such as: GWP_{100} (IPCC 2006); acidification CML 2001 (Guinée et al. 2002); eutrophication CML baseline 2000 2.5 (Guinée et al. 2001); land occupation CML 2001 (Guinée et al. 2002); non renewable energy, fossil + nuclear SALCA (pers. com. SALCA – Swiss Agricultural Life Cycle Assessment) have been studied.

2.3. Comparison with other studies

The selection of the LCA studies for the comparison (Table 5) was based on a modified version of the criteria defined by de Vries and de Boer (2010). Our criteria were: i) studies published in peer-reviewed scientific journals or scientific reports; ii) studies from OCDE countries and partners; iii) studies of systems that produce pig, poultry, beef, milk, egg or fish; iv) attributional LCA studies; v) studies using economic allocation for co-products; vi) "cradle to farm gate" studies; vii) studies published after 2004.

A common FU is needed to compare our results to literature results. When necessary, literature results were recalculated to match AGRIBALYSE FUs. In this article, we focussed the comparison on GWP. To facilitate comparison, AGRIBALYSE results were recalculated using economic allocation instead of biophysical allocation. Economic allocation factors used and sources for economic data are presented in Table 2.

Table 2. Economic allocation factors and sources used to recalculate AGRIBALYSE results.

Products	Sources and allocation factors (%)	Products	Sources and allocation factors (%)
Cow milk	Nguyen et al. (2013)	*Goat milk*	Kanyarushoki et al. (2009)
Milk	86.6	Milk	97
Calf	4.2	Cull goat and kid goat	3
Cull cow	9.2		
Suckler cow	Nguyen et al. (2012)	*Pig*	Basset-Mens and van der Werf (2005)
Cattle weaner	68	Pig	93.5
Cull cow	32	Cull sow	6.5
Ewe milk	IDELE (2011), A. Gac (IDELE) pers. com. (2014)	*Egg*	P. Ponchant (ITAVI) pers. com. (2014)
Milk	79.9	Egg	99
Cull ewe	2.8	Cull hen	1
Lamb	17		
Wool	0.3		

3. Results and discussion

A synthesis of AGRIBALYSE animal product LCA results is presented in Table 3[1] (detailed results available: www.ademe.fr/agribalyse-en). Relative to current LCI databases and LCA results for agricultural products the AGRIBALYSE database presents a major advance, as it contains detailed LCI data for a wide range of agricultural products at farm gate, using a homogeneous methodology. For several products a large number of variants, corresponding to different production systems (13 systems for beef, 6 systems for cow milk; 8 for pigs, 6 for eggs, 9 for poultry), are available. Furthermore, AGRIBALYSE contains some products (goat and sheep milk, rabbit, duck, turkey) for which very little or no LCA results were available so far.

Due to the limited size of this paper we will focus our analysis on results for pig production. Several scenarios for feed supply and overall production system were compared to the reference scenario, which represent an average conventional production of pig in France (Table 4). The impacts of the three "feed" scenarios are quite similar to those of the reference scenario. An increase of land occupation is observed for *Pig, fed rapeseed meal*, because rapeseed meal had a higher land occupation than the raw materials it replaced. A modest increase of all impact categories is observed for the *Pig, fed soybean meal* scenario. The *Pig, on-farm feed supply* scenario requires less energy that the reference scenario, as feed is mainly produced on-farm less transport is required.

Table 3.Summary of AGRIBALYSE LCA results[1] for animal products, using a biophysical approach for co-product handling. Means represent an average of impact values of all inventories calculated for a product category within AGRIBALYSE. Results are expressed per kg FPCM (Fat and Protein Corrected Milk) for milk, kg of live weight for animals, kg of egg. CV: Coefficient of Variation.

			Product category

Table 4. AGRIBALYSE LCA results of for pig production systems, calculated using the AGRIBALYSE "biophysical" allocation method.

System	**Scenario**	**GWP**	**Acidification**	**Eutrophication**	**Land occupation**	**Energy**
		kg CO_2 eq	**g SO_2 eq**	**g PO_4^{3-} eq**	**m^2a**	**MJ eq**
Pig, French average, conventional production	Reference	2.40	35.2	13.6	3.41	17.0
Pig, fed rapeseed meal, conventional	Feed	2.36	35.5	14.0	3.78	16.6
Pig, fed soybean meal, conventional	Feed	2.51	35.8	14.1	3.60	17.6
Pig, on-farm feed supply, conventional	Feed	2.33	35.0	13.9	3.49	15.6
Pig, excess slurry treatment, conventional	Production System	2.42	35.9	14.0	3.90	16.6
Pig, pig with outdoor run, Label Rouge quality label	Production System	2.83	40.9	15.3	3.66	16.4
Pig, pasture system, Label Rouge quality label	Production System	2.15	49.5	19.8	5.48	15.4
Pig, organic production	Production System	3.47	54.4	30.5	10.56	16.7

For the comparison of production systems, our results show an increase of land occupation for the scenario *Pig, excess slurry treatment*. The use of feed raw materials with higher land occupation than in the reference scenario, explain this difference. The two *Label Rouge* scenarios and the *Organic* scenario used less energy (respectively 4%, 9%, 2%), because the animals live outdoors or in buildings that are not heated nor mechanically ventilated. The systems *Pig, with outdoor run, Label Rouge* and *Pig, organic* used deep litter in buildings, which favours N_2O emission. Consequently, they presented higher GWP impacts. Acidification, eutrophication and land occupation impacts were higher than the reference for the *Pig, pasture system Label rouge* scenario and for the *Pig, organic* scenario. This results from the presence of pigs on pasture in these systems. For *Pig, organic*, which presented the highest values, this trend was reinforced by the use of organic crops as the raw materials for the animal feed. Organic crops had lower yields than conventional crops and consequently higher land use per kg product, while emission per hectare were similar. For those systems, the technical performances (kg feed per kg animal growth) were also lower, which led to an increase of many impacts.

Once converted using economic allocation, AGRIBALYSE results for GWP were compared to results from the literature (Table 5, Figure 1). For most livestock species AGRIBALYSE results were in the same range of values as literature results, except for pigs and eggs where AGRIBALYSE results presented less variability and were in the lower range of literature values. The variability observed has three major causes.

Table 5. Summary of AGRIBALYSE results[1] and selected studies from the literature for GWP. Results were calculated using economic allocation. Means represent an average of GWP value of all inventories calculated for a product category within AGRIBALYSE or literature. Results are expressed per kg FPCM (Fat and Protein Corrected Milk) for milk, kg of live weight for animals, kg of egg. CV: Coefficient of Variation.

AGRIBALYSE	1	1.03	1.03	-	AGRIBALYSE	3	2.96	2.41	45.1
Literature[8]	1	1.32	1.32	-	Literature[14,15]	4	2.71	2.51	24.1
Pig									
AGRIBALYSE	8	2.74	2.62	14.5					
Literature[1,9]	6	4.10	4.65	24.6					

The first source of variability is the diversity of production systems. Indeed, both for the literature results and within AGRIBALYSE, many different production systems exist within a product category. This is particularly true for "cattle for beef" where different production systems, but also different types of animals (dairy cull cow, dairy calves, suckler cull cow, suckler cow) are represented.

The second source of variability is the LCIA method used. The GWP results presented here have been calculated according different methods: Houghton et al. (1994) for the study by Thomassen et al. (2008); IPCC 1996 for the studies by Casey and Holden (2005, 2006); IPCC 2001 for the studies by Williams et al. (2006), Katajajuuri (2008), and Thomassen et al. (2009); IPCC 2006 for AGRIBALYSE, Leinonen et al. (2012), Nguyen et al. (2012, 2013) and Prudencio da Silva et al. (2014). This heterogeneity contributes to the variability of the results.

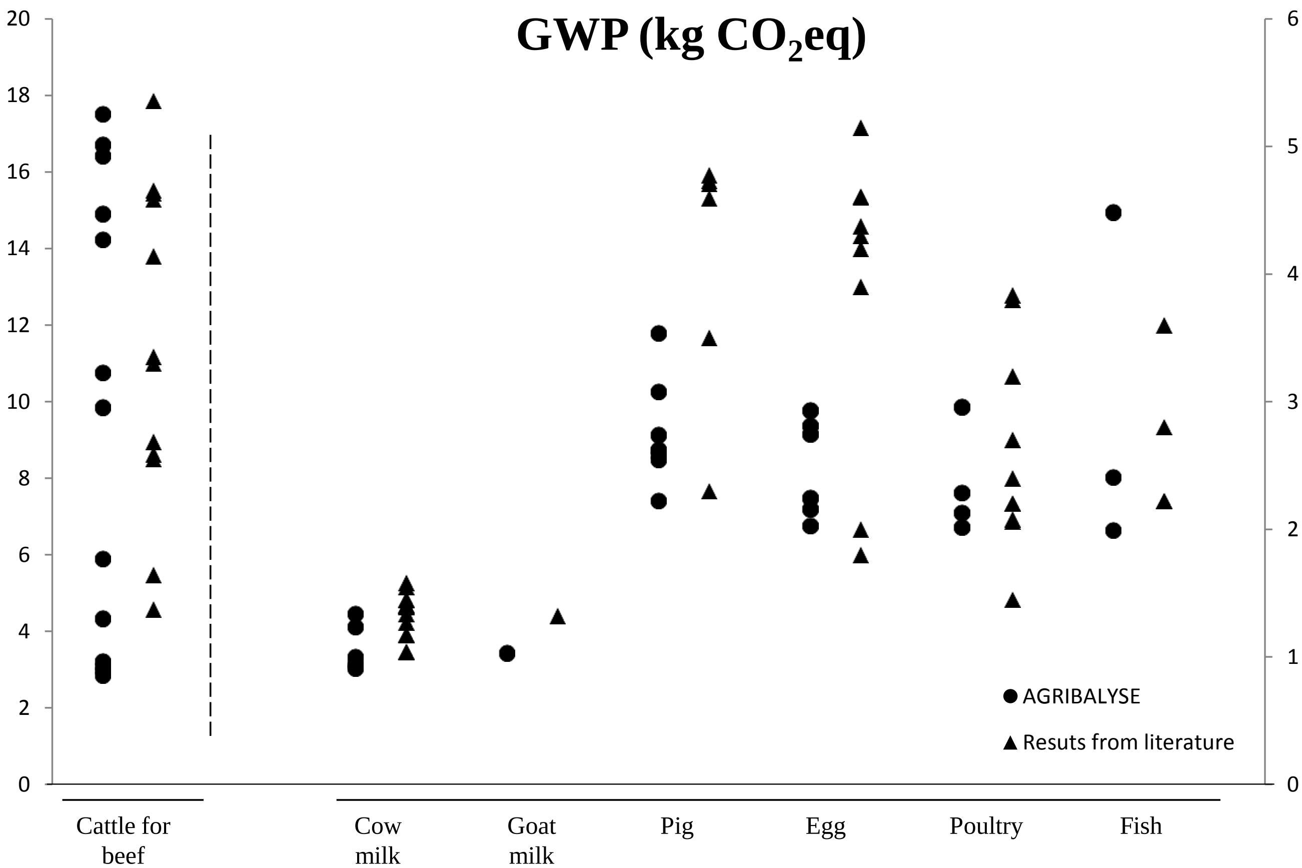

Figure 1. GWP values for products at the farm gate. AGRIBALYSE results[1] are compared to literature references. All results were calculated using economic allocation. Results are expressed per kg FPCM (Fat and Protein Corrected Milk) for milk, kg of live weight for animals, kg of egg. For "Cattle for beef" see left scale, for other products see right scale.

LCI methodological choices are the third source of variability. While all the studies are "cradle to farm gate", many aspects of system modeling vary from one study to another. This particularly concerns the models used to calculate direct emissions, which vary greatly between the selected studies. As an example, N_2O emissions have been calculated according several methodologies depending on studies. Gac et al. (2006, 2010), IPCC (1996, 2000, 2006), UNECE (1999), van der Werf et al. (2009), MfE (2006), among others, have thus been used.

4. Conclusion

AGRIBALYSE provides a large LCI database containing data for French crop and animal products. Its objective is to provide references for a wide range of production systems to support environmental labelling of products and redesign of production systems for improved eco-efficiency. As shown for pig production, the great diversity of production systems of the database combined with AGRIBALYSE methodological framework allows an accurate analysis of farming systems and a transparent comparison of their environmental impacts.

Our results also show that the AGRIBALYSE methodological framework produces results that are largely consistent with literature references, even if differences due to the three sources of variability identified in this article remain.

[1]The results presented here anticipate several corrections that will be taken into account within the version V1.2 of the database. This version V1.2 will be published at the beginning of 2015.

ABSTRACT

We used data from the Swiss household budget survey and applied multiple linear regressions based on generalized linear models to model the at-home consumption of food products and beverages of individual households. Seven household characteristics such as size, income, and educational level served as input variables for the regressions. The food products and beverages demands of 3,238 individual households of a Swiss municipality were environmentally assessed with life cycle assessment. Carbon footprints per household and year vary from 84 kg CO_2-eq. to 4.97 t CO_2-eq. with a mean value of 1,098 kg CO_2-eq. This variability is significantly smaller than the footprint variability for the consumption areas of housing and mobility in Switzerland, where 25% of the people are responsible for 50% of the environmental impacts. Differences between high- and low-impact households can be primarily explained by differences in meat and dairy consumption.

Keywords: Household food impacts, Multiple Linear Regression, Generalized Linear Models

1. Introduction

Together with housing and mobility, food is one of the three environmentally most relevant areas of consumption (Tukker and Jansen, 2006). Households form the smallest organizational units in society and many decisions about food consumption are taken on this level. Understanding the drivers of household food consumption is thus important to design effective policy measures. Existing studies often work with average household demands (Jungbluth et al., 2011) or artificial diets (Dalgaard et al., 2007). Only few studies have considered variability between different household consumption patterns (Girod and De Haan, 2009).

In this study we present a way to model the amount of food products and beverages consumption for individual households on a monthly basis. The model relies on multiple linear regression performed on data of household surveys and is able to predict demand with the help of seven explanatory household parameters.

2. Methods

We used multiple linear regressions to establish relationships between household characteristics and consumption of different food products and beverages. We distinguished between 44 different comestible good categories of unprocessed and pre-processed food products and beverages. The regression was performed with generalized linear models (GLM) using data from the Swiss household budget survey (HBS) (Swiss Federal Statistical Office (SFSO), 2012b).

2.1. Base data

A household budget survey is an inquiry of household financial budgets and expenditures. Such surveys are conducted in all EU states and many other countries worldwide (European Commission, 2003). HBS consist usually of three parts: a record on household variables, a record on household member variables and a revenue and expenditure journal. Information about revenues and expenditures has to be entered by selected households over a certain time period, usually a month. Expenditures are categorized according to the United Nations' "Classification of Individual Consumption according to Purpose" (COICOP) (United Nations Statistics Division 2012). The Swiss version of the HBS is conducted annually from January to December in the seven major regions of Switzerland (i.e. Lake Geneva, Espace Mittelland, North-Western Switzerland, Zurich, Eastern Switzerland, Central Switzerland, and Ticino) and inquires around 10,000 households, of which usually around 30% respond.

2.2. Multivariate regression analysis

Linear regressions were performed for different food product and beverages categories employing GLM and using an iteratively weighted least square algorithm for the maximum likelihood estimation of the parameters. GLM is a unifying approach to generalize linear regression and estimate parameters from multiple linear regressions with dependent variables that are not necessarily normally distributed (Gill, 2001). GLM uses a so-called link function to relate linear regression of independent variables to their dependent response variable. The link functions are chosen according to the distribution of the response variable. Link functions have been formulated for various distributions like binomial, Poisson and normal. The inverse link functions relate the estimated parameters and the explanatory variables to the dependent variable.

Characteristics that we used as independent variables for the regressions were household size (i.e. number of household members), number of rooms in their apartment, number of apartments in their building, age of the oldest household member, and age of the youngest household member. These variables were all given as integer value greater or equal to zero. Monthly household income and highest education of household members were also used. They were given as categorical values. Income is scaled from 1 to 10. Category 1 is equal to 0-1,999 Swiss Francs (CHF), 2 is equal to 2,000 to 2,999 CHF, and so forth. Category 10 is equal to 10,000 CHF or more. Education is also divided in 10 categories ranging from no education (1) to graduate degree (10) (see Supporting Information). These seven explanatory variables were chosen because they can be easily derived from national census data.

The dependent variables of the regressions were the amounts of purchased food products and beverages per household during the reporting period. For the modeling of household demand we pursued a two-tier approach, in which we multiply two multiple linear regressions. The first regression estimates the probability of a good being bought and the second regression determines the bought amount. For instance, vegetarian households are not likely to purchase meat. Some households do not drink wine and pork meat might not be consumed due to religious reasons. Thus, the probability to buy a certain good is higher for some households than for others. We applied multiple logistic regression to dichotomous demand data (i.e. the value was 1 when the purchased amount was greater than zero and 0 otherwise). The multiplication of the probability of a household buying a certain good and the amount of good that will be purchased, if the household buys the good, led to the expected amount of a certain good bought by a household.

The purchase data of one household as reported in the HBS is only collected during one month. Thus, the regressions can only predict the goods demands per households and month. Therefore, we had the choice to either fit regression models for each month of a year or to aggregate the monthly data and fit regression models for an average month of that year. We pursued both possibilities and used always 70% of the applicable data for fitting, 15% for validation and 15% for testing.

The regressions were fitted in a stepwise fashion, meaning that explanatory variables were iteratively eliminated from the regression, if they did not significantly improve the maximum likelihood estimation. Then, the estimated parameters were validated with the corresponding data. Spearman ρ, a rank order correlation coefficient, and the root mean squared error (RMSE) between observations and modeled values were calculated. RMSE describes the standard deviation of the residuals between observed demands $\hat{y}$ and modeled demands.

Each stepwise regression was performed 30 times. After each time the regression was validated. Each time the data for fitting and validation was randomly selected. In the end the best set of estimated parameters was selected according to the combination of the highest ρ and the smallest RMSE.

We performed multiple linear regressions for each possible combination of normal and Poisson distributed response variables and monthly or aggregated data. Finally, the goodness of best set of regression parameters was tested with the testing data. Thereby, RMSE, Spearman ρ and the absolute difference between total observed demand of good and total modeled demand were calculated.

2.3. Case Study

A case study was performed to illustrate the possible application of the household consumption model. The household data for the Swiss municipality Wattwil was drawn from Swiss census data for the year 2000 (Swiss Federal Statistical Office (SFSO), 2012a). Based on the household characteristics from the census, the demands for 44 different food product and beverages categories of 3,238 households in Wattwil (8,075 inhabitants) were quantified, using the outcome of the regression analysis. For each modeled comestible good we derived life cycle impact results for their global warming potential (IPCC, 2007) (GWP, in kg CO_2-eq. per kg comestible good). Most data was taken from ecoinvent 2.2 (ecoinvent Centre, 2012) and the study of Stoessel et al. (Stoessel et al., 2012). This study contains life cycle inventory data from different production countries, thus, we were able to calculate average yearly supply mixes based on foreign trade statistics from the Swiss Federal Customs Administration (Swiss Federal Customs Administration, 2012). For certain comestible goods groups (e.g. meat, fish, and dairy products) we relied on impact results from scientific articles and reports (Alig et al., 2011; Alig et al., 2012; Büsser and Jungbluth, 2009a; Büsser and Jungbluth, 2009b; Eymann, 2012; Humbert et al., 2009; Jungbluth, 2006; Kendall et al., 2010; Martignoni et al., 2012; Mattila et al., 2012; Nemecek et al., 2011; Sonesson et al., 2009; Thrane, 2006).

3. Results and discussion

Figure 1 shows the observed demands of 44 food products and beverages for 3,235 nation-wide surveyed households in the Swiss HBS for the year 2004 (left) and the modeled demands for these households (right). The demands per households were normalized by the number of household members to adjust for different household sizes.

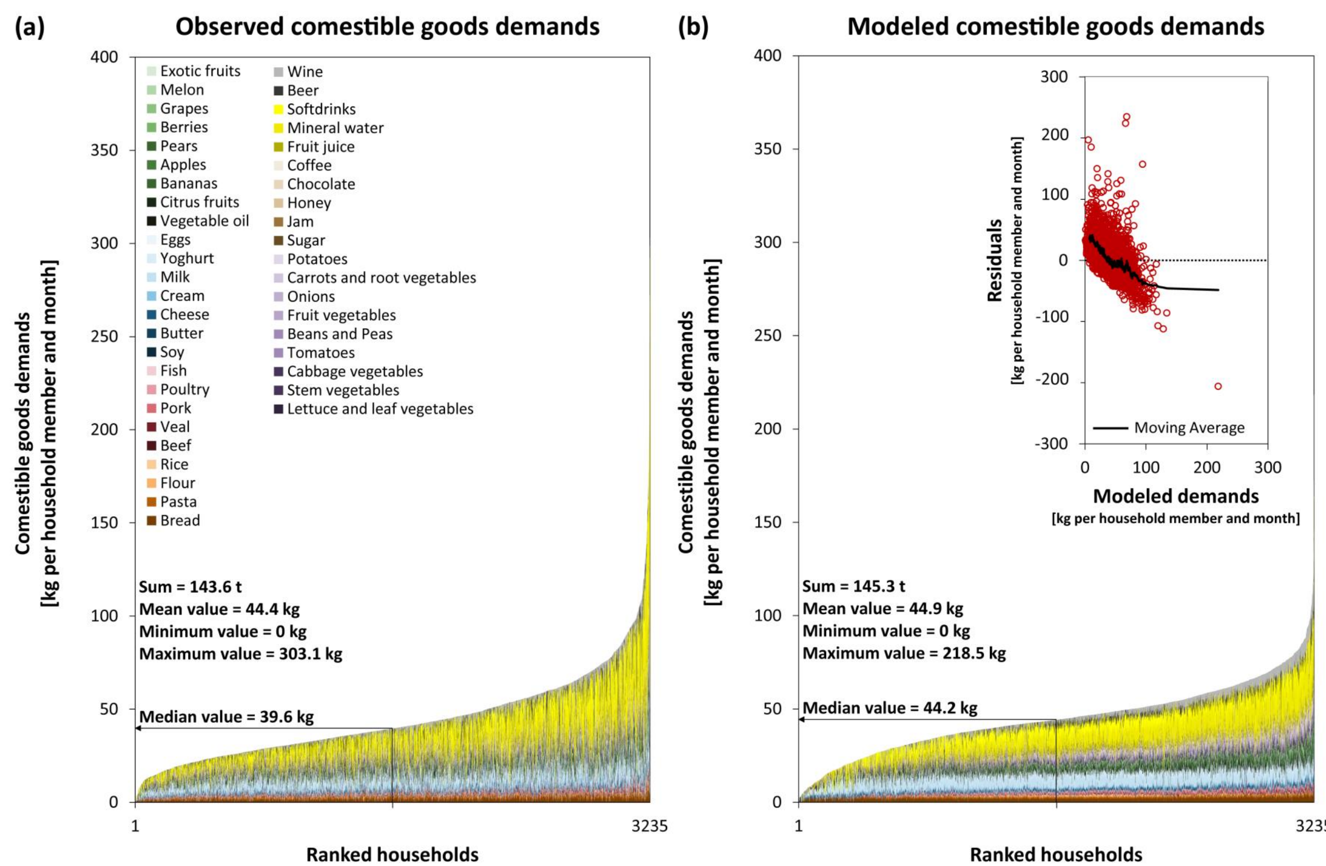

Figure 1. Observed (left) and modeled (right) demands of comestible goods for data reported in the Swiss household budget survey for the year 2004. Household demands are normalized by household size and ranked from smallest to largest demands.

A visual comparison of the two graphs (Figure 1) as well as the comparison of the five statistical parameters sum, mean, median, minimum and maximum value suggest that the accuracy of the modeling of demands is high. The relative differences between the statistical parameters for the observed and the modeled values are 1.2% for the sum, 1.1% for the mean, 0% for the minimum value. Only for the median (12%) and the maximum value (28%) the relative differences were larger. The accuracy was further investigated with a residuals plot (in the upper right corner of Figure 1b). It shows that the modeled values are slightly overestimated for low observed demands and more strongly underestimated for high observed demands. However, this is not a severe inaccuracy as observed high demands might also be a result of occurring events during the reporting period of that specific household. Events like birthday parties or anniversary celebrations might have led to extraordinary large food purchases.

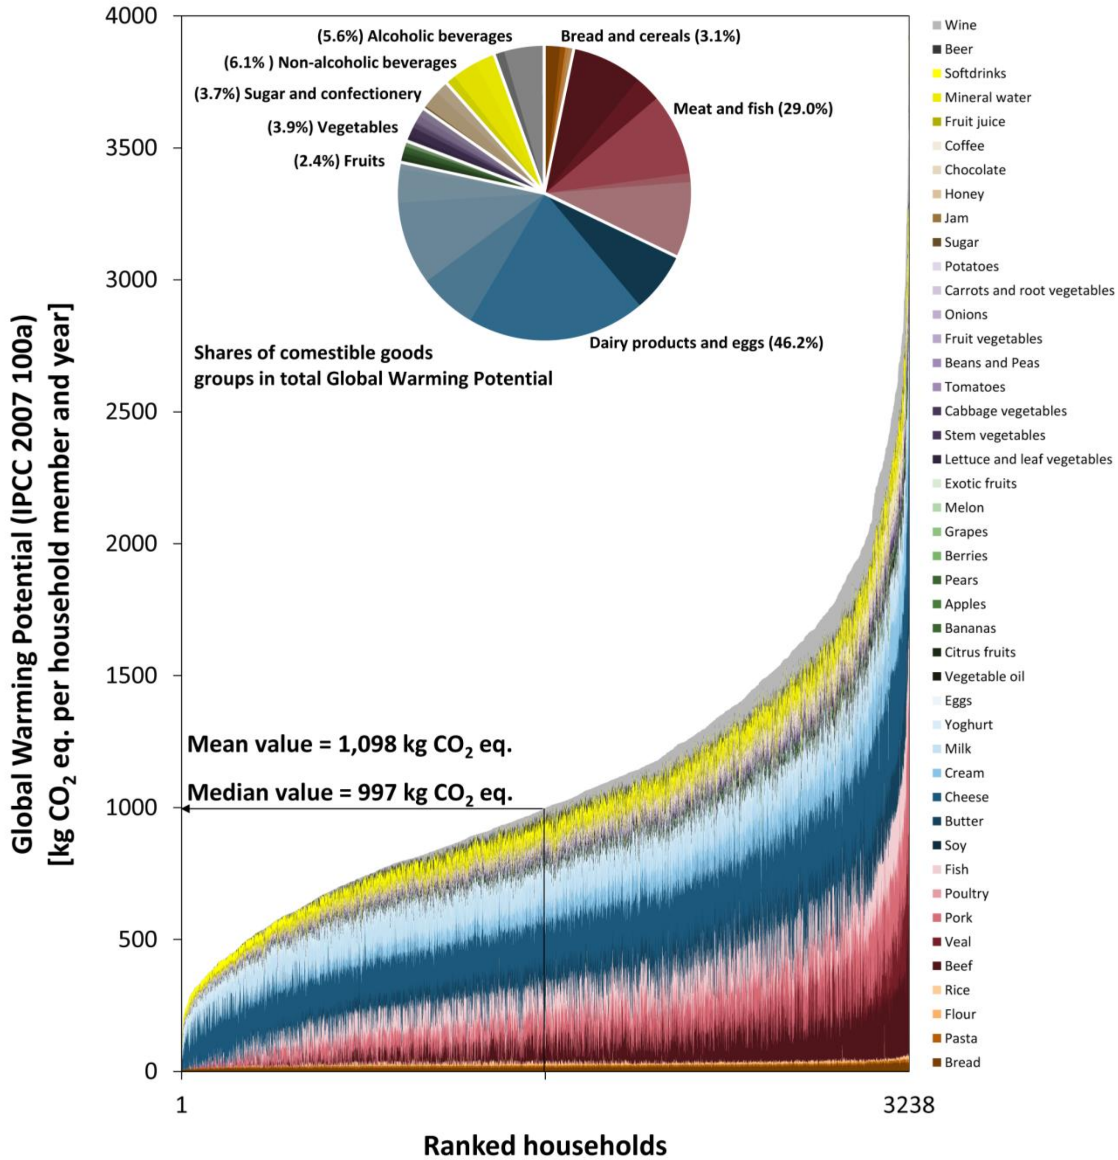

Figure 2. Global warming potential induced by in-home household consumption of 44 different food product and beverage groups in the case study municipality. The results are normalized per household member.

As we were able to reproduce the observed comestible goods demands with our two-tiered regression approach, we applied the method to a case study region. The results for the global warming potentials from at-home household consumption in Wattwil are shown in Figure 2. Greenhouse gas emissions are normalized by the number of people living in the households to adjust for different household sizes. Households are ranked according to the aggregated impact results. Results vary from 84 kg CO_2 eq. to 4.97 t CO_2-eq., with a median value of 997 kg CO_2-eq. and a mean of 1,098 kg CO_2-eq per year. The pie chart shows the shares of products in the total GHG emissions of the municipality. The consumption of meat & fish and dairy products are responsible for three quarters of total life cycle GHG emissions from at-home food products and beverage consumption in Wattwil.

Figure 2 shows that there is variability in the food carbon footprints. Some households consume almost no comestible goods at home, whereas others have significantly higher consumption than the rest. However, this variability is not so great compared to the variability of household environmental impacts in other consumption areas (Saner et al., 1013).

4. Conclusion and outlook

The food products and beverages demands of 3,238 individual households of a Swiss municipality were environmentally assessed. We found that the carbon footprints per household member and year vary from 84 kg CO_2 eq. to 5 t CO_2 eq. with a mean value of 1 t CO_2 eq. This variability is significantly smaller than the footprint variability for the consumption areas of housing and mobility, where 25% of the people are responsible for 50% of the environmental impacts (Saner et al., 1013). Differences between high- and low-impact households can be primarily explained by differences meat and dairy consumption, with vegetarian households in the lowest impact percentile, while the consumption of beverages and plant-based food was not decisive for the overall impact.

The presented study concentrated on at-home demand and supply of food products and beverages. The main reason was that for at-home consumption physical demand data is available from the household budget survey. However, we saw that only around 60% of food products and beverages are consumed at home. The rest is consumed in restaurants, cantinas, and takeaways, etc. Thus, future studies in this area should also focus on the modeling of out-of-home dining.

ABSTRACT

The Rooftop Greenhouse (RTG) of the Rooftop Greenhouse Lab (ICTA-UAB) is analyzed from an environmental perspective as a new form of urban agriculture. The global warming potential of an RTG structure was 2.5 kg of CO_2 eq., while the cumulative energy demand was of 46.4 MJ, considering a functional unit of 1m^2 and 1 year. When comparing the RTG structure with a multi-tunnel greenhouse, these values resulted in 80% and 53% higher, respectively. 1 kg of tomato produced in an RTG had a GWP of between 178 and 297 g of CO_2 eq. and a CED of between 2.9 and 4.8 MJ, depending on the crop yield. When compared with the horticultural production in a multi-tunnel greenhouse, 1 kg of tomato can be 33% less impacting or 25% more impacting for the GWP and 31% less impacting or 26% more impacting for the CED.

Keywords: rooftop farming, greenhouse technology, urban agriculture, smart cities

1. Introduction

Urban agriculture (UA) is spreading over the urban areas of developed countries in response to a growing awareness of the environmental impact of food systems (Howe and Wheeler 1999; Cohen et al. 2012; Mok et al. 2013). UA types are numerous and vary in placement, property and aim, such as community gardens for social inclusion, private backyard gardens for self-supply and public-property spaces for individual small gardens. Nowadays, UA is also colonizing buildings through building-based UA forms. These forms of UA have been defined by multiple authors as Vertical Farming (Despommier 2010), Skyfarming (Germer et al. 2011), Building-Integrated agriculture (Caplow 2009) or Zero-Acreage Farming (Specht et al. 2014).

Within the multiple forms of building-based UA, rooftop farming is the most common since rooftops are currently unused spaces that can be occupied and revalorized. Rooftop Greenhouses (RTGs) are greenhouses built on the rooftop of buildings devoted to, mostly, horticulture production (Cerón-Palma et al. 2012). Up to now, several companies in North America have built RTGs for their local production businesses. Gotham Greens (Brooklyn, New York) or Lufa Farms (Montreal) sell different kind of vegetables that have been produced in RTGs of 1400 m^2 and 2900 m^2, respectively, by offering, thus, km.0-products that avoid food-miles.

1.1. Current research on rooftop greenhouses

Only few studies have focused on rooftop greenhouses as urban horticulture systems. Cerón-Palma et al. (2012) identified the barriers to and opportunities of implementing RTGs in the Mediterranean region, by performing discussion groups with experts on architecture, agronomy and urban sustainability. Specht et al. (2014) did a literature review of urban horticulture in and on buildings, including RTGs, to determine the potentialities and limitations of these systems. Both studies found opportunities in the three pillars of sustainability: environment (e.g., reducing food-miles and transport emissions), society (e.g., improving community food security) and economy (e.g., revaluation of unproductive spaces). Notwithstanding the large potential benefits, barriers were also noted. Particularly, the studies highlighted social (e.g., lack of acceptance) and economic limitations (e.g., investment costs).

Sanyé-Mengual et al. (2013) quantified the potential environmental benefits of the local food production in terms of the avoided distribution of products from RTGs in Barcelona. A kilogram of tomato produced in a RTG in the city of Barcelona could substitute 1 kg of tomato from Almeria (1000 km), where 60$ of the tomatoes consumed in Barcelona are produced. The local production could avoid 441 g of CO_2 eq. and 12 MJ of energy per kg due to the optimization of the packaging use, and the reduction in the transport requirements and in the product losses. Moreover, RTGs can integrate their flows (i.e., energy, water, materials, gases) in the metabolism of the building. Cerón-Palma (2012) has worked on the quantification of the environmental benefits of the interconnection of the energy flow.

However, the implementation of greenhouses in cities must accomplish legal specifications of the urban context that imply an intensification of the materials consumption for the structure. Greenhouse structures in urban areas may face strict reinforcement, stability and security requirements. As a result, the greenhouse structure of RTGs may have larger environmental burdens than current horticulture production technologies, in contrast to the already quantified potential environmental savings of these systems in the literature (e.g., transport savings).

1.2. The Rooftop Greenhouse Lab (RTG-Lab)

The Rooftop Greenhouse Lab (RTG-Lab) is a RTG implemented for horticulture production in Bellaterra (Barcelona, Spain). The RTG-Lab is placed on the new building that houses the Institute of Environmental Science and Technology (ICTA) in the Universitat Autònoma de Barcelona (UAB). The RTG-Lab consists of two greenhouses of around 125m^2 each that are integrated in the rooftop of the building and aim to produce vegetables by means of soil-less techniques (i.e., substrate) (Figure 1).

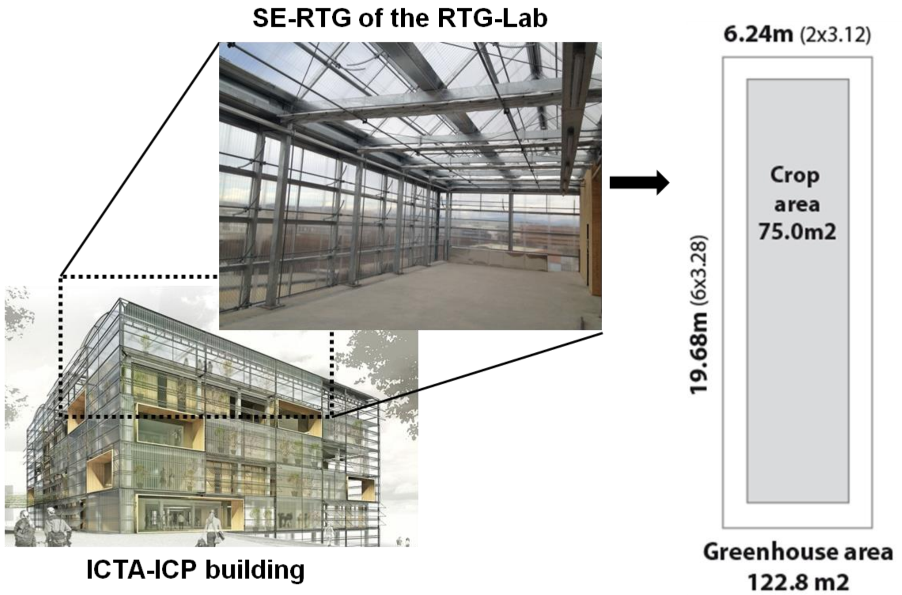

Figure 1. Situation of the RTG-Lab in the ICTA-ICP building, image of the South-East Rooftop Greenhouse of the RTG-Lab and RTG dimensions.

Research in the RTG-Lab will focus on three main issues: to proof the feasibility of crop production through RTGs in Mediterranean urban areas, to demonstrate and quantify the potential exchange of flows between the RTG and the building (i.e., energy, water, CO_2), and to quantify the environmental balance (both positive and negative impacts) of RTGs and their products. The RTG-Lab will start operating the late summer 2014 as well as the related projects. However, since the construction phase has already finished early environmental research regarding the RTG structure can be performed.

1.3. Objectives

The aim of the research is to perform an environmental assessment of the structure of a real RTG project in order to quantify the impacts of this new urban horticulture structure. To do that, the RTG of the RTG-Lab is analyzed through an attributional LCA that follows a cradle-to-grave approach. The assessment focuses on the structure itself (i.e., impact of the greenhouse life cycle) and on the agricultural production of the system (i.e., impact of the tomato production). Furthermore, the results are compared to a common industrial greenhouse structure of the study area, as a reference.

2. Methods

2.1. Goal and scope

This section presents the methodology of the study which follows the goal and scope definition of the ISO 14044 (ISO 2006).

2.1.1. Goal of the study

The aims of this LCA are to determine the environmental burdens of a Rooftop Greenhouse (RTG) as a new form of urban agriculture production structure and to compare it to the multi-tunnel greenhouse, which is one of the most used greenhouse structures in the industrial horticulture of the South Mediterranean region. The assessment also distinguishes between the greenhouse structure itself and the tomato production, where the greenhouse is an input.

2.1.2. Description of the system

The study focuses on the Rooftop Greenhouse of the RTG-Lab, as an urban agriculture system, although an industrial production system is used as a reference for comparative purposes. Moreover, this study considers the RTG of the RTG-Lab as an isolated RTG that do not exchange any flow with the building. For both systems, the system boundaries defined in the assessment are shown in Figure 2. The analysis of the greenhouse structures done from a cradle-to-grave perspective, where stages embraced are from materials extraction to the end of life of the structure. Secondly, attention is paid to tomato production and, thus, greenhouse structures become part of the life cycle of the agriculture production process. In this case, system boundaries are cradle-to-farm gate, which encompasses from the needed structure and equipment to the waste management. Tomato was chosen as horticulture product due to its importance in the vegetable market of the study area, where represents the second most sold product in MercaBarna (the food distribution center of Barcelona).

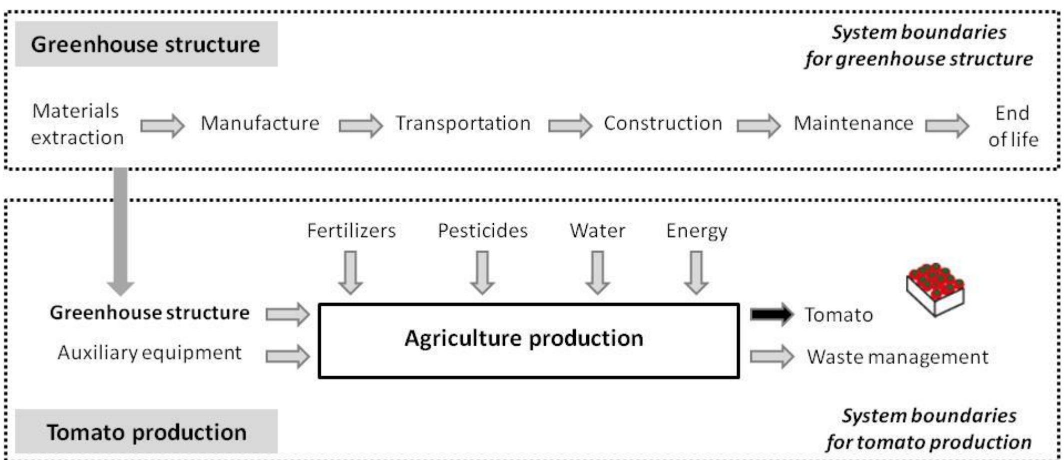

Figure 2. System boundaries of the assessment of the greenhouse structures and the tomato production.

The main differences between the RTG and the industrial system involve the greenhouse structure. The design and construction of the RTG-Lab had to overcome some legal barriers that imply a modification of the greenhouse structure: the Spanish Technical Code of Edification (CTE) (RD 314/2006 (BOE 2006)) and to fire safety laws (RD 2267/2004 (BOE 2004), Law 3/2010 (BOE 2010)). As a result, the RTG structure resulted heavier than an industrial greenhouse due to more intensive use of resources (e.g., steel). Moreover, Mediterranean greenhouses are light structures and commonly use LDPE covers, in contrast to glasshouses from colder areas (e.g., The Netherlands). However, the cover of the RTG-Lab was finally made of polycarbonate to be heavier but more resistant (particularly, offering a higher wind resistance). Finally, the construction requirements of an RTG are more intensive than for a soil-based greenhouse because materials must be raised to the rooftop.

2.1.3. Functional unit

The functional unit varies during the research as follows. First, when analyzing the greenhouse structure, the functional unit corresponds to 1m^2 of greenhouse structure for a timeframe of 1 year. Second, the functional unit of the analysis of the tomato production is 1 kg of tomato produced in a timeframe of one crop period, which is of 11 months in an RTG in Barcelona and 9 months in a multi-tunnel greenhouse situated in Almeria (Montero et al. 2011), due to the different climatic conditions. Although functional units correspond to 1 year, both assessments reflect the different lifespan of the greenhouse structures by including the maintenance stage. While the lifespan of the RTG is of 50 years according to project data and building elements, the lifespan of a multi-tunnel is of 15 years, according to law specifications (CEN 2001).

2.1.4. LCIA: method and impact categories

Two impact categories are included in the analysis. On one hand, the global warming potential (GWP, kg of CO_2 eq.) is calculated through the IPCC method (IPCC 2007) as an environmental indicator. On the other hand, the cumulative energy demand (CED, MJ) (Hischier et al. 2010) is accounted as an energy flow indicator. The SimaPro 7.3.3 program (PRé Consultants 2011) is used for the Life Cycle Impact Analysis (LCIA), which follows the classification and characterization phases defined as mandatory by the ISO 14044 regulation (ISO 2006).

2.2. Life cycle inventory

The life cycle inventory for the assessment of the rooftop greenhouse and the data collection process are detailed in the following section.

2.2.1. The Rooftop Greenhouse (RTG) system

(a) The greenhouse structure

The life cycle of the greenhouse structure consists of 6 stages, as illustrated by Figure 2: materials extraction, processing, transportation, construction, maintenance, and end of life. Data from the architectural project was used to quantify the amount of materials and their processing requirements. The transportation of materials was calculated according to the production site of each one, as reported in Table 1. The construction stage comprises the energy consumption of the machinery used to raise the materials to the rooftop and to build the greenhouse. Machinery consumed electricity from the grid and total consumption was calculated according to technical specifications. The maintenance of the structure was calculated based on the lifespan of the different materials, which according to producers' data were: 50 years for the steel and the concrete, 10 years for polycarbonate, 5 years for the climate screen, and 3 years for LDPE. In the maintenance stage, the amount of each material to complete the expected lifespan of the RTG (50 years) was considered. The end of life of the greenhouse structure includes both the transportation and the waste management. The structure is expected to be 100% recycled and recycling plants are 30 km far from the site.

Table 2 shows the life cycle inventory data of the Rooftop Greenhouse of the RTG-Lab for the entire greenhouse (122.8 m^2) and a lifespan of 50 years, and by functional unit (1m^2 and 1 year). The ecoinvent database v2.2 (Swiss Center for Life Cycle Inventories 2010) was used to complete background data of the LCI. The electricity mix for 2013 of Spain (REE 2013), of The United Kingdom (DECC 2014) and of The Netherlands (CBS 2013a; CBS 2013b) were used in the assessment of the materials processing.

Table 1. Origin, distance, and mode of transportation, by material of the RTG structure.

Material	**Origin**	**Distance (km)**	**Mode of transportation**
Steel	Martorell, Spain	77	Lorry 16-32t, EURO5
Polycarbonate	Doncaster, UK	1008.44	Transoceanic freight ship
		991.7	Lorry 16-32t, EURO5
Polyethylene	Tarragona, Spain	101	Lorry 16-32t, EURO5
Concrete	Barcelona, Spain	40	Lorry 16-32t, EURO5
Climate screen	Hellevoetsluis, The Netherlands	1487	Lorry 16-32t, EURO5

Table 2. Life cycle inventory of the 122.8-m^2 Rooftop Greenhouse of the RTG-Lab for a lifespan of 50 years, and for the functional unit of 1 m^2 and 1 year, by life cycle stage.

Flow	Unit	Total (50 years)	Per m^2 and year	Source

(b) The tomato production

The potential tomato production in the RTG of the RTG-Lab is assessed from a cradle-to-farm gate approach. Therefore, further life cycle stages, such as distribution and retail are excluded. Moreover, the RTG of the RTG-Lab is considered as an isolated RTG that do not exchange any flow with the building. The life cycle of the tomato production includes the equipment, the agriculture inputs and the management of the outputs (i.e., waste) as shown in Figure 2. The equipment consists of both the greenhouse structure and the auxiliary equipment, which includes the elements used in the crop system (i.e., perlite as substrate), in the irrigation (i.e., pipes, pumps, injectors, water distribution system, water tank) and in the inputs application (i.e., fertilizer tank). The application of fertilizers and pesticides includes their production as well as their emissions to air and water. Finally, the waste management accounts for the transportation requirements for the disposal of the outputs of the crop system, which are expected to be 100% recycled and recycling plants are 30 km far from the site.

Data for the auxiliary equipment was obtained from the EUPHOROS project (Montero et al. 2011), while fertilizers, pesticides and energy consumption was adapted from the same project by enlarging the crop period from 9 to 11 months. Water consumption was calculated through the “PrHo v2.0 for irrigation systems of greenhouse horticulture” of the Fundación Cajamar (González et al. 2008). No experimental data was available to determine the crop yield for producing tomato in a RTG, although the expected crop yield for a crop period of 11 months in the geographic context it is expected to be of 25 kg·m^{-2}, which combines a spring-summer and a summer-autumn crop cycles. However, since this value is still uncertain, two scenarios were assessed: an expected yield scenario (RTG), 25 kg·m^{-2}, and a low yield scenario (RTG$_L$), 15 kg·m^{-2}, to show potential constraints of crop production in RTGs, such as shadows from the structure or adjacent buildings.

2.2.2. Industrial horticulture: the multi-tunnel greenhouse

An industrial horticulture system is used as reference to compare with the RTG results. Horticulture production in Almeria is one of the most competitive horticulture production regions in Europe and, particularly, 60% of the tomatoes commercialized in MercaBarna (the food distribution center of Barcelona) are produced in Almeria. In this study, the multi-tunnel greenhouse structure and the tomato production in Almeria are used as reference for comparative purposes. LCI data for these systems were obtained from the EUPHOROS project, which assessed protected horticulture in Europe (Montero et al. 2011). According to the project, the crop yield considered for the industrial system is 16.5 kg·m^{-2}.

Table 3. Life cycle inventory of the tomato production in a RTG for 1 crop cycle (1 year) per area and per kg of product, by life cycle stage and crop yield scenario (RTG – 25 kg·m^{-2}; and RTG$_L$ – 15 kg·m^{-2}).

3. Results and discussion

3.1. Environmental assessment of the RTG structure

The global warming potential of an RTG structure is of 2.50 kg of CO_2 eq., considering the functional unit of 1m^2 for a timeframe of 1 year. The impact is mostly associated to the materials stage (including materials extraction, materials processing, transportation, and maintenance requirements) which contributes up to 99% on the GWP (Figure 3). The energy consumption during the construction phase and the transportation to the waste management site had, thus, a little impact on the entire life cycle of the structure. Consequently, the implementation of greenhouses on buildings has no large differences with industrial greenhouses on rural areas regarding their construction requirements.

Among materials, polycarbonate is the most contributor to GWP (54.7%), due to three factors: (a) the extraction and processing requirements (i.e., oil-based material); (b) the transportation requirements; and (c) the maintenance requirements that increase the polycarbonate consumption during the life cycle, even though other materials (i.e., steel) have a large presence in the structure in weight terms. For instance, steel contributes only to 29% of the GWP although representing the 68.0% of the total amount of materials. Polyethylene and the climate screen contribute to 10.4% and 5.2% of the GWP, respectively. Particularly, the transportation of the climate screen is the most contributing stage of this material. Finally, the anchor is the least contributing material to the GWP.

The cumulative energy demand of the system is of 46.4 MJ per m^2 and year. The distribution of the impact follows the same pattern as for the GWP regarding the life cycle stages (Figure 3). Among the materials, polycarbonate and steel are the most contributors, although the impact of polyethylene represents the 20% of the CED, because of the energy demand during the extraction and processing phases of this material.

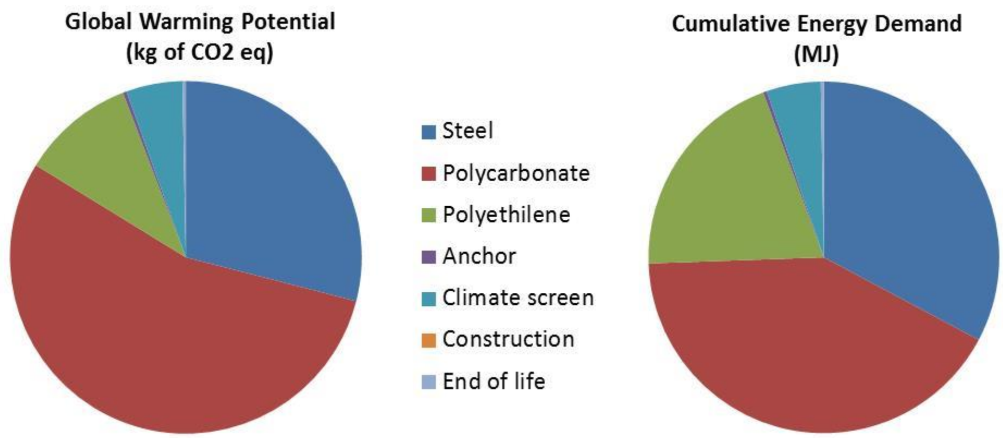

Figure 3. Distribution of the global warming potential impact and the cumulative energy demand of the RTG structure among the materials, construction and end of life stages.

In comparison to the industrial system, the global warming potential of an RTG structure resulted 81% more impacting than for a multi-tunnel greenhouse, while the cumulative energy demand was 53% higher (Figure 4). Main differences among the structures are of resources consumption for the materials. The RTG must accomplish more restrictive laws due to their situation in urban areas (e.g., security and resistance of building structures) and in height (e.g., wind resistance). For instance, the steel requirements per m^2 are 5 times higher in an RTG than in a multitunnel. Beyond law requirements, the analyzed RTG is an experimental system with an area of 122.8 m^2, while the industrial system operates in a 19440 m^2 commercial greenhouse. Therefore, certain "(in)efficiency of scale" produces a bias on the results for the RTG scenario and further case studies should be assessed in future research.

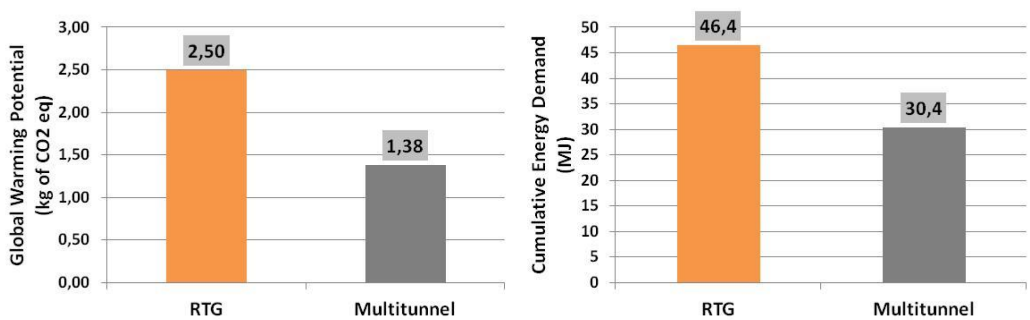

Figure 4. Comparative environmental assessment between the RTG and the multi-tunnel system, for a functional unit of $1m^2$ for a timeframe of 1 year.

3.2. Environmental assessment of the tomato production in RTGs

The production of 1 kg of tomato in an RTG has a global warming potential of between 178 and 297 g of CO_2 eq., depending on the crop yield. The RTG structure is the most contributor to the GWP (56.2%), a fact that is commonplace in horticultural systems (Torrellas et al. 2012), because of the large amount of materials consumed (e.g., steel and polycarbonate). Fertilizers and auxiliary equipment contribute to 22.8% and 17.1% of the GWP, respectively, since there is little energy and inputs consumption rather than fertilizers and water in an unheated greenhouse (Torrellas et al. 2012). Pesticides and waste management are the least contributors to the GWP value (<4%). The cumulative energy demand of 1 kg of tomato produced in an RTG is of between 2.9 and 4.8 MJ, depending on the crop yield, and the distribution of the impact among the life cycle stages follows a similar pattern as for the GWP indicator (Figure 5).

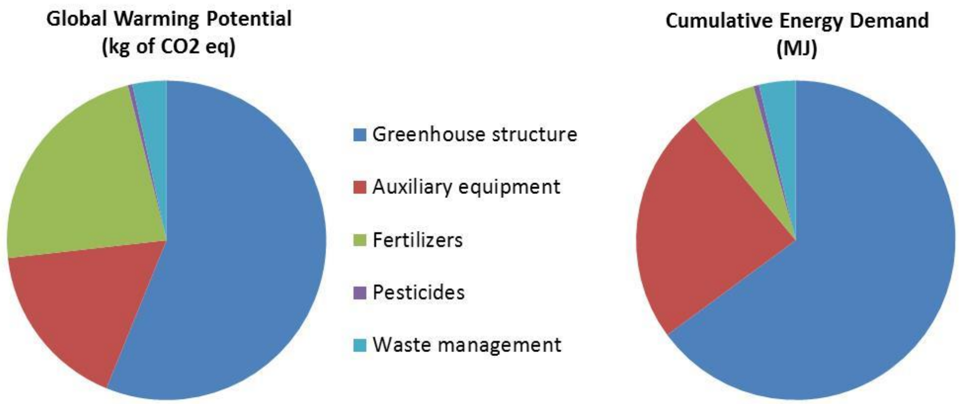

Figure 5. Distribution of the global warming potential impact and the cumulative energy demand of the tomato production in an RTG among the different life stages.

When comparing the tomato production in an RTG to industrial systems, the crop yield value becomes the most important variable. 1 kg of tomato produced in an RTG that has an expected yield of 25 kg·m^{-2} has a 33% lower GWP than produced in a multi-tunnel. However, assuming a crop yield of 15 kg·m^{-2} for an RTG can change drastically the results obtaining a GWP 25% higher per kg of tomato. The same results are obtained in the CED assessment, where the RTG scenario has a 31% lower value than the multi-tunnel, while the RTG_L scenario was 26% higher (Figure 6). Therefore, the assessment of the horticultural activity is sensitive to the crop yield considered, and there is a need to obtain experimental data from horticultural crops in RTGs in the Mediterranean area to reduce uncertainty in further studies.

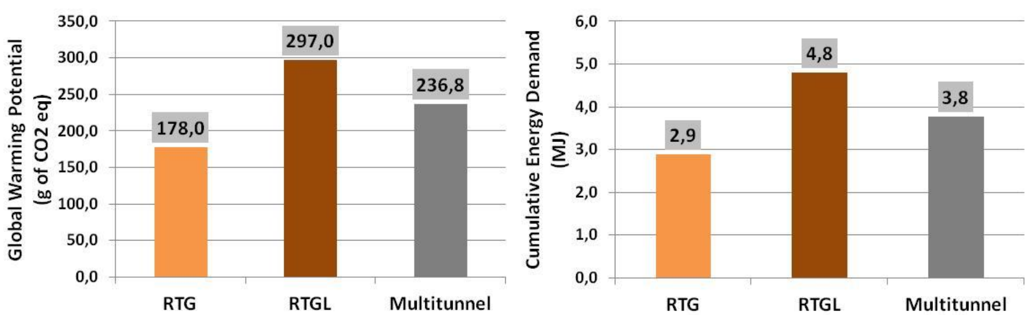

Figure 6. Comparative environmental assessment between the tomato production in a RTG with the expected crop yield – light orange; a RTG with a low crop yield – dark orange; and in a multi-tunnel system, for a functional unit of 1kg of produced tomato.

4. Conclusion

The RTG of the RTG-Lab (Bellaterra, Spain) was assessed to quantify the environmental burdens of a real case study of rooftop greenhouses to analyze new urban horticulture structures that are spreading over the developed world. The global warming potential of an RTG structure resulted of 2.5 kg of CO_2 eq. per m^2, where most of the impact came from the materials. Polycarbonate and steel were the most contributing materials to the total GWP. The construction and end of life stages of the life cycle of the structure were negligible to the final GWP value. The cumulative energy demand of the system was of 46.4 MJ per m^2, and the distribution of the impact followed the same pattern as for the GWP regarding the life cycle stages. When comparing the RTG structure to an industrial greenhouse structure, the impact was 80% higher for the GWP and 53% higher for the CED. This is caused, mainly, by the larger amount of materials used in an RTG structure due to legal requirements, which are more strict in buildings of urban areas than in rural areas (e.g., security).

The RTG system was also assessed as horticultural production system. The production of 1 kg of tomato in an RTG had a global warming potential of between 178 and 297 g of CO_2 eq., depending on the crop yield which is expected to be between 15 and 25 kg·m^{-2} (although no experimental data is still available). The cumulative energy demand of 1 kg of tomato produced in an RTG was of between 2.9 and 4.8 MJ. For both indicators, the greenhouse structure, the fertilizers and the auxiliary equipment were the most contributing elements. Compared to an industrial system, results were sensitive to the crop yield considered in the RTG. As a result, the GWP was 33% lower for 1kg of tomato produced in an RTG (25 kg·m^{-2}) than in a multi-tunnel system, although when produced in an RTG with a low yield the GWP of 1 kg of tomato resulted 25% higher. For the CED indicator, the RTG scenario obtained positive results (31% lower) when compared with the horticultural production in a multi-tunnel greenhouse, in contrast to the RTG_L scenario (26% higher).

Rooftop greenhouses (RTGs) had a larger environmental impact than industrial greenhouses. The main cause of the results was the law requirements in the urban context, which lead into an increase in the materials use in order to ensure the stability and resistance of RTGs. However, further case studies should be assessed in future research since the RTG-Lab has a largely smaller area than industrial systems. The environmental impact of horticultural production in RTGs is sensitive to the crop yield and, thus, showed benefits or negative impacts when compared with the production in a multi-tunnel greenhouse. Experimental data from horticultural crops in RTGs in the Mediterranean area are needed to reduce the uncertainty in future studies. Moreover, the integration of the RTG flows with the metabolism of the building can benefit the horticultural production by reducing the impact of water consumption (e.g., rainwater harvesting in building's roof) or increasing the crop yield (e.g., energy and CO_2 exchange). Nevertheless, further research and experimental data may demonstrate the potentialities related to integrated RTGs and their environmental balance.

ABSTRACT

The ENVIFOOD Protocol is a food and drink-specific guidance document created by the European Food Sustainable Consumption and Production Roundtable, a multi stakeholder initiative co-chaired by the European Commission and business associations from the food and beverage supply chains. The Protocol has been published in November 2013 and shall be used as a complementary guidance to the Product Environmental Footprint (PEF) and Organizational Environmental Footprint (OEF) guides in the PEF/OEF pilot testing launched by the European Commission. This paper describes the process of creating the ENVIFOOD Protocol as a consensus guidance document from the European food supply chain partners, and describes the key outcomes of the two public testing periods organized in 2013. Finally, we explain how the ENVIFOOD protocol is expected to be used as part of the PEF/OEF pilot testing, and the role it may play outside the application of the PEF/OEF guides.

Keywords: sectorial guidance, PCR/PEFCR, simplified ecodesign, harmonized environmental communication, Europe

1. Introduction

Lack of consistency in the methodologies for assessing and communicating the environmental performance of food and drink products has the potential to confuse consumers and other stakeholders involved in relevant supply chains. It also poses an unnecessary burden on organizations requested to evaluate their product's environmental footprint on the basis of different guidance leading often to different results. In order to address this issue, business associations, other food supply chain partners and the European Commission (EC) have established the European Food Sustainable Consumption and Production Round Table (RT).

This article provides an overview of the process to arrive at the Protocol, describes the process and outcomes of the public consultation and pilot testing and illustrates the next steps for the RT on the development and adoption of Product Category Rules (PCRs) in line with the Protocol and the EC's Product and Organization Environmental Footprint (PEF-OEF) guides. It also provides recommendations on the development of streamlined tools and an adequate database to best support such assessment tools. Finally, it provides insights on the future applications of the Protocol, especially in relation with the EC's PEF. The Protocol and PCRs will allow the development of user-friendly and affordable tools for assessment and communication of the environmental performance of food and drink products in Europe and beyond.

2. Methods: the process to create the ENVIFOOD Protocol

2.1. Setup of the Food Roundtable

The RT is co-chaired by the EC and food supply chain partners on equal footing and supported by the UN Environment Programme (UNEP) and European Environment Agency. When applying a life cycle approach, the RT's unique structure based on transparency and dialogue facilitates an open, results-driven and evidence-based dialogue among all players along the food chain which leads to further harmonization. The RT has delivered on its objectives according to schedule: the publication of the ten "Guiding Principles on the voluntary provision of environmental information along the food chain" (European Food SCP Roundtable, 2010), the Reports on "Communicating environmental performance along the food chain" (European Food SCP Roundtable, 2011) and "Continuous Environmental Improvement" (European Food SCP Roundtable, 2012) and the ENVIFOOD Protocol (European Food SCP Roundtable, 2013).

2.2. Creation of the ENVIFOOD Protocol

Since 2009, RT members have been working together on a commonly-agreed and science-based framework for assessment and communication of the environmental performance of food and drink products in Europe. Based on the above mentioned "Guiding Principles", the RT reached agreement on key methodological aspects at scientific workshops in 2010 and 2011 (Peacok et al., 2011; De Camillis et al., 2012). An analysis of relevant data, methodologies and guidelines for assessing the environmental performance of food and drink was also conducted. The analysis led to a harmonized methodology for environmental assessment, the ENVIFOOD Protocol. The Protocol provides guidance to support environmental assessments of food and drink products conducted in the context of business-to-business and business-to-consumer communication and the identification of improvement options. A public consultation period has been organized between November 21st 2012 and March 31st 2013. The consultation was specifically targeted at stakeholders in the food production chain, but open to anyone interested. The feedback from the public consultation was managed through the Roundtable Secretariat and addressed by subject matter experts from the Working Group 1.

2.3. Use of the ENVIFOOD Protocol in the PEF/OEF testing

The European Commission launched in January 2014 a second call for volunteers to test the development process of PEF/OEF guides. This second call was dedicated to food, feed and drink products. This call also included a testing of the ENVIFOOD Protocol in the development of the PEFCRs. The call closed on March 28th, the selected pilots presented in May, and the testing period started in June 2014. In this testing, the ENVIFOOD Protocol shall be used as a complementary guidance to the PEF/OEF guides (European Commission 2013). The RT will support the PEF/OEF testing as decided in the mandate for Working Group 1 for 2014, mainly on two axes: recommendations on the use of databases, as well as coordination of PCR/PEFCR development.

A first workshop on database development has been organized on June 11th 2014 in Brussels, and key database providers for the food sector have been invited to present their initiatives to the selected pilot testers as well as to interested stakeholders from the RT.

The working group will coordinate the development of product-specific rules (PEFCR/PCR) through the PEF pilot by:

- facilitating coordination and consistency between the pilots, including through participation in PEF pilot consultations and organization of technical workshops
- providing technical support for the interpretation of the ENVIFOOD Protocol, in relation with the EF Technical Helpdesk

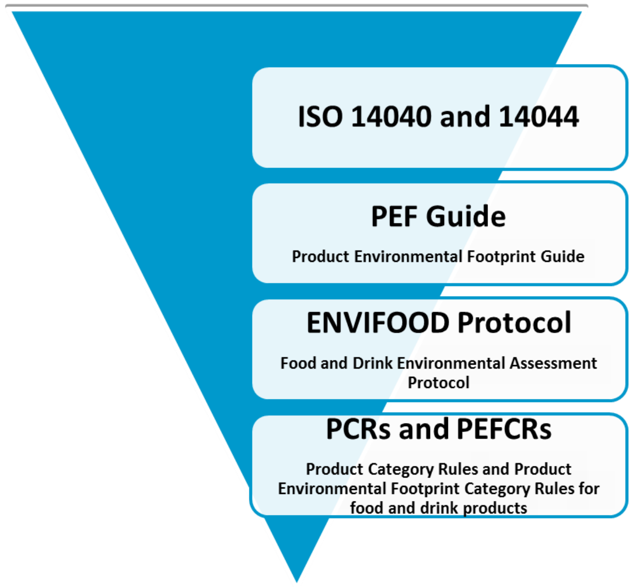

Figure 1. The intermediate position of the ENVIFOOD Protocol as a sectoral guidance in the context of the PEF/OEF pilot phase

As illustrated in Figure 1 above, the ENVIFOOD Protocol lies between the PEF Guide and the PCRs and PEFCRs. For example, assuming we are to assess on environmental performance of different coffee beverage products we would rely on the general guidance on LCA provided by the ISO norms 14040 and 14044 (e.g. the different phases of LCA). The methodology to follow would further be specified in the PEF Guide (e.g. which impact assessment model should be used). The ENVIFOOD Protocol then provides additional guidance specific to the food sector – in the example on coffee, this might be related to functional unit and the calculation of land use change associated to the development of coffee plantations. Finally, PCRs and PEFCRs would specify further details of how the assessment should be conducted at product level, including for instance on the consumer use phase (e.g. heating of water to drink the beverage). Based on all documents, calculation tools to assess environmental impacts of coffee beverages could be developed. Such tools would be sufficiently simple to use without the need of a deep understanding of all available guidance.

3. Results

3.1. Outcomes of the Public Consultation

A total of 11 stakeholders of different affiliations (industry, consulting, government agencies, and research institutes) have submitted feedback during the public consultation period. The feedback highlighted contradictions within the Protocol, misalignments with guidance provided by other institutions, further need for clarifications, as well as highlighting guidance with which certain stakeholders could not agree. Altogether, 144 comments have been received and have been analyzed by members of Working Group 1 of the RT to be included in the updated version of the ENVIFOOD Protocol. Many of the comments received could be used to improve the clarity of the guidance provided. However, a certain number of requests could not be followed because, among other reasons, a consensus on certain questions could not be achieved in the RT or because the points raised were considered more relevant for PCR than for the ENVIFOOD Protocol itself.

3.2. Outcomes of the Pilot Testing

A call for volunteers to evaluate the draft version of the ENVIFOOD Protocol has been made by the RT at the end of 2012. The pilot testing period lasted from March 27th 2013 to October 15th 2013 and actors of the food supply chain have been invited to test the ENVIFOOD Protocol in their organizations on case studies of new product developments or comparisons of existing products with product alternatives or competing products. The participants were free to choose the product to test. Also, the participants could choose whether or not to also communicate environmental performance based on the outcomes of the testing (the RT did not, at that time, recommend specific communication tools).

Overall, 18 organizations participated to the pilot testing. The participants included a wide range of manufacturers from the food and drink sector, research institutes, as well as trade associations. Written feedbacks were gathered from the 18 pilot projects and a workshop with pilot testers and RT members took place in February 2014 in order to reach consensus among the pilot testers on the modifications to include in the ENVIFOOD Protocol. The comments have been assessed by the Working Group 1 of the RT and classified into three categories:

1. Comments for immediate change, mainly concerning editorial comments or clarification needs. These comments have been incorporated into version 1.0 of the ENVIFOOD Protocol (published on Nov 20th 2013)
2. Medium term changes: some comments were requesting further guidance which could not be incorporated into the ENVIFOOD Protocol in the small amount of time available between the pilot testing and the publication of the Protocol. Therefore, these comments have been addressed in a separate guidance document which will be available in spring or early summer 2014 on the RT's website. In this document there will be a clear focus on Land Use Change (LUC) as the need for clarification on this topic was often mentioned (although the technical recommendations from the ENVIFOOD Protocol were not challenged)
3. Long term comments: some comments on fundamental questions could not be addressed, either because they would have required significant changes to the document, or because no consensus could be reached on them in the Working Group 1. They will be kept in a separate list and addressed during the next major revision of the ENVIFOOD Protocol.

3.3. Example: specific Results from the Testing of the Feed Sector

This paragraph describes the main outcomes of the pilot test of the ENVIFOOD Protocol undertaken by the EU feed industry, represented through the European Feed Manufacturers Federation (FEFAC), as an illustrative example of feedback from the pilot testing.

As an active member of the EU Food SCP, FEFAC contributed to the development of the ENVIFOOD Protocol. It was then a logical step to participate in the pilot test of ENVIFOOD Protocol in order to practically evaluate its relevance and applicability for the compound feed industry. This pilot test was undertaken by a consortium of feed associations and feed companies from the EU but also from outside EU.. Testing the recommendations of the ENVIFOOD by undertaking a concrete cradle to gate assessment for 21 feed compositions for feed for land animals as well as fish enabled to draw the following conclusions:

- It is currently necessary to be an experienced LCA practitioner in order to be able to deal with the requirements of the ENVIFOOD Protocol. Further work remains necessary so that these recommendations can be implemented by feed companies on a regular basis.
- The development of a comprehensive database, aligned with the requirements of the ENVIFOOD Protocol would be useful to facilitate the implementations of the requirements of the ENVIFOOD Protocol.
- For impact assessment, going through all the impact categories mentioned in the ENVIFOOD Protocol was not considered as something feasible. The selection criteria recommended in the ENVIFOOD Protocol were really useful to reduce the list to a manageable level.
- The recommendations regarding assessment of data quality were difficult to implement and considered as a way to try to quantify a subjective interpretation of data quality, which can often be just as well (or even better) discussed in a qualitative way. Moreover, there is no easy way to combine these types of quality indicators for a large range of data points (like in compound feed production) and end up in a meaningful cumulative assessment.
- The ENVIFOOD Protocol however provides added value when it comes to the environmental assessment of feed and constitutes a very relevant starting point for a feed PCR.

4. Discussion

The ENVIFOOD Protocol is also intended to be used outside the context of PEF/OEF. The main reason for this is that many actors in the food sector are interested in applying one single LCA methodology throughout their organization, which may be located in more than a country and even beyond the EU. Therefore, if the ENVIFOOD guidance is implemented as part of the PEF/OEF approach in these organizations, they would like to also use the same guidance outside the context of PEF/OEF. The RT therefore is in contact with organizations inside and outside Europe that work on sustainability in the food sector, and is interested in promoting the guidance developed in the RT also in other organizations.

5. Conclusion

The RT as a large European stakeholder initiative has successfully established scientifically solid and harmonized guidance on life cycle assessment for the food and drink sector. A number of guidance documents have been published (ENVIFOOD Protocol, but also related documents on communication, databases, PEFCR/PCR development, etc.) over the past years. While the ENVIFOOD Protocol and associated documents do not solve all challenges in assessing the environmental impacts in the food sector, the RT has created a platform for exchange of views between stakeholders, and has managed to establish a methodology that can further evolve as consensus forms and scientific methods improve.

Does the environmental gain of switching to the healthy New Nordic Diet outweigh the increased consumer cost?

ABSTRACT

The New Nordic Diet (NND) was designed by gastronomic, nutritional and environmental specialists to be a palatable, healthy and sustainable diet containing 30-40% less meat than the Average Danish Diet (ADD), ≥75% organics, and more locally grown wholegrain products, nuts, fruit and vegetables. In this study, the NND was based on economic modelling to represent a "realistic NND bought by Danish consumers". The objective was to investigate whether the ADD-to-NND diet-shift has environmental consequences that outweigh the increased consumer cost of the diet-shift. The diet-shift reduced the three most important environmental impacts by 16-22%, mainly caused by reduced meat content. The surcharge to consumers of the ADD-to-NND diet-shift was €216/capita/year. In monetary terms, the savings related to the environmental impact of the diet-shift were €151/capita/year. 70% of the increased consumer cost of the ADD-to-NND diet-shift was countered by the reduced socioeconomic advantage associated with the reduced environmental impact of the NND.

Keywords: ADD (Average Danish Diet), Environmental impact, LCA (Life Cycle Assessment), NND (Optimal well-being, development and health for Danish children through a healthy New Nordic Diet), Socioeconomic cost.

1. Introduction

On a global scale, agricultural production consumes large amounts of resources and releases large amounts of greenhouse gases (7.3–12.7 Gt CO_2-eq, or 14–24% of total global emissions; Vermeulen et al. 2012), air pollutants, nutrients, and pesticides. In 2011, Danish agriculture contributed with 0.01 Gt, or 17% of the total Danish greenhouse gas emission (Nielsen et al. 2010). Agricultural production alters soil structure and carbon storage in the soil, contributes to eutrophication, diminishes biodiversity, and causes unintended toxic effects on flora and fauna, including humans. Whereas the growing and production of feed, food and beverages have serious impacts on the environment, we all have to eat and drink. But what we choose to eat and drink greatly affects the environmental impact on ecosystems, human well-being and resource expenditure. Our choice of diet is our own, although it is often associated with ethnicity, social status, habit, age, and sex and is influenced by policy and economics (Steptoe and Pollard 2005).

Production of livestock and dairy products typically cause greater environmental impacts than the production of cereal, fruit, vegetables and legumes (Audsley et al. 2009, Tukker et al. 2011, Saxe et al. 2013, Saxe 2014). Reducing the content of animal produce, particularly meat, and increasing the content of grain products, fruit and vegetables in the typical Western diet would decrease the environmental impact of eating and drinking (Weidema et al. 2008).

This study is part of the Danish multidisciplinary OPUS project that develops, tests, and aims at disseminating a New Nordic Diet (NND). The NND was designed by gastronomic, nutritional and environmental specialists to be a palatable, healthy and sustainable diet of Nordic origin containing 35% less meat than the Average Danish Diet (ADD), more fish, wholegrain products, nuts, fruit, berries and vegetables, locally grown food in season, and more than 75% organic produce (Mithril et al. 2012, 2013, Poulsen et al. 2014). The impact of an ADD-to-NND diet-shift on climate change (Saxe et al. 2013) and on a wider range of environmental impacts (Saxe 2014) has already been investigated. The first of these studies was based on the OPUS dietary recommendations (Mithril et al. 2012), while the second was based on 180 OPUS recipes for the NND.

In the present study we apply an economic model to fulfill the above-mentioned NND dietary recommendations in the most incentive-compatible way, i.e. composing the most realistic NND bought by the population of Danish consumers.

The Objective of this study was to investigate the environmental consequences of an ADD-to-NND diet-shift – in “real life” – and if the socioeconomic value of these consequences outweigh the increased consumer cost of the diet-shift.

2. Methods

The ADD is the reported Danish consumption of foods and beverages in 2010 as represented in the consumer household survey published by Statistics Denmark (2013). The consumer survey displays the composition of the food and beverage budget on COICOP (United Nations, 2014) commodity categories, and these budget components are converted to physical quantities using consumer price data estimated on the basis of household purchase data from a commercial market survey company (GfK).

The ADD serves as the point of departure for determining the composition of the NND. In particular, the composition of the NDD is estimated by adjusting the items in the ADD by means of an economic simulation model developed for the purpose, which describes the consumers' preferences, such as preference-based substitutability between different food and beverage commodities. For example, if two commodities are close substitutes, an increase in the price of one of these products would induce a relatively strong shift in the consumption of these two commodities – the consumption of the commodity with increased price will decrease relatively strongly and the consumption of the other product will increase. In contrast, if a commodity is not very substitutable with other products, the consumption of this product will only be affected to a limited extent. Hence, sensitivity to price changes (measured by price elasticities) reflects commodity substitutability. Because substitutability between food and beverage commodities - both with regard to nutritional value and with regard to their appeal to consumers' preferences - varies significantly, the adjustments in the consumption patterns will also vary accordingly. Price elasticities (reflecting substitutability between food and beverage commodities) have been estimated econometrically on the basis of the above-mentioned commercial market survey data from GfK for five income classes of households.

Compared with the ADD, the NND involves a number of restrictions, including lower bounds for the intake of some products (categories of fruit, vegetables, seafood and whole-grains) and upper bounds for other elements (meat, sugar, saturated fat). These restrictions are implemented in the economic model by calculating the set of (implicit) prices that would be consistent with the restricted diet in utility-maximizing equilibrium. In addition to ensuring compliance with the requirements to the NND, the implicit prices also induce specific changes in the consumption of each individual commodity, as a consequence of the above considerations about substitutability. Hence, the consumed quantities are estimated by adjusting the ADD figures by means of implicit price changes and price elasticities, and these estimated quantities are multiplied by the original market prices in order to calculate the households' food budget in the NND.

The environmental impact of the ADD and the NND was compared based on 15 impact categories (carcinogenic and non-carcinogenic toxicity, respiratory inorganics, ionizing radiation, ozone layer depletion, aquatic and terrestrial ecotoxicity, nature occupation, global warming, acidification, aquatic and terrestrial eutrophication, respiratory organics, photochemical ozone effects on vegetation, and non-renewable energy; Weidema 2009), which were monetized to evaluate the overall effect in “shadow price” associated with an ADD-to-NND diet-shift. In this context, the term “shadow price” signifies the environmental cost of the diet-shift.

The comparison was based on consequential life cycle assessment (cLCA) using the Simapro 8 software, and the international Ecoinvent (Ecoinvent 2014) and the Danish LCA food databases (2004), and the Stepwise method to calculate the environmental impact and the external environmental cost (shadow price) (Weidema et al. 2008, Weidema 2009). When the LCA food and Ecoinvent databases lacked information, supplementary data that best fit the Danish production conditions were taken from the literature. All environmental impacts were for each food or beverage item calculated according to the ISO standard 14040 (2006). The consumer price was found in order to calculate the consumer cost of the diet-shift in order to relate this to the shadow price.

CLCAs seek to identify the environmental consequences of a decision or a proposed change in a system under study (oriented to the future), which means that market and economic implications of a decision may have to be taken into account (Earles and Halog 2011). The functional unit was 1 person year’s diet measured in kg manufactured food and beverage products. Waste is included in the calculations to the extent that the diets are made up of what is produced for diets, not what is consumed, i.e. the waste from the farm gate to the table is included. The scope of the study included the response of 15 environmental impact categories associated with all activities, energy, and resource consumption from soil to supermarket. However, for clarity, only data for the three most important impact categories (in terms of monetized impacts) is presented in the Figures 1 to 3.

The ADD was the reference against which the environmental impact of the NND was measured. In this study, the ADD was represented by 66 food and beverage products or categories supplied to the average Dane for private consumption. However, the products were pooled into 53 categories to fit the available cLCA data. For the graphic representation in Figures 1 to 3, all foods and beverages were further pooled to into 11 categories to ensure a lucid presentation.

In the present paper, we only study effects of the ADD-to-NND diet-shift based on the difference in the dietary composition, while in previous NND studies the commodity import distances and production strategy (conventional vs. organic) were taken into account (Saxe et al. 2013, Saxe 2014). At the present level of aggregation it neither makes sense to include the impact of import distances nor to include effects of the production strategy since these vary between individual products in each of the product categories assumed for this study. As an example the category "cheese" include imports from several different countries (import distances), where cheese of each origin can be of either conventional or organic origin, all sold to consumers in Denmark. In the present study, the focus is on the "real life" NND modeled to be bought by Danish consumers, its consumer price and shadow price.

Substituting animal produce with vegetables, legumes, whole grain products and fruit may reduce the intake of protein and some essential nutrients. In this study the ADD and the NND had similar energy and protein contents. This was obtained using the above-mentioned price elasticities for backward calculation of "implicit prices". These implicit prices represent the prices that would give the consumers the incentive to choose a diet with unchanged energy and protein contents, but with a dietary composition consistent with the NND specifications. But in addition to ensuring fulfillment of the NND-specifications, these implicit prices also determine the consumption of individual products within the commodity groups, which was the basis for the cLCA. Hence, only diets with similar energy, protein and nutrient content may be directly compared.

For effective and comprehensible presentation of the potential of the ADD-to-NND diet-shift in reducing the environmental impact of diets, the annual mileage driven in a Euro class 5 passenger car was used reference (Ecoinvent 2014).

We tested one more diet in this study – a so-called "SensWell" modification of the ADD diet (SW-ADD). SensWell is a research project that develops and tests new healthy and satisfying foods and drinks that though improved taste may substitute unhealthy foods and drinks in the daily diet. In the SW-ADD, soft drinks are replaced with a theoretical designer drink with a high *umami*. *Umami* is the 5th faculty of taste (besides sweetness, sourness, saltiness and bitterness), commonly found in its salt form as the food additive monosodium glutamate. For that reason, scientists consider *umami* to be distinct from saltiness. *Umami* is detected through specialized receptor cells present on the human and other animal tongues due to detection of the carboxylate anion of glutamate. *Umami* can be described as a pleasant "brothy" or "meaty" taste with a long lasting, mouthwatering and coating sensation over the tongue. 0.2 liter of the designer drink was assumed to be consumed by a third of the mature population every workday to replace soft drinks at "snack time". Our models show that it would not only replace a certain amount, i.e. about 15% of the total Danish consumption of soft drinks, but also other beverage and food, noticeably meat, e.g. beef and pork because of its high "*umami* content".

3. Results

The composition of the studied ADD and NND are given in Table 1. According to the NND dietary recommendations, tomatoes, cucumbers, coffee, tea, cocoa, wine, beer, and spirits of non-Nordic origin should not be part of the NND since they are not of Nordic origin. However, in the present version of the NND they are accepted at the level recommended in the Danish dietary guidelines (Astrup et al. 2005) based on the expectation that few people will do without these commodities in "real life". And as already stated, this paper aims at studying the Danish implementation of the NND in "real life". Table 1 shows that the modeled NND contains 39% less meat than the ADD, which are the OPUS NND recommendations of a 30-40% reduction.

The NND mass is 13.9% larger than that of the ADD mainly caused by a higher content of fruit and berries, vegetables and grain products. Fruit, berries and vegetables have higher water content than most other commodities and their mass is together with grain products genuinely larger in the NND (Figure 1).

Table 1. The mass and consumer price of each of the 53 food and beverage products or categories supplied to the Danish population in 2010 named the Average Danish Diet (ADD). The ADD is the reference to the modeled New Nordic Diet (NND)

Ingredients	ADD, Kg/ capita/y	ADD, €/ capita/y	NND, Kg/ capita/y	NND, €/ capita/y
Apples	8.6	22.0	13.7	39.1

NND increase relative to the ADD	**100%**	**100%**	**13.9 %**	**9.1 %**

The NND reduced the environmental impact relative to the ADD measured by 12 of the 15 impact categories. The socioeconomically most important impacts (in terms of monetized impacts: respiratory inorganics, i.e. fine particles < 2.5 µm in aerodynamic diameter ($PM_{2.5}$), nature occupation and global warming) were all decreased by 16% to 22%, mainly caused by the reduced meat content in the NND (Figure 1). According to the LCA food database (2004) and the Ecoinvent database (2014), meat has a higher environmental impact per kg than most other commodities, and therefore dominates the environmental savings associated with the ADD-to-NND diet-shift.

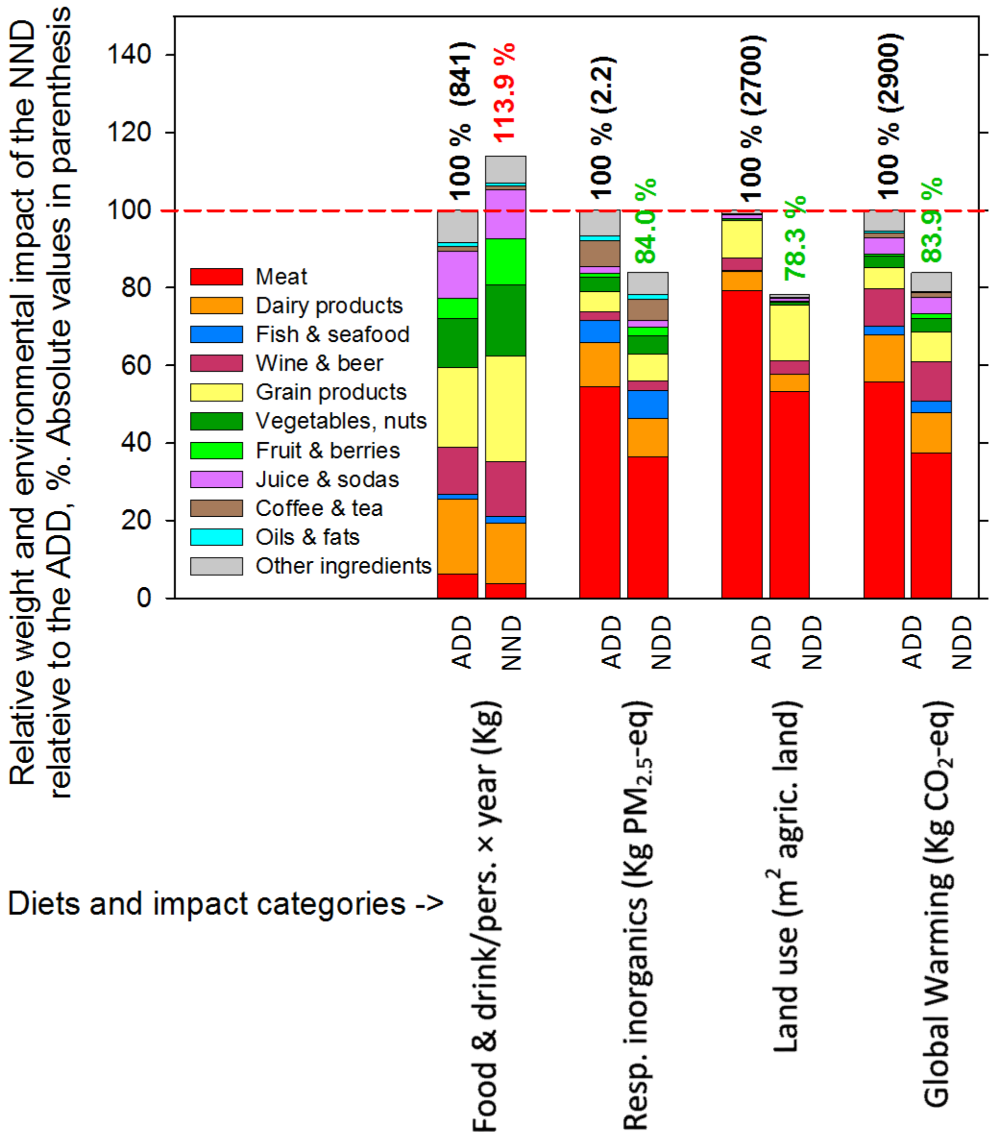

Figure 1. The quantities consumed and selected environmental impacts of the Average Danish Diet (ADD) and the modeled New Nordic Diet (NND) showing the environmental benefit of the ADD-to-NND diet-shift.

The absolute values in Figure 1 are given in parenthesis, e.g. 2900 kg CO_2-eq released per capita and year with the ADD, and 16.1% less for the NND (2440 kg CO_2-eq). It should be noted, that the land use change (LUC) was included in the global warming calculations as implemented by Saxe (2014). The inclusion of LUC (using values taken from Audsley et al. 2009) more than doubled the difference between the GWP of the ADD and the NND and nearly doubled the difference between the overall (monetized) environmental impacts of the two diets (Saxe 2014). The content of meat and dairy products in both diets dominate in each of the three environmental impact categories.

The environmental cost to society (shadow price) of the ADD was found to be €820 and that of the NND €669 (Figure 2). The ADD-to-NND diet-shift therefore potentially saves society for €151/capita/year in terms of improved environmental conditions. Figure 2 shows that the meat content of both diets dominate the shadow price most through its impact on nature occupation and global warming and least through the sum of remaining impact categories. The second most important impact on nature occupation is grain products. The ingredients in the "sum of remaining impact categories" that dominate the environmental cost (shadow price) are sweets, coffee and cocoa. Fish and seafood have its highest relative impact on respiratory inorganics ($PM_{2.5}$; Figure 1, 2). This impact is caused by the considerable diesel consumption of fishing boats and the ice for onboard storage of the catch.

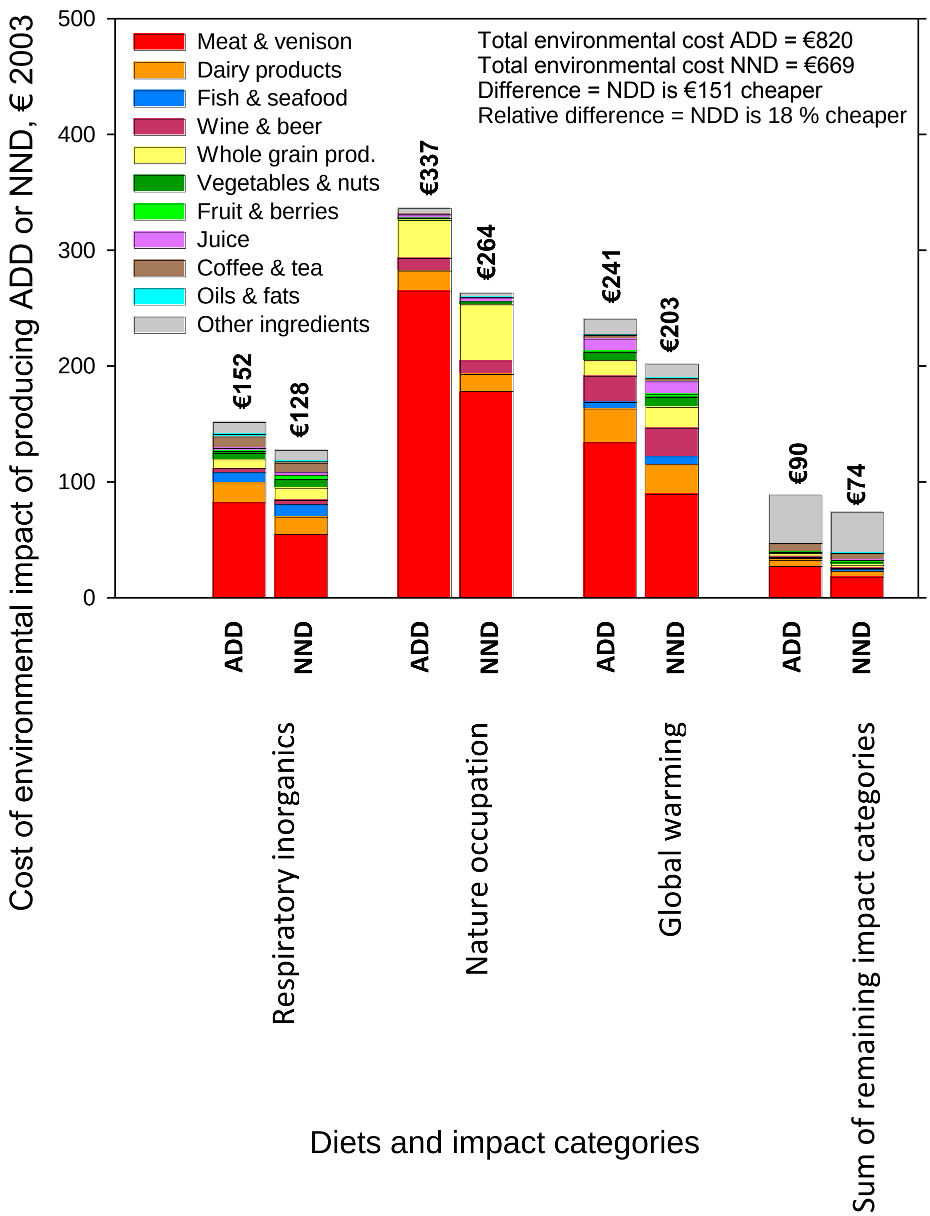

Figure 2. The potential environmental cost to society (shadow price) of the Average Danish Diet (ADD) and the modeled New Nordic Diet (NND).

Figure 3 compares the consumer price with the shadow price (potential environmental cost) of the two diets. The consumer price of the ADD was €2369/capita/year and of the NND €2585/capita/year when neither the price premium for organic production nor the savings by (mainly) having local produce in the NND was included (Figure 3). The increase in consumer price associated with the ADD-to-NND diet-shift was therefore €216 /capita/year, or a 12 % increase in consumer price, compared with ADD.

The potential savings (€151) reflected by the shadow price of the NND cover 70% of the increased consumer price (€216) for the NND. The environmental cost of driving a Euro class 5 car 1 mile was found to be 0.078 € per mile (Ecoinvent 2014). The savings caused by the diet-change (mainly caused by the lower meat content in the NND), equals the environmental impact of driving a EURO class 5 passenger car 1935 miles per year, i.e. a quarter of the average annual mileage for a Danish passenger car.

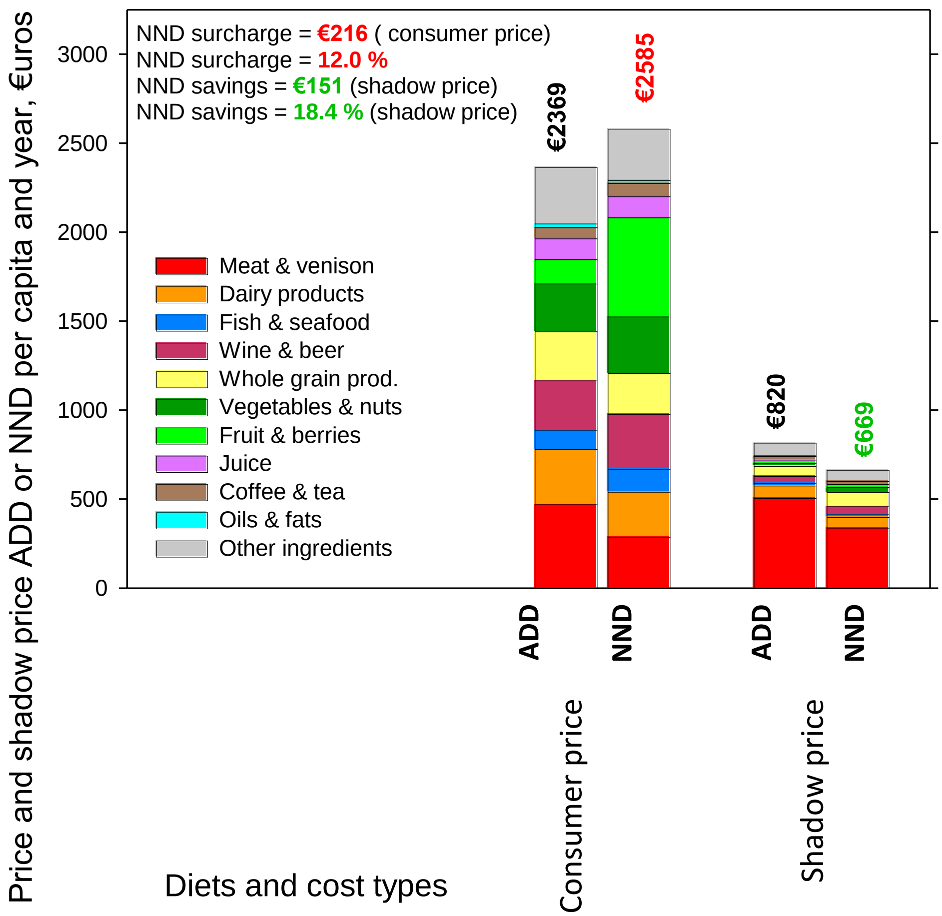

Figure 3. Consumer price of the modeled Average Danish Diet (ADD) and New Nordic Diet (NND) compared with the shadow price of the same diets.

Figure 3 also shows that the shadow price of the meat content in both diets exceeds the consumer price. For the ADD the shadow price exceeds the consumer price by €35.78 or 8%. For the NND the shadow price exceeds the consumer price by €51.46 or 18%. Reducing the meat content in either diet is consequently the most effective way to lower the impact of diets seen in a socioeconomic perspective.

The SW-ADD increased the kg intake relative to the ADD by 0.8%, while the main impact categories were decreased by 1.9-2.8% (data not shown). The consumer price for the SW-ADD increased by €96.54 or 4.1 %, over the ADD consumer price, while the shadow price decreased by €22.32 (data not shown), compensating for about a quarter of the consumer price increase.

4. Discussion

The prerequisite for trusting in the calculated reduced shadow price associated with the ADD-to-NND diet-shift is that (1) the Ecoinvent and the LCA food data are adequate for the purpose, and (2) that the Stepwise method calculates the environmental impacts correctly, and monetizes these impacts correctly. In this study, we assume both prerequisites to be fulfilled. It should however be mentioned that there are significant variations in findings regarding the economic value of some of the environmental benefits across studies, where some studies come out with lower shadow prices than those used in the present study.

The principles behind the OPUS NND have proved to be of great advantage to the environment, and to the potential socioeconomic savings associated with this healthy diet. The shadow price of the ADD-to-NND diet-shift was found to cover 70% of the increased consumer price of the diet-shift. In this study we have not included health advantages of the diet-shift, but since the NND was created to be a healthier diet than the ADD, it can be presumed that there will also be a socioeconomic advantage due to improved health when choosing the NND. All in all it may be cheaper to consume the NND than the ADD seen from a societal point of view – and this should be reflected in the price we pay for the ingredients of our diet. To have a direct consequence for the consumer prices, the Rio Declaration Principle 16 (1992, "the polluter pays principle") should be implemented for food consumption. Animal produce should be more expensive and vegetables and fruit cheaper. That would motivate more consumers to protect the environment and improve their health through their free choice of diet.

With the above in mind, it makes sense to consider further steps that make our diets even more environmentally friendly and socioeconomically beneficial. Saxe (2014) found that a vegetarian version of the NND could reduce the GWP by 67% when transport associated with imports of both the ADD and the NND was taken into account and by 59% when an 84% content of organics in the NND and the actual 8% content of organics in the ADD was taken into account. These reductions are more impressive than in the present study. One reason for this is that the ratio of meat types in the NND study by Saxe (2014) based on NND recipes was more advantageous. The recipes took into account that the production of beef, in particular (Cederberg et al. 2011), and pork is more harmful to the environment than is the production of grass-fed lamb, poultry, or fish. Relative to the distribution of meat types in the ADD, the NND in Saxe (2014) included only 30% beef and veal, 36% pork, and 73% chicken, but 680% grass-fed lamb and 820% venison. In the present study the meat content relative to the ADD was 68% beef and veal, 57% pork, 39% chicken and 98% lamb. Though the overall meat reduction in the present study was 39% vs. a 35% meat reduction in the study by Saxe (2014), the smaller reduction in beef and pork resulted in a smaller reduction in environmental impact in the present "real life" version of the NND. Another contributing factor to a lower effect of the NND on environmental impact was that import distances were not included in the present study.

The NND studies (Saxe 2013, Saxe 2014, and the present study) have shown that the diet composition, the meat quantum and meat type ratio, the transport distance of imported commodities and the inclusion of organics all affect the environmental impact of what we eat and drink. So we asked ourselves if there are *other* factors which could affect the environmental impact of a diet. The modeled substitution of soft drinks with a designer drink in the SW-ADD proved that in theory, manipulating with the sensory quality of what we eat and drink can affect our sense of satiety and thus make us eat less. Eating less effectively saves the consumer unnecessary expenses and saves society and citizens environmental impact and thereby reduces the shadow price of diets. Since two billion people worldwide are overweight or obese, a sensory improvement of our diets would not only increase the palatability, but also improve our health - by "manipulating" consumers to eat less.

There are indications that a high-protein diets are more satisfying (e.g. Padon-Jones et al. 2008), which may also be a way to decrease our intake, and thereby improve the general health and the environmental impact of diets.

5. Conclusion

This study supports the findings by Saxe (2014) that the OPUS NND is a surprisingly efficient tool in environmental protection – even when modeled in a "real-life" scenario based on expected consumer preferences; an instrument that can be further tuned and refined.

The increased consumer cost (284 €/capita/year) associated with an ADD-to-NND diet-shift is only partly (70 %) countered by the reduction in environmental costs (€151/capita/year) associated with the NND. Therefore, only if the health benefits of the ADD-to-NND diet-shift is at least half of the environmental benefits, will it be a socioeconomic advantage to society if consumers prefer the New Nordic Diet over the Average Danish Diet. The potential savings associated with the reduced environmental impact of consuming the NND rather than the ADD is significant, as it equals a quarter of the environmental impact of driving a modern passenger car per capita and year.

The fact that the shadow price of a diet's meat ingredients, in contrast to the shadow price of all other ingredients was found to be higher than the consumer price, supports that a regulation of meat prices would be of singular importance for politicians and legislators when focusing on in future environmental regulation. The consumer should pay for the environmental (and health) impacts inflicted through their diet choices – no more, no less. That is the way of regulating the prices of automobiles, heat and power in Denmark. So why not apply the same instrument for food?

Though reducing the meat content in a diet seems to be the most efficient way to reduce the environmental impact of eating and drinking, there are obvious alternatives. One is to substitute a proportion of red meat with white meat, even when keeping the meet content constant. Another alternative is to eat less, either induced by our own free will (e.g. to "get in shape") or by seducing us to eat less through a higher protein content in our diet, or because of a higher sensory satisfaction e.g. via content of *umami* in your diet. Other alternatives include buying more local and less imported produce (which is true for most but not all commodities, Saunders et al. 2006), and overall buying less organics (or better, focusing on the environmentally friendly organics). The latter statement is based on comparing the monetized environmental impact of a range of organic vs. conventional products (Saxe 2014). Most organic produce has a higher overall environmental impact than their conventional counterpart.

ABSTRACT

With the rising atmospheric carbon dioxide concentration [CO_2], crops will assimilate more carbon. This will increase yields in terms of carbohydrates but dilute the content of protein and minerals in crops. This consequential life cycle assessment study modelled the environmental consequences that such altered chemical composition and crop yields would have for the production of pig feed. Results revealed, among others, that an extra European demand of pig feed under an atmospheric [CO_2] of 550 µmole mole^{-1} would lead to ca. 6% less expansion of additional arable land worldwide, in comparison to feed produced under today's conditions. However, this did not translate into lower greenhouse gas emissions, because the benefit of increased crop yield was counteracted by changes in the composition of the feed formulation. Among the important changes, feed produced under high [CO_2] was shown to integrate 23% more soymeal and 5% less wheat than at present.

Keywords: Compound pig feed formulation, consequential life cycle assessment, land use changes, amino acids.

1. Introduction

During this century, the rising atmospheric carbon dioxide concentration ([CO_2]) is expected to increase crop yield due to increased carbon assimilation, for example in wheat grains by 10% (Högy et al. 2009). On the other hand, the higher carbon uptake causes increased starch content and, consequently, also a dilution of the relative protein and mineral content in food and feed crops.

The animal feed market, which currently absorbs approximately 45%, 58%, and 80% of the world cereal, maize and soy, respectively (International Grain Council 2012), is likely to be affected by such changes in crop yield and composition. In fact, as the composition of animal feed for intensive livestock production is carefully optimized in order to meet both the applying legislation and the nutritional requirements in a cost-effective manner, any change in both the chemical composition and the yield of feed crops will affect the future formulation of the feed.

Although the environmental consequences of the forecasted future increases in meat (and thus feed) demand have been overly studied (e.g. Steinfeld et al. 2006; Nellemann et al. 2009; Meul et al. 2012), there are no studies, to the authors' knowledge, that attempted to address the environmental impacts related to the changes that a higher [CO_2] would induce to the feed market. On an environmental perspective, a (CO_2-induced) higher crop yield would contribute to reduce both the land use and the land use changes associated with increased demand for animal feed. On the other hand, lower protein content would trigger an increased need for protein-rich crops like soybeans, which in turns would involve an increased land use change, the environmental impact of which may be considerable (e.g. Searchinger et al. 2008; Gibbs et al. 2008; Hamelin et al. 2014). Yet, it is not clear which effect would dominate over the other. Further, a change in protein content has to be addressed with regards to the specific amino acids affected, as a change in some non-essential amino acids (e.g. proline) is rather meaningless for the overall feed composition.

Focusing on the effects of elevated [CO_2] alone, this study endeavours to assess the environmental consequences of compound pig feed grown at the "present" atmospheric [CO_2] (taken at 380 µmole CO_2 mole^{-1} dry air) and at a "future" [CO_2] (550 µmole mole^{-1} dry air by 2050; IPCC 2007). From this point onwards, the former will be referred to as "present feed", and the latter, as "future feed" with the understanding that these are both compound feeds. Compound (or complete) feed means multi-component feed produced at a competitive price to satisfy all nutritional and technical needs in terms of carbohydrates, protein, oils, fibre, enzymes, vitamins, etc.

2. Methods

2.1. Feed Formulation

For a market-based approach, the feed formulation software Bestmix® (Adifo Software 2014) was used to establish both the present and future feed formulation for piglets, sows and slaughter pigs (a feed mix consisting of 20% piglet feed, 20% sow feed and 60% fattening pig feed was considered). Through optimization algorithms, Bestmix® formulated the best compromise between profitability, nutritional value and animal health, while ensuring that the Danish and European legal requirements of the feed are met. This procedure allowed determining the exact ingredients constituting the present and future pig feed, and in which proportion.

One important input to Bestmix® is the chemical composition of crop ingredients, in terms of starch, protein, amino acids and macro- and micro-nutrients, for both today's and future's conditions (Table 1). Another important input parameter to Bestmix® is the price of feed ingredients. However, as the aim of this study is primarily to investigate the consequences of crops' composition changes, and as no reliable estimate is available on future crop prices, prices of crop ingredients under a high [CO_2] future were taken to be equal to the present prices.

2.2. LCA Model

The functional unit to which all input and output flows were related is "the production of one extra tonne of pig feed". Background LCA data (e.g. fertilizers, electricity, etc.) were taken from the Ecoinvent v.2.2 database (Ecoinvent Centre 2014), while foreground data were essentially related to the cultivation, yield and chemical composition of the crops used in the feed formulation. The geographical scope considered for the foreground system was Denmark, i.e. the pig feed was considered to be manufactured for the Danish market. The Danish example is taken as representative for most industrialized countries in a temperate climate. The chosen method of normalization was to monetize the environmental impacts (expressed in €2003; Stepwise2006 v1.2 impact assessment method, Weidema 2009). Although the results from this step are not presented here, this allowed the selection of the key characterized impact categories for this study; global warming (100y horizon), nature occupation, respiratory inorganics and non-carcinogenic human toxicity.

All processes affected by the production of 1 tonne of pig feed, i.e. from crop cultivation to harvest, and up to the mixing of the feed were included in the LCA system boundary, including, among others, the cascading effects induced by a change in the biochemical composition of the ingredients. This change implies an overall change in the feed formulation, both in terms of the ingredients employed and in their quantities in the feed, which was quantified though Bestmix® (output of Bestmix®; Table 2).

2.3. System Boundary of Crop Ingredient and Life Cycle Inventory (LCI)

This study involves 5 main crop ingredients, and for all these, land use changes were taken into account. The wheat needed for the pig feed considered in this case study is grown in Denmark. In a country like Denmark, where 65% of the total land is already used for cropland and where policies have been adopted in order to double the forested area (nowadays representing ca. 13% of the total land; Nielsen et al. 2011), very limited conversion from forest or alike nature types is occurring. Most likely, the land needed to grow this extra wheat will be taken from actual Danish cropland, involving that one crop cultivated today will be displaced. Such a displaced crop is, in consequential LCA, referred to as the marginal crop. In this study, the marginal crop was assumed to be spring barley (a carbohydrate crop), based on Schmidt (2007) and Dalgaard et al. (2008). The environmental consequences of cultivating wheat instead of the spring barley that was already cultivated represent, in this case, the so-called direct land use changes (dLUC).

Table 1. Chemical composition and yield of the four main crop ingredients, at present (380 µmole mole^{-1}) and future (550 µmole mole^{-1}) atmospheric CO_2-concentration

[1] VSP 2012; [2] Högy and Fangmeier 2008; [3] Taub et al. 2008; [4] Erbs et al. 2010; [5] Högy et al. 2010 (extrapolation assuming linear responses to elevated [CO_2]); [6] Hamelin et al. 2012; [7] Högy et al. 2009 (extrapolation assuming linear responses to elevated [CO_2]); [8] Fangmeier et al. 2000; [9] Dalgaard et al. 2008; [10] Morgan et al. 2005; [11] FAOSTAT 2014 (average 2005-2010); [12] Clausen et al. 2011.

Indirect land use changes (iLUC), on the other hand, represent the environmental consequences related to how this missing supply of Danish spring barley will be supplied on the world market. Such increased crop production may stem from increased yield, also referred to as intensification, or from land conversion to cropland, also referred to as agricultural land expansion. Both were taken into account, as further described in 2.4.

Barley, rapeseed meal and sunflower meal were also considered to be imported from Europe. Similarly to wheat, an increased demand for land in Europe in order to cultivate the barley, rapeseed (rapeseed meal) and sunflower (sunflower meal) resulting from an extra demand of Danish pig feed was considered to take place at the expense of spring barley. In the case of rapeseed and sunflower, the meal needed for the feed is however co-produced with respective rape and sunflower oil, leading to a corresponding decrease production and supply of the marginal oil, here taken as palm oil (Schmidt 2007; Dalgaard et al. 2008). In terms of land use changes, this represents an avoided cultivation from the marginal supplier of palm oil, here considered to be South-East Asia, where the largest increases occurred since the mid-1960s, as highlighted by the production statistics from the Food and Agriculture Organization (FAO) of the United Nations (FAOSTAT 2014). Yet, along with this palm oil, palm meal would have been produced as well (Schmidt 2007). As a result of the no longer produced palm meal (supplying both carbohydrates and protein), the cultivation of the marginal source of carbohydrate and protein is induced, here taken as Canadian barley (Schmidt 2007) and soybean meal (Dalgaard et al. 2008), respectively. Because the production of the marginal protein, soybean meal, interacts with the oil market again, a loop system is thus created, and this loop should be stopped at the point where the consequences are so small (i.e. when the differences between two subsequent iterations approach zero), that any further expansion of the boundaries would yield no significant information for decision support (Ekvall and Weidema 2004). These cascading effects are referred to as the "oil-meal loop". The substitution ratios were quantified on the basis of the carbohydrates and lysine content of the displaced and induced/avoided crops. The content in lysine was used instead of the crop’s content in total protein; it is in fact the composition of the protein in terms of amino acids, or rather in terms of limiting amino acids, which matters for feed, and lysine is the most important limiting amino acid in pig feed.

For soybean meal, based on an analysis of the historical data available in the statistical database of FAO (FAOstat, 2014), soybean meal from Argentina and Brazil was identified as the one most likely to react to an increase in demand for soy. For palm fatty acid distillates (palm fruit), as above-mentioned, the palm meal from South-East Asia was considered. The system expansion considered for these two oil crops is as described above, both involving the oil-meal loop.

For fermentation-based amino acids, which are produced from of a mix of different crops, the same principles as described above were applied to define the system boundary.

The inventory data for barley and wheat cultivation in Denmark were taken from Hamelin et al. (2012; wet climate, sandy soil), while life cycle inventory (LCI) data from the Ecoinvent (v.2.2) database were used to model the cultivation of imported soybean (Brazil), rapeseed (Germany), sunflower (Spain) and palm oil (Malaysia). For fermentation-based amino acids, the generic recipe of (Mosnier et al. 2011) was used, while all enzymes and vitamins were modelled as phytase, this being the best proxy found given the availability of LCI datasets at the time of modelling. For other ingredients (mineral, salts, fish meals), LCI datasets from the Ecoinvent (v.2.2) database were used.

2.4. Land Use Changes

In this study, the iLUC impact was defined as the sum of: 1) net arable land expansion, 2) intensification, and 3) cultivation of the reacting crop on the new agricultural land. To quantify this impact, it is necessary to identify: i) which regions are likely to be affected; ii) in these, which types of biomes are converted; iii) in each affected region, how much land is affected and how (i.e., expected share of intensification and expansion); iv) C losses from the converted land; v) changed use of N-fertilizers associated with intensification; vi) cultivation practices for the crops established on the cleared land.

To this end, the approach described in (Hamelin et al. 2012b) was applied. The reader is referred to this, and to Hamelin (2013) and Tonini et al. 2012, for additional details on the modelling of land use changes.

3. Results

Table 2 presents the optimization output performed in Bestmix®, i.e. the composition of present and future compound pig feed based on the biochemical composition of the main crop ingredients (Table 1) and the current price of these. The results in Table 2 support the hypothesis that pig feed based on wheat, barley and rape grown in Northern Europe under higher [CO_2] will need a higher supplement of protein as well as less carbohydrate ingredients. Table 2 also highlights that both present and future feed consist of at least 46% wheat, 25% barley, 9% soy meal, 7% rape meal and 4% sunflower seeds, these five ingredients making up approximately 93% of the feed.

Characterized LCA results are presented in Table 3, with focus on the four socio-economically most important impact categories identified through normalization in Stepwise 2006, as described in 2.2.

Table 2. Change in ingredients of compound pig feed under a future [CO2] (550 ppm) (output of Bestmix®)[1]

Product	Main function in the feed	Amount in compound pig feed		
		present ($kg\ t^{-1}$ feed)	future ($kg\ t^{-1}$ feed)	relative change
Wheat	Energy	479.9	455.2	-5.1%
Barley	Energy	250.0	250.0	0.0%
Soy meal	Protein	92.2	113.7	+23%
Rape meal	Protein	68.0	68.0	0.0%

[1]The number of digits does not reflect the precision; these are simply shown in order to facilitate the comparison between the different feed ingredients.

4. Discussion

The environmental impact of producing one extra tonne of compound pig feed was expected to decrease in the high [CO_2] future due to the higher yields (and thus lower land use) caused by the higher CO_2 uptake from the atmosphere. But even though the yield increases were found to be non-negligible, e.g. 10% for wheat and 28% for rape (Table 1), the net land use did not decrease to the same extent. Still, however, the net fall in land use per tonne of pig feed was found to be around 6% (Table 3). Unexpectedly, this did not lead to a net fall in greenhouse gas emissions per tonne of feed, on the contrary it increased by 9% for crops grown at the future [CO_2]. This is essentially due to the change in feed composition, where considerably more soybean meal is required under a high [CO_2] (23% more; Table 2), which involves the conversion of biomes with relatively high C stocks.

The biggest differences, however, are found for the impact categories respiratory inorganics (fine particles) and non-carcinogenic human toxicity (17% increase and 18% decrease, respectively). Again, these differences between the present and future [CO_2] scenarios can be explained by the change in feed's chemical composition, especially the increased need for soy meal and decreased need for wheat (Table 2).

For all impact categories, nearly all impacts are caused by the crop-based ingredients, i.e. the sum of others (non-crop ingredients) is infinitesimal (Table 3). For non-carcinogenic human toxicity, rape and wheat are the biggest contributors (caused by the agrochemicals used for rape and wheat cultivation, but for wheat much reduced by the displaced barley). For respiratory inorganics, soy and wheat are the major contributors (caused by soy and wheat cultivation, but for wheat much reduced by the displaced barley, and for soy somewhat reduced by soy oil displacing palm oil), while rape contributes negatively (mainly due to displaced palm oil). For nature occupation all the main crop ingredients contribute, and sunflower the most (due to the low yield of sunflower cultivation and the displaced barley). For global warming, soy is the biggest overall contributor (essentially because of iLUC), followed by barley. Amino acids produced by fermentation contribute negatively to each of the main impact categories. This is because sugar production (one of the substrates in the fermentation process producing amino acids) gives rise to by-products (molasses and pulp) which can substitute the use of marginal carbohydrates for animal feed. The saved carbohydrates production (and the land use changes it would have generated) had a greater negative impact than the positive impact from the consumed sugar substrate. Yet, these effects are of course highly dependent upon the data quality used to model them. As three crop ingredients are used to produce these amino acids (sugar beet for the sugar input, corn for the corn starch input and wheat for the wheat starch input), and as each of these crops involve at least three co-products, a considerable degree of uncertainty is introduced in the model, as a result of the numerous assumptions involved regarding the displacement effects (i.e. system expansion).

One limit of this study is that it only focussed on the effect of elevated [CO_2] to represent the future conditions under which pig feed will be produced. In fact, higher atmospheric [CO_2] is not the only global change to determine the yield and the chemical composition of crops in the future. The results of this study are thus not to be seen as representative of the future state of global climate and meteorological conditions (data for this is as yet unavailable), but as an illustration of the cascading consequences a change in crop yield and composition (in this case triggered by an increase in atmospheric [CO_2]) can have for pig feed formulation. As for any LCA, the results of this study are closely linked to the quality of the inventory data and assumptions taken. For example, no changes in amino acid composition were considered for barley and soy as a result of increased [CO_2], because no data or reliable estimation proxy could be found. Nevertheless, the study provides a solid framework for assessing the consequences a changed crop composition due to elevated atmospheric [CO_2] would have on pig feed, which was not, to authors' knowledge, available so far.

Another limit is that the changes in manure composition resulting from a change in feed composition have not been taken into account. In fact, a feed containing less protein from cereals (which are difficult to digest) but more easily digestible protein from e.g. soy or rapeseed meal, involves a better digestion, and thus a reduction in excreted N can be expected. This could have consequences for the subsequent use of the manure as a fertilizer, as it would involve a reduced potential for emission of N flows (e.g. ammonia, nitrous oxide, nitrate losses). Based on Table 2, considering these induced changes in manure composition would likely have induced additional benefits for the future pig feed, which comprises significantly more soymeal and less wheat.

Finally, one of the most important sources of uncertainty probably lies in the estimation of the environmental consequences generated by land use changes, as clearly emphasized in several publications already (e.g. Plevin et al. 2010; Warner et al. 2013). Nevertheless, it should be highlighted that although the actual magnitude of environmental impacts related to land use changes is uncertain, the potentiality of adverse effects arising from it is hardly subject to dispute (Marelli et al. 2011; Khanna and Crago 2012).

5. Conclusion

The main findings and highlights of this study can be summarized as follows:

- A methodological framework was presented in order to assess the cascading environmental consequences a change in crop yield and chemical composition (triggered by an increase in atmospheric [CO_2]) can have for pig feed formulation, including land use change consequences;
- Due to changes in biochemical crop composition, pig feed grown under an elevated [CO_2] would contain more soy (ca. 20%) and less wheat (ca. 5%), in comparison with today's feed.
- The positive environmental effect of elevated [CO_2] on crop yield (carbohydrates) was counter-balanced by a need for increased soy content in pig feed, and the land use consequences this generated;
- The four most important environmental impact categories in pig feed production under current and future atmospheric [CO_2], as determined by the monetized normalization methodology of Stepwise 2006 were human toxicity in terms of non-carcinogenic toxicity and respiratory inorganics, nature occupation and global warming;
- Since the protein crops (soy, rape and sunflower) account for about 60% of the overall environmental impact of pig feed, it is important, in the perspective of a future with expected growing demands for food and bioenergy (and thus for land), to optimize their supply in feed as well as their amino acids profiles (rather than their content in total protein).

ABSTRACT

Results of LCA studies from single supply chains or of specific contexts are often generalized and transferred to a global perspective. The aim of this paper is to compare results gained from a global land use and mass-flow model and a consistent set of assumptions with product-related attributional LCA results. We apply the model to question of livestock intensification strategies – in particular with respect to the use of human-edible feedstuffs in ruminant rations. From a resource efficiency perspective of attributional LCAs, our results show that concentrate-based ruminant production outperforms grass-based production. From a global perspective, however, a reduction of concentrate feedstuffs could reduce environmental impacts of the total sector while producing the same amount of human-edible energy and protein. Dietary patterns, however, would have to change towards less meat consumption. We conclude that if aiming at drawing conclusions with large-scale relevance, a global perspective needs to complement an efficiency-centered LCA perspective.

Keywords: food security, physical mass-balance model, dietary change, greenhouse gases, attributional LCA, consequential LCA

1. Introduction

Life cycle assessment is a useful approach for comparing different products or production methods to each other, because LCA relates all environmental impacts to a functional unit. As this functional unit mostly refers to the food production, food availability is implicitly addressed in the assessment. However, contrary to many other economic sectors, in agriculture there are absolute natural boundaries for growing specific crops, complex interdependencies between crop and livestock production, and differences between site-specific climatic and soil conditions (Rockström et al., 2009; Stoorvogel, 2014). Non-linearity can only be covered in a limited way, by an LCA creating a ratio between environmental impacts and a functional unit.

The environmental impacts of livestock production are frequently evaluated using carbon footprints or life cycle assessments including the assessment of different environmental impacts (Basset-Mens und van der Werf, 2005; Steinfeld, 2006). Especially the question of livestock intensification is often addressed (e.g. Gerber *et al.*, 2011). The frequent conclusion is increasing milk yields mostly over-compensate additional environmental impacts of feed production (Nguyen *et al.*, 2013). Besides breeding, concentrate feed is the important factor in such an intensification strategy The impacts of concentrate feed is particularly relevant for greenhouse gases of ruminants, as with longer fattening periods, more methane is emitted (Gerber *et al.*, 2013) through enteric fermentation. Thus, from a single-supply-chain perspective, we can conclude that the use of concentrates should be favorable for the environment.

However from a global perspective, two thirds of the global agricultural area is covered by grasslands (FAOSTAT, 2013). A large share of this grassland cannot be converted to productive arable land either due to slopes, soil characteristics or due to rainfall patterns (Suttie *et al.*, 2005). Using crops grown on arable land increases pressure on a globally scarce resource. So, does it makes sense to increase livestock productivity by increasing shares of human-edible feedstuffs and crops grown on arable land in feeding rations or alternatively rather reduce this share? Analyzing such a fundamental question requires an approach taking into account the absolute boundaries in availability of natural resources from a global perspective.

In this paper, we aim to present a new LCA-based approach for analyzing the impacts of fundamental changes in the global food system. We apply this approach for analyzing the impacts of a reduction in concentrate feed use for ruminant production compared to a reference scenario for 2050. We compare the results on resource efficiency per kg of milk with results at global level, using the amount of energy available for human nutrition as a global functional unit. This allows us not only to analyze at resource efficiency but also consistency and efficiency as two complementary sustainability strategies (Schaltegger *et al.*, 2003). Finally, we draw conclusions about the explanatory power of single-supply chain LCAs with respect to global environmental challenges.

2. Methods

To analyze the environmental impacts of global food system scenarios, we used the global model SOL-m (Schader et al., 2012) and further developed it to a LCA database for global land use activities. The model builds upon FAOSTAT, including the food balance sheets, tradestat, fertistat and other databases (FAO, 2013). Further data sources for life cycle inventories were based on LCA databases (Nemecek und Kägi, 2007) and additional scientific literature and datasets (e.g. GLC2000 data transformed according to Erb *et al.*, 2007). Plant production (180 activities) and livestock production (22 activities) are defined for 229 countries. Activity and country-specific defined inputs and outputs allow to model environmental impacts and to aggregate them to regional or global level (Figure 1). The model is programmed in GAMS (General Algebraic Modeling System).

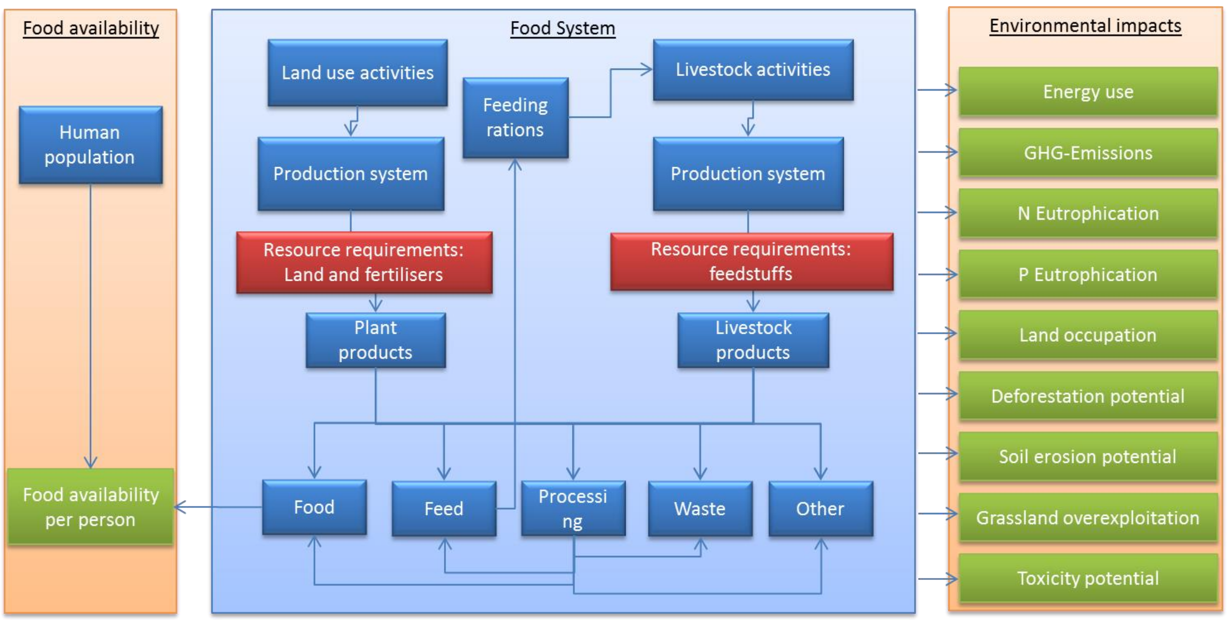

Figure 1. SOL-m model structure with food availability and environmental impacts as model outputs

Global food availability is calculated according to Equation 1, summing up the outputs in terms of mass, energy and protein used for food for all activities, production systems and geographic units.

$$GlobalFoodAvailability_{i,m} = \sum_{ijk} AL_{i,j,k} * OUT_{i,j,k,Yield,Mass} * NCHC_{i,j,k,m} * UF_{i,j,k,food} \forall_{i,m} \quad (1)$$

Where i = index of geographic units;
j = index of activities;
k = index of farming systems;
l = index of inputs and outputs;
m = index of nutrients for human consumption;
n = index of utilization types;
s = index of units of inputs and outputs;
FA = food availability [kcal or g protein]
AL = activity level [ha/year for land use activities, number of animals/year for livestock activities]
OUT = output [kg/ha or kg/animal]
NCHC = nutrient contents for human consumption [%]
UF = utilization factor [%]

The model covers the environmental impacts land occupation (differentiated by arable and grassland), energy use, greenhouse gas emissions, from a life cycle perspective, based on Equation 2. Greenhouse gas emissions were calculated using the method GWP_IPCC100a. For agricultural emissions a Tier 1 approach was used, except for methane emissions from enteric fermentation for which we used a Tier 2 approach (IPCC, 2006). Allocation procedures can be switched between mass, energy, protein and economic allocation. N and P-surplus are modelled correspondingly but taking into account only nutrient flows in the agricultural system.

$$Environmental\ impact_{i,o} = \sum_{ijk} AL_{i,j,k} * (IN_{i,j,k,l,s,o} + OUT_{i,j,k,l,s,o}) * IF_{i,j,k,l,s,o} \quad (2)$$

Where o = index of environmental impacts:
IN = inputs [kg]
IF = impact factors [environmental impact / kg of input]

For each activity, we defined inputs and outputs, i.e. all relevant physical flows related to individual activities. Inputs for livestock activities include four categories of feedstuffs: a) forage from crops grown on arable land, b) concentrate feed (grains, pulses grown on arable land), c) grassland-based fodder and d) agricultural/agri-industrial by-products. Further inputs for livestock activities are energy input for buildings, in-stall processes and fences. While a) and b) are in competition with production of human-edible food, c) and d) are not. Outputs of animal production activities include human-edible products (meat, milk, eggs, honey) plus hides and wool, manure excretion, nutrient losses and GHG emissions due to enteric fermentation and manure management (CH_4, N_2O, NO_3, NH_3). Amounts of concentrate feed and by-products subsume country-specific feed amounts according to the food balance sheets from FAOSTAT. Inputs for plant production activities included arable or grassland areas, mineral fertilizers (N, P, K), manure, crop residues, symbiotic nitrogen fixation, herbicides, fungicides, insecticides and management practices (tillage, seeding, fertilization, spraying, irrigation, flooding of paddy rice, harvesting, transport and drying). Outputs from plant production activities include crop yield quantities, crop residues and nitrogen losses during fertilizer application.

Thus, main drivers (yields, fertilizer and nutrient balances) of environmental impacts could be covered based on country and crop-specific data. The model can thus illustrate impacts of major changes in production patterns, processing, food waste and food demand and serves to understand possible interdependencies.

We model pesticide use potential, freshwater use for irrigation, annual deforestation pressure and soil erosion potential as additional environmental indicators. The pesticide use intensity model takes into account three parameters: pesticide intensity levels of crops, pesticide legislation in a country and access to pesticides by farmers. Parameter are expressed on a semi-quantitative scale and multiplied with each other. Freshwater use for irrigation is based on AQUASTAT datasets and covers estimations by crop and country. Annual deforestation pressure is derived from additional arable land and grassland required for agricultural production. We calculated an average annual deforestation rate for the years 2005-2009. Soil erosion is based on soil loss rates (Schwegler, 2014) and soil erosion susceptibility of crops as a function of the period of time when soil is left bare.

Apart from global scenarios, the model allows to show results by country or region respectively. Also crop and livestock type-specific data can be displayed. This allows comparing the resource use of average crop or livestock production activity for the functional units of a) mass, b) human-digestible energy produced, c) human-digestible protein produced, d) revenues generated and e) per hectare of land and year. The possibilities for presenting results are only limited by lacking or low-quality data, particularly on production systems in developing countries.

The model was calibrated to a base year which is constituted by the arithmetic mean of 2005-2009. Agricultural greenhouse gas emissions were compared with FAOSTAT emissions database (Tubiello *et al.*, 2013) and non-agricultural emissions for inputs were mainly taken from ecoinvent (Frischknecht *et al.*, 2007).

The besides the base year, the following scenarios were calculated for 2050:

Reference scenario: The reference scenario was developed according to Alexandratos and Bruinsma (2012), which forecast the global population increase, food demand patterns, land use patterns, livestock numbers and technical progress in terms of crop and livestock yield increases. Potential technical progress in the energy sector (e.g. increases in renewable energy use in the national energy mixes) was not considered.

Zero-concentrate ruminant production: This scenario builds basically on the same assumptions as the reference scenario, with respect to population increase, land use patterns, and technical progress. However, the use of human-edible concentrates and forage crops grown on arable land is minimized. This means that only grass and shrubs as well as plant-based waste from the food industry are used. The area of permanent grasslands was fixed and ruminant per head productivity was assumed to reduce by 0-40%, as there is clear reliable data about potential reductions on potential yield reductions. In this paper, we show only the results of the medium scenario which assumes on average 20% of yield reduction due to concentrate reduction. Livestock numbers and dietary patterns, however, are modelled as an endogenous variable in the model by looking at the bio-physical planetary boundaries.

3. Results

Figure 2 shows the impacts of a reduction in human edible concentrate use on global warming potential (GWP) per kg of milk produced. Regions in which a low average milk yield is dominant (Africa, South Eastern Asia, Latin America) show a high global warming potential as compared to regions with intensive dairy production (Europe, North America, Western Asia). Furthermore, the reduction of human-edible concentrates in ruminant rations results in an increase in GWP by 25-88% compared to the reference scenario. At global level, the impact categories total land occupation (+91%), deforestation potential (+95%), N-surplus (+20%), P-surplus (+59%), and soil erosion potential (+67%) increase per ton of milk. However, decreases can be shown for energy demand (-52%), freshwater use (-62%), occupation of arable land (-100%) and pesticide use intensity (-100%).

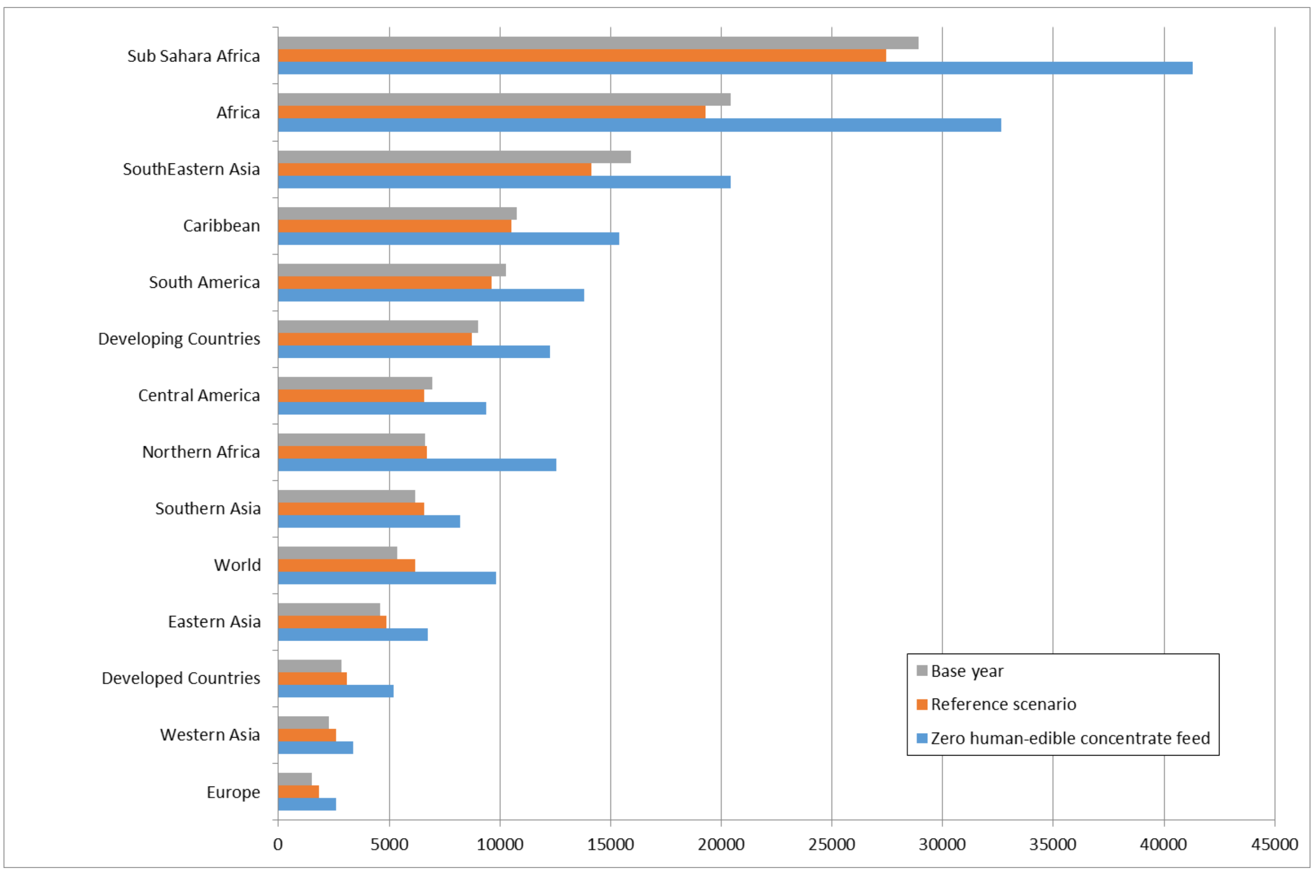

Figure 2. Comparison of average global warming potential [kg CO2-eq] in different regions per t milk delivered by dairy cattle

In Table 1, the impacts of the reduction in human-edible concentrate use on meat and milk availability are presented. As a consequence of reducing human-edible feed, the occupation of agricultural land decreases by 2.6% compared to the reference year, as the arable land goes down by 8.4%. This is a direct result of the lower amount of concentrates and forage crops that are cultivated on arable land. However, livestock yield reductions and lower cattle numbers partly compensate this effect. Cattle numbers will have to decline by almost 32%, buffaloes, goats and sheep numbers only decline by 2-6% due to lower shares of concentrates in current rations.

The share protein in human diets which is delivered of animal products goes down by 17% (4% compared to the base year), the energy shares delivered by animal products go down by 20%, compared to the reference scenario (6% compared to the base year).

This results in a 12% reduction in GWP. Other environmental impacts go down by 2% (freshwater use) to up to 20% (N-surplus).

Table 1 Impacts of a global reduction of concentrate feed for ruminant production on environmental impacts, agricultural production, dietary patterns and food availability.

		Base year	Reference scenario 2050		Reduced human-edible feeds in ruminant rations

Freshwater use	km3	1,135.4	1,277.0	*12.5%*	1,247.5	*9.9%*	*-2.3%*

4. Discussion

Our analysis shows for the example of dairy production that per kg of milk GWP would increase, while other environmental impacts will decrease (e.g. energy use, freshwater use, not presented in this paper), assuming a 20% decrease of global productivity in a scenario where human-edible feeds in ruminant diets are reduced to zero. Land occupation is an impact category which has a special importance for our study as we distinguish between arable land and permanent grassland. Permanent grassland covers about 2/3 of the utilized agricultural area globally (FAOSTAT, 2013). It is a resource with can hardly be utilized for human consumption without ruminants. Arable land on the other hand, is scarce and feed production on arable land directly competes with food production.

Using our model, we can take into account the absolute global scarcity of arable land and its indications for production and consumption patterns. We could demonstrate that there is a causal linkage between production patterns and dietary patterns, as the mere physical unavailability of products that are forecasted to be demanded increasingly in 2050 will not be present if concentrate use will decline. This takes into account the non-linearity of the impacts of the ruminant production system, i.e. once the existing grassland is occupied, arable land needs to be made available.

Attributional LCAs focus on strategies that enhance resource efficiency. The other sustainability strategies that concentrate on consistency and sufficiency (Schaltegger *et al.*, 2003) cannot be analyzed in a sound way with single-supply chain LCAs. Experts agree that pure efficiency gains may not be sufficient for global sustainable development in the food sector (Smith *et al.*, 2013). Therefore, fundamental changes in the agri-food sector should not be decided upon on a single-supply chain LCA basis only, but complemented with global impact assessments of long-term scenarios both using physical mass balance models as presented here and consequential LCAs, covering market interactions.

5. Conclusion

At global level, we face a trade-off between three strategies of sustainable development: efficiency, consistency and sufficiency strategies. Even if resource efficiency is maximized, we will global planetary boundaries are likely being overstepped. Sustainable intensification can help improving carbon and environmental footprints of livestock production. However, we have shown in this paper that depending on the perspective, LCAs may come to fundamentally different conclusions. In order to complement the efficiency strategy with other sustainability strategies dietary patterns need to be considered. Consistency strategies, e.g. organizing the food system closer to the natural cycles by feeding ruminants on grass, and sufficiency strategies, e.g. reducing meat demand, can complement efficiency strategies for fostering sustainable development at global level.

The model allows analyzing sustainability-related research questions with respect to resource efficiency, consistency and sufficiency. A formal functional unit (either protein or calories provided for human nutrition, can even be defined at global level. So, sustainability strategies should refer to both production and consumption and models for the assessment of such strategies should consider both production and consumption parameters as variables and not as constants. Our approach of a global physical mass balance model using LCI data is a tool complementary to single-product attributional and consequential LCAs for seeking sustainable solutions to global challenges.

ABSTRACT

Carbon footprint of Asparagus, a major crop with 300,000 ha worldwide, was based on primary farm data. These included four Asparagus sources to extent the short cultivation period in Germany a) forcing local asparagus by soil heating, or sourcing of imports b) from e.g. Turkey or Greece by truck or by c) ship or d) plane from Peru, different supply chains and the unproductive first years after planting within 11 years of an asparagus plantation - according to PAS 2050 for horticulture (BSI, 2012), using 1 kg asparagus as functional unit with system boundaries from plantlet to end of life at consumer stage. Environmental-friendly cultivation was with waste heat viz energy from a local soot factory; therein, PE tubing, and pumps for the hot water dominated in the product carbon footprint (PCF) of 1.75 kg CO_2e/kg for the heated local asparagus. In case of the Peruvian asparagus, air-freight played the major role in comparison to transport by container ship. Regional asparagus scored best with 0.82 – 1.3 kg CO_2e/kg including 29 g/kg biogenic carbon as offset, whereas air-freighted Asparagus from Peru had 8 kg CO_2e/kg similar to 12.2 kg CO_2 e/ kg air-freighted asparagus by Stoessel et al. (2012).

Keywords: Asparagus, airfreight, carbon footprint, import, greenhouse gas

1. Introduction

Asparagus is chosen as a prime example for a carbon footprint analysis with different produce sourcing and marketing strategies. With ca. 24,000 ha, asparagus is not only the largest vegetable crop in Germany, but a major vegetable with 300,000 ha worldwide with increasing popularity in a healthy diet. Expansion of the short cultivation period between May and June in Germany, however, can be achieved only by a) forcing asparagus by soil heating, sourcing by imports b) from e.g. Turkey or Greece by truck or by c) ship or d) plane from Peru. The objective of this contribution was to evaluate the carbon footprint of these four asparagus sources to aid consumer decision-making and determine GHG hot spots and climate-friendly sourcing.

The challenge is to combine the largest field grown vegetable commodity in horticulture with the new PAS 2050-1 for horticulture. The only two carbon footprint studies on asparagus were in the UK (Audsley et al., 2009) and Switzerland (Stoessel, 2012) before the PAS 2050-1 hort standard (BSI, 2012) became available. For a number of reasons, neither biogenic carbon nor the relevant use phase was included in these previous studies. For the first time, the new PAS 2050-1 (hort) is used as methodology including the new approach to biogenic carbon and Land Use Change (LUC) emissions for the shorter time period of only 20 years (old 100 years) and different crop rotation systems. This study was part of the pilot projects towards the development of the PAS 2050-1 hort (BSI, 2012).

Hence, the objective of this study is to assess the carbon emissions of different asparagus field production systems using a number of supposedly improvements such as waste energy for forcing asparagus to satisfy consumer demands for all year around vegetable supply. Since regional asparagus is not available all year round, the airfreight import of fresh asparagus from other parts of the world is used to fill in the marketing gap. Asparagus is employed here as a model crop for the comparison of heated and un-heated early (forcing) local production. Import of asparagus from Peru by ship and airfreight is included as a different way of sourcing for the European market.

2. Methods

2.1. Primary data assessment

Primary data from two farms in Germany with different supply chains include the unproductive first years after planting within the overall 11 years of an asparagus plantation. Biogenic carbon was also accounted for following the special requirements of the new PAS 2050-1 for horticulture (BSI, 2012). A heated cultivation was compared with an unheated standard cultivation system and marketing via two different ways (retail and farm shop).

2.2. Calculation of carbon footprint

The carbon footprint was calculated for the supply of asparagus based on the new PAS 2050-1 "Assessment of life cycle greenhouse gas emissions from horticultural products - Supplementary requirements for the cradle to gate stages of GHG assessments of horticultural products undertaken in accordance with PAS 2050" (BSI, March 2012), which includes the GHG emissions CO_2 (1x), CH_4 (25x) and N_2O (298x) and results in CO_2 equivalents (CO_2e). The new horticultural PAS 2050-1 (BSI, March 2012) includes specific requirements for different cultivation systems like perennial crops such as asparagus or orchards over their complete lifetime from plantlet supply to grubbing. Additionally, there is the opportunity to include the biogenic carbon in the harvested product, if used for food and feed, which is not considered in previous studies.

2.3. Functional unit and system boundary

Two functional units were employed for carbon footprint assessment:

- Acreage [ha] for asparagus cultivation (PAS 2050-1)
- Weight [kg] of saleable product at farm gate (PAS 2050-1) and for further marketing, use phase and disposal (PAS 2050)

The results for the assessed greenhouse gas emissions (GHG) are shown for the cultivation phase up to the harvest with the specific Farm Carbon Footprint (FCF), including the post-harvest activities up to the farm gate (B2B) and with transportation, marketing, consumer use phase and disposal (B2C, PCF).

2.4. Cultivation and marketing systems for asparagus

Three cultivation systems on two farms were selected on the grounds of representativeness, different primary energy use and marketing strategies. The large farm used one cultivation system with an underground soil heating system and another one without heating system. On the second farm the overall asparagus acreage was smaller and not heated. The marketing strategies differed in that the large enterprise (farm one) with its large volume of asparagus markets exclusively via nationwide wholesale and retailers. By contrast, farm two sales the smaller volumes of asparagus through farm shops and regional street markets direct to the consumer. Consumer shopping tours with private vehicle differ in distance and size of the shopping basket (20 kg with 1 kg asparagus for retail and various scenarios depending on specific marketing system combined for farm two). Home storage and cooking as well as composting were modeled.

3. Results

3.1. Carbon Footprint of Asparagus

The carbon footprint of asparagus was calculated over the entire life-span including the productive and unproductive phases, i.e. 11 years. In this case study for the new PAS 2050-1 only one farm with one cultivation system was analysed to study the ease of implementation of the new rules. LUC was calculated with an Excel tool that was developed in the pilot project. The result of the LUC for asparagus following annual crop land was negative for our specific growing and environmental conditions. To avoid any criticism of offset it was assumed zero in our calculation. The biogenic carbon was calculated from its 6 % dry matter with 47 % carbon content based on average (11 year) yield (7t/ha) including the unproductive phase of the cultivation. The result for the Farm Carbon Footprint (FCF) was 2.307 t CO_2-eq/ha asparagus, after the biogenic carbon was subtracted.

Including the cooling, grading and packaging the business to business carbon footprint according to the new PAS 2050-1 was 414 g CO_2-eq/ kg asparagus (Table).

The transportation to retail and the use phase (shopping tour, fridge and cooking) at the consumer amounted to 401 g $CO_{2\text{-eq}}$/ kg asparagus using the guideline of the PAS 2050:2011. The overall business to consumer (B 2 C) carbon footprint of 815 g $CO_{2\text{-eq}}$/ kg asparagus shows the result over the all life-cycle stages of asparagus.

Since waste energy was employed from a separate enterprise, viz a soot factory, this energy was excluded from the asparagus carbon footprint. However, the carbon footprint of heated asparagus doubled to 1.75 kg CO_2e/kg relative to unheated asparagus due to the plastic tubing to distribute the hot water to the plants and due to the energy consumption to pump the hot water

Table 1: Carbon footprint of asparagus cultivated in an integrated production system (asparagus regional)

	Integrated Production (IP) of Asparagus
Farm carbon footprint per acreage [t/ha]	
Average asparagus yield per ha and per year (over 11 years)	7.02 t/ ha
Yearly cultivation, tillage and planting (per ha) without bio-genic carbon	2.503 t CO_2-eq/ ha/a
LUC (asparagus after annual cropland)	0.0 kg CO_2-eq/ ha/a*
Biogenic carbon per ha (6 % dry matter of asparagus)	-0.198 t CO_2-eq/ ha/a
From planting to harvest (over 11 years) (ha)	2.307 t CO_2-eq/ ha/a
Farm carbon footprint [g per kg]	
From planting to harvest (over 11 years) (kg)	328 g CO_2-eq/ kg asparagus
Cooling, grading and packaging (5 kg cardboard carton)	086 g CO_2-eq/ kg asparagus
Carbon footprint from seedling to harvest according to PAS 2050 -1 (B 2 B)	**414 g CO_2-eq/ kg asparagus**
Product carbon footprint [g per kg]	
Overall transportation farm to retail	096 g CO_2-eq/ kg asparagus
Use phase (shopping tour, fridge and cooking)	305 g CO_2-eq/ kg asparagus
Product Carbon Footprint from harvest via use phase to disposal	**401 g CO_2-eq/ kg asparagus**
Product Carbon Footprint (PCF) CO_2 eq /kg asparagus **(B 2 C)**	**815 g CO_2-eq/ kg asparagus**
Product Carbon Footprint (PCF) CO_2 eq /kg asparagus **(B 2 C) excl. offset of biogenic carbon**	**843 g CO_2-eq/ kg asparagus**

*LUC result was negative but assumed as zero.

Alternatives to heated regional asparagus in spring for the consumer are imports by truck from Greece (2,100 km by ship or plane from Peru, resulting in 6- 12 kg CO_2e/kg asparagus in comparison with forced regional asparagus 1-2 kg CO_2e/kg asparagus.

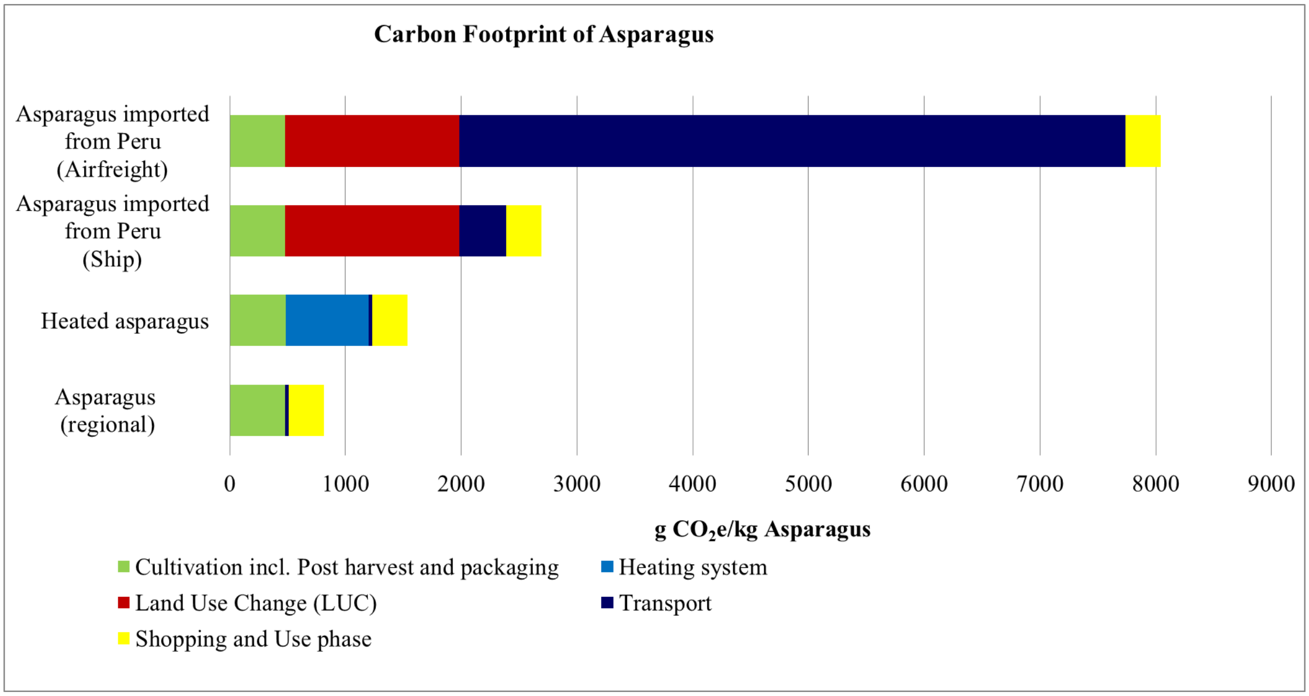

Figure 1: Product Carbon Footprint of different sources of Asparagus

3.2. Biogenic carbon

Biogenic carbon, i.e. the carbon contained in the harvested product exported outside the system boundary (out of the farm gate), is offset in the PAS 2050-1 against the carbon emissions during horticultural production, if used for food or feed. Similarly, bio-genic carbon not used for food or feed, e.g. tree trunks for the timber or furniture industry, can be offset against horticultural production (BSI, 2012) (Table).

Capital goods in horticulture such as greenhouse support structures for poly-tunnels, buildings, grading facilities and cold stores are defined and excluded from the Carbon Footprint calculations in PAS 2050-1.

Consumables, which are replaced on a regular basis, such as plastic foils for plant covering and growing substrates, are included. Similarly, fertilisers and plant protection compounds are included in the product carbon footprint.

4. Discussion

The larger carbon footprint of 1.9-2.4 kg CO_2e/kg asparagus by Audsley et al (2009) for asparagus cultivated in England may be due to the calculation from basic root vegetables and adjustments made for yield deviations from the average root vegetable crop. Our value of 8 kg CO_2e/kg airfreighted asparagus from Peru compares favorably with 12.2 kg CO_2 e/ kg asparagus by Stoessel et al. (2012), who used a stopover on the flight to Switzerland compare with a direct flight to Frankfurt in the present study.

5. Conclusion

The present study is, to our knowledge, the first approach based on the new dedicated PAS 2015-1 (2012) and utilizes comprehensive primary data assessed on carefully selected farms. Different marketing scenarios are presented, which include farm sale (regional asparagus) and supermarket shopping (Peruvian asparagus), in which the consumer played a relevant role with his shopping trip (2 x 5 km) with a standard 20 kg shopping basket with 1 kg asparagus (Schaefer, 2012).

Democratization of Food Environmental Product Declarations, with a Beer Example

Rita Schenck*, Neil Huizenga, Seth Lalonde, Matt Leighton, Anna Nicholson

IERE
* Corresponding author. E-mail: *Rita@IERE.org*

Abstract
Type III EPDs are becoming more and more common, and are a must-have in some fields. However, the cost of developing them is high, leaving small companies at an extreme disadvantage. To address this economic barrier, IERE has developed automated EPDs using beer as an example. The system depends on a deep understanding of the process and the range of options for making the product, but the results is a piece of software that can be used by any brewer with only business information needed as inputs to the calculation. Calculations are in real time, feedback as to sources of impacts is given to the brewer, and the public can see the results in an online EPD. The cost is reasonable, with the lowest fees only $150 per year, allowing EPDs to be created for each batch of beer, providing ISO compliant EPDs for a few dollars each. This model can be applied to all food products, with the outcome of a democratized EPD system.

1. Introduction

Type III Environmental Product Declarations (EPD) are an increasingly common tool used by companies to communicate the environmental impacts of their products. They are especially useful for business to business (B2B) communication as organizations attempt to better understand the impacts of their supply chains. The use of EPDs is also being driven by industry groups such as the US Green Building Council (USGBC) and even government as is the case with the French Grenelle Environnement.

Generating EPDs, performing the life cycle assessments (LCA), and undergoing third party verification can be costly endeavors. Some companies, especially small and medium enterprises (SMEs) such as farmers and small food processors, may find these costs prohibitive and forego EPDs thereby putting them at a competitive disadvantage.

In an attempt to address the cost barrier to EPD adoption several programs, including those mentioned above, have made allowances for the use of industry average or sectorial EPDs within a product category.

However, these average EPDs inherently fail to meet many, if not all, of the objectives of Type III environmental labels as defined by ISO 14025:2006:

a) "to provide LCA-based information and additional information on the environmental aspects of products";
b) "to assist purchasers and users to make informed comparisons between products";
c) "to encourage improvement of environmental performance";
d) "to provide information for assessing the environmental impacts of products over their life cycle."

While industry average EPDs may provide some value with respect to objectives "a" and "d" they lack the ability to differentiate similar products or incentivize environmental improvement. This paper proposes an alternative approach to increasing the use of EPDs while keeping costs low by using an automated EPD system. A pilot study that utilized an automated system to generate EPDs for multiple products within the same product category was conducted with micro-breweries in the Pacific Northwest.

2. Method

2.1. Automation Overview

An automated EPD system is not only cost effective, it also mitigates many of the issues associated with comparability among EPDs by providing a consistent modeling framework and background data. The process PCR development addresses many important modeling decisions and assumptions (system boundary, functional unit, cut-off rules, data quality requirements, impact assessment results, and reporting requirements). However, there are typically several instances where decisions are left to the discretion of the LCA practitioner. The result is potentially large variation in model design and impact results for EPDs that are published under the same PCR.

An automated system takes EPD standardization a step further than the PCR by using a single modelling framework, default background data, default assumptions, and a simple user interface that is accessible by non-technical users.

The pilot study developed an automated EPD system for a group of small-scale brewers that would not have the time or money to develop a custom EPD for one of their products, let alone all of the different beers they produced. The tool is available on an annual subscription basis and subscribers are able to generate EPDs for as many batches as they would like. Users can perform what-if analyses when planning new brews or to investigate opportunities for reducing their impacts.

2.2. System Design

The LCA model used in the EPD tool conforms to the Earthsure Beer Product Category Rule, number 50202201:2012 (IERE, 2012) as well as ISO 14040, 14044 and 14025 (ISO, 2006; 2006b; 2006c). The functional unit for the EPD is twelve ounces of beer delivered to the point of consumption. However, the tool allows users to calculate impacts associated with other commonly used units (e.g. 16 oz., ½ barrel). Figure 1 shows the system boundary used for the EPD system's underlying LCA model. The beer life cycle is separated into three life cycle stages. Upstream production includes the raw material use, manufacturing and transport of all inputs to the brewery stage. Beer production includes all brew house operations from grain mashing, through boiling and fermentation, to packaging and cleaning of equipment for the next batch. The use phase consists of distribution to the point of consumption (either retail or restaurant) as well as treatment of waste products. Capital goods, employee activity, and recycling of discarded materials are excluded from the study.

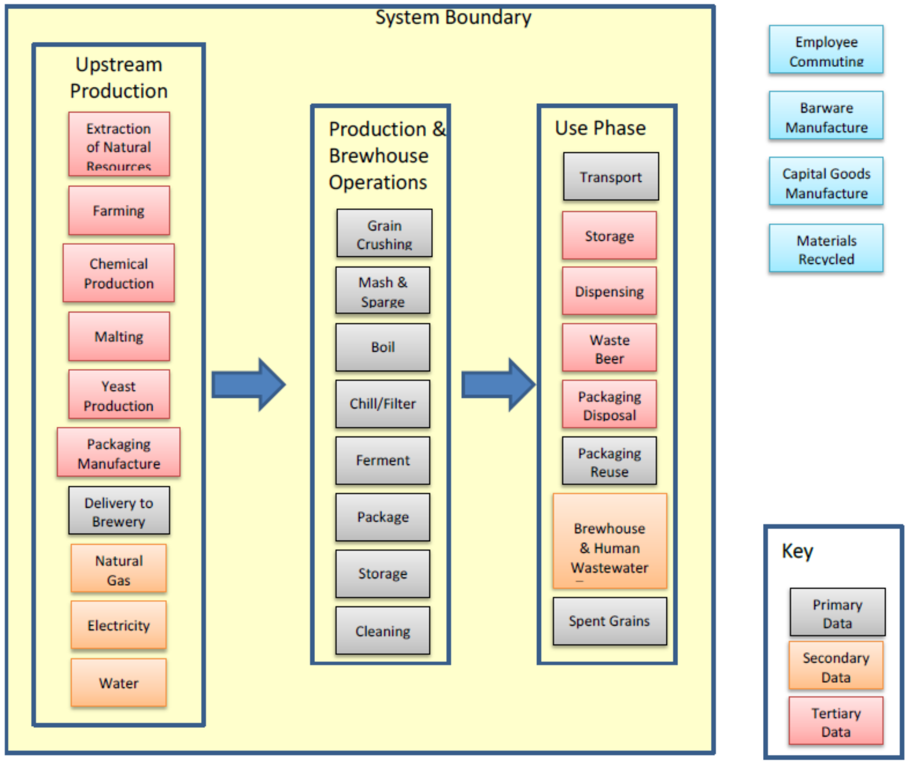
Primary data was collected for all unit processes under the direct control of the brewery with a reference flow of one batch. Information on the beer recipe, production volume, equipment usage and packaging were input directly by the brewers into the software.

Production data for agricultural products was obtained from USDA National Agricultural Statistics Service Information, USDA National Agricultural Library Digital Commons (USDA, 2012), and the Ecoinvent database[vi]. Material content data for cleaners and other chemicals were obtained from Material Safety Data Sheets (MSDS) provided by suppliers and linked to life cycle inventory data from the Ecoinvent database.

Regionally specific process LCI data was used whenever possible. This included the creation of an electrical grid mix to represent each brewery's local electric utility. When regional process data were not available, US average process LCI data were used.

The cutoff rules used specified that at least 95% of all mass and energy and all known toxic materials are included in the analysis. No product representing more than 1% of the total mass or energy of the system was excluded. Life cycle impact assessment was performed using the US EPA TRACI 2.1 methodology (Bare, et al, 2002). Total life cycle inventory amounts for water use and land occupation are also calculated per the PCR guidelines.

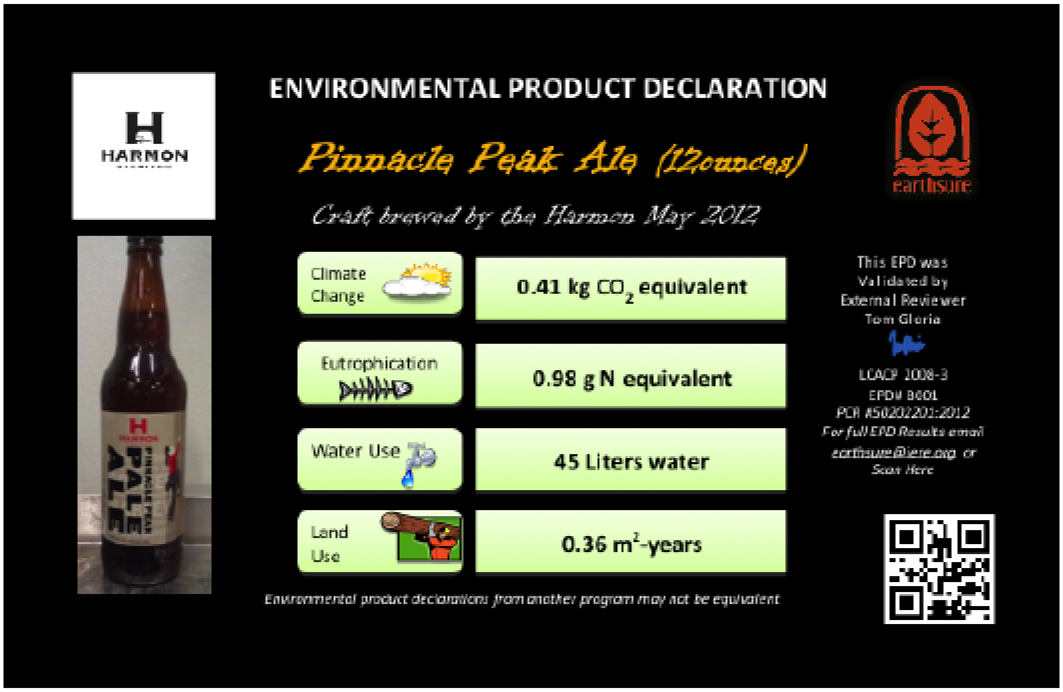
Figure 1: LCA System Boundary



3. Results and Discussion

Figure 2 shows an example EPD created by a brewer that participated in the pilot. While the reported impacts for each beer analyzed were generally of the same order of magnitude, the largest sources of those impacts varied for several of the brewers. The environmental impacts of the beer life cycle are primarily related to material inputs, brewery operations, and beer consumption. The ingredient phase of the life cycle is the main contributor to ecotoxicity, ozone depletion, and water use at all five breweries; it is also the prime factor in eutrophication, land use, and smog at four breweries. The brewery phase is the primary contributor to climate change and acidification at three breweries; this phase has the highest smog value at a single brewery. The consumer use phase contributes heavily to climate change given the release of CO_2 when beer is consumed. The packaging phase is not a common prime source of impacts among the breweries; nonetheless, it is the main contributor to eutrophication and land use at an individual brewery.

Figure 2: Example Beer EPD



The EPDs were made publically available online for customers to view and compare the impacts of the different beers. In addition, the brewers were able to use the results in their own marketing materials. The pilot was able to achieve the goal of producing a high quality EPD for a group of small and medium enterprises at an affordable price. Cost per EPD varied based on the size of the brewery and the number of EPDs each generated. However, the costs were still quite low, especially compared to conventional EPD development, with one brewer paying the equivalent of $50 per EPD.

The pilot also showed that EPDs can be an effective tool for companies to measure their environmental impacts and provide incentive to improve the environmental performance of their production. All five of the participating brewers have modified or plan to modify their practices after creating their EPDs. Examples of these changes include: insulating storage tanks to reduce energy requirements; changing cleaning procedures to limit chemical use; investing in energy efficient equipment; the purchase of an electric vehicle for distribution.

4. Conclusion

The pilot study showed that an automated system is capable of providing accurate, verifiable and cost effective EPDs that adhere to the goals and ISO 14025. This was achieved at a low cost per EPD and required little technical knowledge on the part of the EPD owner. More importantly, it provided companies that are interested in sustainability with valuable information that they can now use to reduce their environmental impact. The brewers would likely not have access to this information otherwise as they do not have the time, money or expertise required to generate EPDs in a conventional manner.

Such a system bridges the gap between a one-time single product LCA and a sector level average by utilizing primary data for operations occurring within the organization. Because these operations are under the direct control of the organization, they are most likely to be the source of differences between similar products. The use of default data for all other background processes significantly reduces the resources required for data collection when compared with a traditionally developed EPD.

Many more such automation systems are needed to bring EPDs into the hands of the small producer and subsequently their customers. Agricultural products are prime candidates for EPD automation due to the similarities in the production of a crops as well as the large number of farms. We estimate that crop EPDs could be produced at an even lower price point than the beer pilot, further democratizing EPDs. Information technology coupled with parameterized LCA models can be a force for achieving better environmental performance for food systems.

5. Acknowledgements

The pilot EPD automation study was supported by the American Brewing Co., Fort George Brewery, Harmon Brewing Company, Hop Works Brewery, The RAM Restaurant and Brewery, Vashon Brewery, and the City of Tacoma Sustainability Program.

ABSTRACT

Nestlé has engaged in the development of a simplified ecodesign tool (EcodEX) for the assessment of products in the development process. EcodEX guides the user along the predefined phases of the life cycle of a typical food product, using a preselected list of life cycle inventory data. The tool is currently being used by a user base of non-LCA-specialists that have been provided with a basic training on the tool use, as well as with basic understanding of sustainability in the food sector. First results indicate that the tool can improve the design of new products and plays a very important role in increasing the understanding of sustainability in the organization. Key challenges are the availability of life cycle inventory data and the training and support process for a large user base.

Keywords: product development, innovation process, ecodesign, simplified LCA,

1. Introduction

Nestlé, the world's leading Nutrition, Health and Wellness Company, has integrated the life cycle approach into its innovation and renovation processes to improve the environmental performance of new food products under development. Over the past years, Nestlé has done life cycle assessments (LCAs) for representative products in each of its business categories, and has summarized and shared them internally using Sustainability Category Profiles. Some of these studies have also been published (Humbert et al, 2009a; Humbert et al, 2009b). While these studies give valuable insight for strategy setting of businesses, the conventional life cycle assessment approach is impractical for widespread application in product development. A company as large and diverse as Nestlé, with thousands of new product developments every year, would have to deploy a considerable amount of resources on these assessments. Furthermore, given the speed at which innovation occurs in the fast moving consumer goods sector, and in particular in the food industry, results from conventional LCA studies will, in many cases, become available only once the Nestlé Product Development Process has advanced significantly (see figure 1 below). Therefore, a simplified, yet reliable, ecodesign tool specific for the assessment of food and beverage products has been developed and rolled-out in Nestlé R&D over the last years. This paper presents the outcomes of this roll-out and assesses the benefits of such an approach for large food companies.

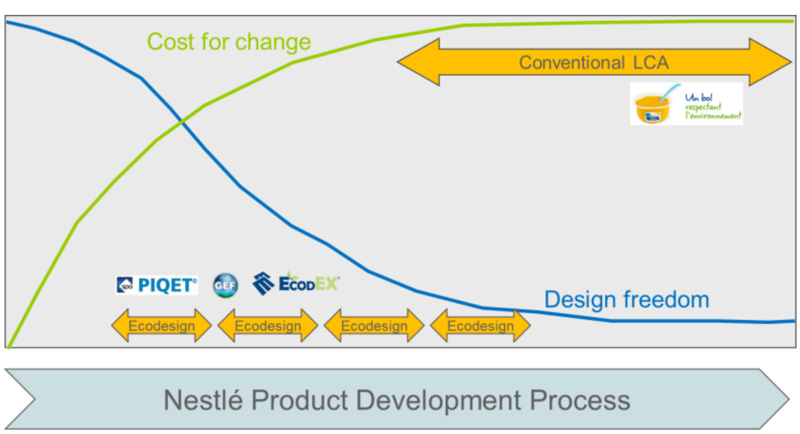

Figure 1. Nestlé Product Development Process and the positioning of conventional LCA (top right) vs. simplified ecodesign tools, which apply the LCA methodology earlier in the design process to optimize their influence on product development.

2. Methods

2.1. Goal and scope definition

EcodEX is a simplified ecodesign tool that guides the non-expert user through the different stages of the life cycle of a typical food product, providing him/her with a reliable estimate of the environmental hotspots in the products value chain, as well as a comparison of the environmental performance of different design alternatives (Selerant 2014). As compared to conventional LCA software, EcodEX has a significantly reduced flexibility in what can be modelled with the tool: the user is guided across the typical life cycle of a food product (ingredients, packaging, processing, distribution, consumer use, and end of life) and can enter only the data appropriate for these life cycle phases. The user mostly selects LCI (life cycle inventory) profiles from a pre-defined list without the possibility of modifying them. In the case of processing, though, default values for electricity, heat, and water consumption may be overwritten with measured factory data.

The tool is linked to the Nestlé recipe management system, extracting high quality data on recipe composition and processing steps directly from an existing IT system. Ingredient specifications in the food industry can easily run into tens of thousands, turning their management into a complex endeavor. This is why a key requirement in the development of the tool was the link to the management system already in place at Nestlé.

2.2. Inventory data

The recipe management data and information entered by the user (e.g. mode of transportation and distance travelled) are then combined with inventory data. The majority of LCI data comes from public data sources, in order to ensure the credibility of the results of the tool. Major databases used in EcodEX are Ecoinvent 2.2 (Frischknecht et al, 2005) (for electricity profiles, transportation, as well as packaging materials), and the World Food LCA Database (Quantis, 2014) (for food ingredients). Also, the Agribalyse database (ADEME, 2014) may be used in the future for additional food ingredients. Some ingredients where no datasets are currently available in public databases have been created based on LCA studies done by consultants for Nestlé. Datasets on novel food ingredients or packaging materials may also come from suppliers.

2.3. Impact assessment methods

The tool calculates environmental impacts according to internationally harmonized LCA methods, such as the ISO 14040 & 14044 norms (ISO 2006a, ISO 2006b), the European Union Product Environmental Footprint (PEF) (EC 2012), and the EU Food Sustainable Consumption and Production Roundtable ENVIFOOD protocol (Food SCP RT 2013). Currently, five environmental impact indicators are taken into account by EcodEX: land occupation and water consumption at the inventory level; GHG emissions at a 100 year perspective (IPCC 2007) and Non-renewable minerals and fuels (CML 2014) at the midpoint level; and Ecosystems Quality (based on the IMPACT 2002+ method and modified to exclude land occupation and thus avoid double counting) at the end-point level (Jolliet et al, 2003).

In addition to the exclusion of land occupation in Ecosystems Quality, the ecotoxicity characterization factors of metal emissions in agriculture have been set to zero. This is because the modeling of metal toxicity in IMPACT2002+ is deemed insufficiently accurate to be taken into account in a simplified ecodesign tool for the agri-food sector. For instance, the impacts of copper used in coffee and cocoa production (application rates of copper pesticides are well below the levels authorized per hectare in organic agriculture for many crops in Europe) result in toxic effects several orders of magnitude above those of “problematic” conventional pesticides such as Aldicarb that are also used in coffee and cocoa production.

2.4. Interpretation

A consequence of the development and application of a simplified ecodesign tool is the introduction of larger uncertainty in the results of the assessments. Therefore, EcodEX is not intended for communication purposes, but for internal decision making only. Work is currently ongoing to develop a specific module to assess uncertainties in a reliable way directly as part of and EcodEX assessment.

3. Results

EcodEX has been regularly used by the Nestlé R&D community for approximately one year now. There are around 100 users of the tool, and approximately 900 LCA scenarios have been calculated in this period. The results of these scenarios have influenced the development process of new products in several ways:

If the environmental performance of the new design worsens:

- Product designers may work on an alternative design that improves the environmental performance of the product. In the past, in the absence of EcodEX, designers were not aware that their designs had worsening impacts for the environment.
- The product development may be interrupted or stopped altogether because environmental performance is of key importance to the business unit and market. Without the information provided by EcodEX, decision makers are not in the position to take timely decisions at the earlier stages of the development process. In case an LCA study was commissioned to an external consultant, the conclusions would become available too late in the design process.
- A decision may be taken where the project goes ahead despite the adverse environmental effects, because of other criteria such as consumer preference, nutrition, quality or legal requirements. In this case, EcodEX did not have any tangible consequence for the environment. However, decision makers will be aware that they are launching a product with higher environmental impacts, and will need to be able to defend their decision e.g. against critical consumers or NGOs.

If the environmental performance of the new design improves, the results can be shared internally to gain support for the new product development. This may result in a faster adoption of the product, or the use of the product in other markets.

In addition to these direct benefits on the product development, the tool has also very strongly increased the understanding on food environmental performance among the users: product developers that calculate the environmental performance themselves get a much deeper understanding of their product life cycle than those who are presented with a report and finalized results. For instance, everybody knows intuitively that meat products have higher environmental impacts than plant-based alternatives. However, if the product developer is able to calculate the difference himself, the actions prompted will be larger and further reaching because the product developer fully engages with the assessment.

4. Discussion

A number of challenges have occurred during the development and implementation of EcodEX:

4.1. Inventory data

For such a tool to be applicable, high quality LCI data for an extensive array of food ingredients used in the food industry are required. This is currently being addressed by a number of initiatives, such as the World Food LCA Database Project (reference). Currently, LCI profiles are available for the majority of key ingredients, but too specific profiles are often not representative of general conditions (e.g. tomato, organic production, Switzerland vs. tomato, global average). First of all, ingredient data representing global averages should be developed. Over time, the amount of data will increase, and will allow the assessment of more specific ingredients (e.g. stevia vs. artificial sweetener), ingredients from specific regions grown under specific climatic conditions (e.g. wheat from Southern Spain vs. wheat from the Nebraska, US), and different cultivation practices (e.g. integrated pest control vs. conventional production).

4.2. Training

Users have to be extensively trained to gain the appropriate understanding on sustainability and life cycle assessment, which inevitably requires time and significant resources. Most users have a background in nutrition, food science, process engineering, or packaging technology, which provides them valuable insight in their focus area. In order to be able to make meaningful decisions on the environmental impacts of the products they develop, they need to expand their skills set to include this topic. It cannot be expected that the quality of the assessments is comparable to that of a trained LCA specialist at the beginning. Practice and frequent use of the tool, along with ongoing training through webinars (conference calls with desktop-sharing) and a review of the studies performed will assure that EcodEX users make high quality assessments over time.

4.3. Alignment with external initiatives

The importance of life cycle assessment for external communication is likely to increase in the future. While EcodEX is intended for internal decision making, EcodEX users will want to use the results for external communication as well. Therefore, it is important that the methodology in the tool is as closely aligned with externally developed methodologies as possible. This is not always a straightforward task, because external methodologies are subject to change and not all requirements are known in sufficient details.

5. Conclusion

Our experience shows that the use of simplified ecodesign tools can be very useful tool to improve the environmental performance of the products of a food company during their innovation and renovation process. In the future, the LCI data in the tool will be complemented with new profiles to make more specific assessments possible. The functionality of the tool will also be extended, in particular to accommodate a module that assesses uncertainty and significance of differences. This will further increase the usability of EcodEX and help improve decision making.

ABSTRACT
Food consumption is a major driver of global environmental impacts. This paper presents an analysis of the life cycle impacts caused by global food consumption based on the newly completed input-output model; Exiobase v2. Exiobase v2 is a multi-regional input-output database covering 43 countries plus five rest-of-world regions for 2007. The data in the model includes all global product, emission and waste flows related to food consumption, i.e. a global mass flow analysis of all food related flows. The functional unit of the study was the global consumption of food in 2007. The included life cycle stages were cultivation/husbandry, processing, retail, preparation in households/restaurants and food waste disposal. The impact assessment focused on GHG-emissions and land-use. In this respect it should be noted that a model of indirect land-use changes is integrated in the Exiobase v2 model used in this study, to account for GHG-emissions caused by the use of land.

Keywords: Global food consumption, Input-output LCA, GHG-emissions, Land-use, Indirect land-use changes

1. Introduction

Food consumption is a major driver of global environmental impacts. Some studies give an indication of the overall magnitude of the global impact of food, e.g. sector specific LCAs (e.g. FAO 2006) and country/region specific input-output LCAs (e.g. Weidema et al. 2005). But yet, no studies have analyzed the total global life cycle environmental impacts from food consumption in detail.

This paper presents an analysis of the life cycle impacts caused by global food consumption based on the newly completed input-output model; Exiobase v2, which was created as part of the EU FP7 project CREEA (http://creea.eu/). Exiobase v2 is a multi-regional input-output database covering 43 countries plus five rest-of-world regions for 2007. Compared to other input-output models, the Exiobase v2 database also contains product flows in physical unit (mass and energy), and it is based on detailed mass balances for each product and industry, and it includes calculated quantities of food waste.

The functional unit of the study is the world's consumption of food in 2007. The included life cycle stages are cultivation/husbandry, processing, retail, preparation in households/restaurants and food waste disposal. The impact assessment focusses on GHG-emissions and land-use. In this respect it should be noted that a model of indirect land-use changes is integrated in the Exiobase v2 model used in this study, to account for GHG-emissions caused by the use of land. The results of the study are presented at the global scale, and they are broken down showing contribution analysis per food category, per life cycle stage, per sector, and per capita impact.

2. Methods and data

2.1. The Exiobase v2 input-output LCA model and mass flow analysis

The basis of the LCA is a detailed mass flow analysis of all flows related to the world's food consumption. This mass flow analysis is carried out using the approach developed in the EU FP6 project FORWAST (http://forwast.brgm.fr/) and extensively implemented at the global scale in high level of detail in the EU FP7 project CREEA (http://creea.eu/). The approach integrates mass flow analysis with economic input-output models, and the outcome of this is a hybrid input-output database where all flows with a physical mass are accounted in dry matter mass unit, energy flows are accounted in energy unit, and the remaining flows are accounted in economic unit. This database, the Exiobase v2, is very similar to a traditional process life cycle inventory database, but a few things differ:

- The level of completeness is higher; Exiobase v2 includes all the transactions in the economy and their associated emissions, whereas e.g. the ecoinvent database generally does not include activities in the service sector (marketing, accounting, legal services, cleaning etc.) and the sum of included activities in specific sectors may not add up to all different productions in this sector. This is also the reason why process based LCAs generally show lower results than input-output based LCAs.

- The level of detail is lower; the Exiobase includes 162 activities whereas e.g. the ecoinvent database includes thousands of activities/processes.
- The database includes transactions in actual flow volumes (e.g. the reference flow of wheat cultivation is equal to the global wheat production) as opposed to process databases, which are typically not integrating this information (they only include normalized processes; the wheat process only show transaction per unit of output of wheat).

The features of input-output databases make them ideal for macro-level analysis with little focus on the very detailed technology factors. But when it comes to life cycle inventories of more specific products (that differ from broader product categories in the input-output model), additional information from process based inventory data are needed.

The Exiobase v2 database is based on very detailed mass balances for each input to an activity in economy. The concept is illustrated in Figure 1. Since the mass balance principle illustrated in Figure 1 is applied to every input to activities/industry sectors in the model, the outcome is a fully mass balanced mass flow account of each included country and region. An example of the application of the principle in Figure 1 is: Raw milk production is an activity in the model. This activity has inputs of feed concentrate (product) and grass (resource extracted on the farm). These inputs become outputs of: milk and meat (supply of products), respiratory emissions (CO_2, CH_4 and H_2O), and manure (material for treatment). Further, for the respiration inputs of oxygen are also needed (resource inputs).

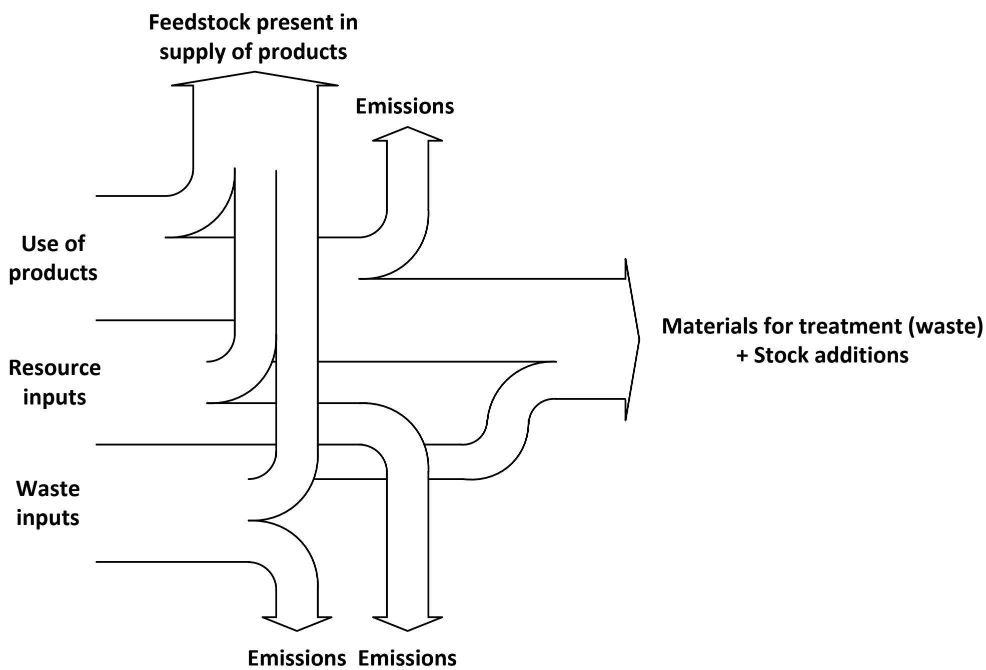

Figure 1. Mass balance concept in the model behind the Exiobase v2 database (Schmidt et al. 2012a). On the left side are the types of any inputs to any activities. The arrows represent the possible different fates of the inputs. Basically, an input (product, resource, waste) can become a product, an emission, a material for treatment (waste) or stock addition, i.e. a material that will become waste at a later stage (this could be an input of a tractor in year 2007 that will become waste 7-10 years later).

The level of detail of the model is 162 products/industries of which 13 are agricultural production of foodstuffs, 1 represents fishery, 11 are food productions, and 6 are treatments of food waste (e.g. landfill, incineration, and sewage treatment). The specific level of detail for food in the model can be seen in Table 1.

In terms of life cycle inventory modelling, by-product allocation is avoided by substitution in accordance with the ISO 14040 and 14044 standards on LCA (ISO 2006a,b). In input-output terms, substitution is equivalent to using the by-product technology assumption. This approach maintains all mass, energy, and economic balances which are also needed for the mass flow analysis (Suh et al. 2010). If allocation had been applied, it would not have been possible to present a mass-balanced product system as in Figure 2 (see e.g. Weidema and Schmidt 2010).

The data related to the food product chain used for the Exiobase v2 model includes data on the total production of crops, animals, fertiliser, and food products. These data are obtained from global statistics such as FAOSTAT, International Fertiliser Association, etc. For each agricultural and food product, a detailed mass balance was established so that inputs equal outputs. The flows of raw materials, energy and emissions from the involved industries are calculated based on e.g. LCI coefficients from existing life cycle inventories, calculated feed requirements (IPCC 2006), parameterized emission inventories based on IPCC (2006) and FAOSTAT (2013) while at the same time respecting national and global product balances, i.e. that the total supply of products equals the total use of products. Also the biomass production and animal and human metabolic balances are taken into account. However, for the biomass production, only the flows relating to photosynthesis are accounted for, i.e. only C, O and H are accounted for, while minerals like nitrogen, phosphorus and potassium in the products are not accounted for.

The used version of the Exiobase v2 database is a preliminary version. It has been aggregated to one global database by adding all 43 countries and five rest-of-world regions. Therefore, when the final version of the database is published, the results may change due to revisions.

2.2. Integration of indirect land use changes in the LCA model

In addition to the emissions accounted for in the Exiobase v2 model, the contribution from indirect land-use changes is also included. According to Le Quéré et al. (2012), around 9% of global CO_2-emissions originates from land-use changes. Therefore, it would be a significant underestimation of the real impacts of food if the land-use change induced emissions were not addressed. The concept of the applied iLUC model is described in Schmidt et al. (2012b and 2014) and the integration of the iLUC model in the input-output framework and the quantification of the iLUC model are described in Schmidt and Muñoz (2014, chapters 3 and 5).

2.3. Using the Exiobase v2 input-output model for LCA of the world's food consumption

When ascribing the flows in the Exiobase v2 database to the functional unit, all food for consumption in the input-output table needs to be identified. Food is generally consumed in three different activities in the input-output model: households, restaurants and in canteens in various activities. All inputs of food to households and restaurants are regarded as being purchased for being consumed. For canteens which are present in basically all activities or industries in the input-output table, care should be taken; some of the inputs of food is used as raw material for the manufactured products in these activities. Some example are: when the chemical industry uses vegetable oil as precursors for surfactants; when oil mills use oil crops for the production of vegetable oils; when animal farms use grains and other food this is used as animal feed; and when oil refineries uses vegetable oil and crops for biodiesel and bio-ethanol. Therefore, a number of inputs of food in some activities are not accounted as being for food consumption. This is especially relevant for agriculture, the food industry, the chemical industry and the oil refinery industry. When all food inputs for consumption are identified, the next step is to estimate how much of this food is actually consumed, i.e. digested by humans. For this purpose, the food consumption data from FAOSTAT (2013) and human metabolic balances (Muñoz et al. 2007). The difference between the use of food in the food consuming activities (households, restaurants and canteens) and the digested food is regarded as food waste. All generated food waste is sent to treatment: landfill (83%), incineration (11%), composting and biogasification (6%); the treatment mix is based on an average of national mixes, the data sources are further described in Merciai et al. (2013). It should be noted that the emissions from landfills in some developing countries are associated with large uncertainties; known figures on landfilled are modelled as managed landfills whereas the rest has been modelled as non-registered waste where there are no other emissions than the CO_2 from decay of organic material. The faeces/urine for wastewater treatment is determined by the human metabolism balance. Also here the emissions in some developing countries are associated with large uncertainties.

Since the functional unit concerns the consumption of food, also the energy, water, cleaning chemicals, domestic machinery, and transport for shopping in the households that relate to food consumption need to be included. The Exiobase v2 database contains information on the total use of these inputs in households. The shares of these inputs that relate to food consumption are estimated using household accounts in Schmidt (2010). For each input, it has been assured that the same quantity is also sent to waste treatment (landfill, incineration, recycling etc.) based on global average of national waste treatment mixes, e.g. when 1 kg domestic machinery is used for food preparation in households, the waste treatment of 1 kg domestic machinery is also included.

3. Results

The results chapter is introduced by a presentation of the outcome of the mass flow analysis of the world's food consumption. After this, the GHG-emissions and land-use related to the food consumption are presented.

3.1. Mass flow analysis results of the world's food consumption

The starting point of the life cycle assessment was a detailed mass flow analysis of all food in the world. The functional unit: 'the world's food consumption in 2007' is specified in details in Table 1. The total food consumption was divided into 25 food items and three different activities where food is consumed: canteens (including events), restaurants, and households. It should be noted that the total food consumption at 2366 million tonne (dry matter) is the input of food to the food consuming activities, i.e. the input of crops, animal products and food items upstream are larger because losses occur along the product chain. The use of food was divided into food from three different sources: crop production, animal production, fishery, and the food industry. 42% of the food was sourced directly from crop production, 3% from animal production, 1% from fishery, and 55% from the food industry. 10% of the food was meat (beef, pig, poultry, fish and other), 5% was other animal products (milk, egg etc.), and 85% was non-meat. It can also be derived from Table 1 that 6% of the world's food was eaten in canteens (industry, schools, at sport events etc.), 14% was eaten in restaurants, and 80% in households.

Table 1. Functional unit: Global food consumption in 2007. Flows are given in million tonne dry matter (except last two columns).

Food item	**Food use in canteens**	**Food use in restaurants**	**Food use in households**	**Total**	**Kg dry matter per capita**	**Moisture content**
Crops: Paddy rice	5	6	74	**85**	13	15%
Crops: Wheat	13	8	82	**104**	16	14%
Crops: Cereal grains, other	16	9	54	**80**	12	15%
Crops: Vegetables, fruit	6	9	459	**474**	71	82%
Crops: Oil crops	9	10	40	**60**	9	9%
Crops: Sugar cane/beet	4	109	3	**115**	17	75%
Crops: Crops, other	2	3	64	**69**	10	79%
Animals: Cattle, beef	0	0	0	**0.5**	0	53%
Animals: Cattle, raw milk	2	2	2	**7**	1	88%
Animals: Pigs	1	1	9	**11**	2	55%
Animals: Poultry	15	0	7	**22**	3	70%
Animals: Meat animals, other	0	1	2	**3**	0	57%
Animals: Animal products, other (e.g. egg)	2	2	16	**20**	3	26%
Animals: Fish	0	1	10	**12**	2	80%
Food: Meat, cattle	2	5	24	**31**	5	61%
Food: Meat, pigs	3	15	53	**71**	11	41%
Food: Meat, Poultry	1	6	31	**38**	6	75%
Food: Meat, other	0	1	8	**10**	1	35%
Food: Vegetable oils	11	25	36	**71**	11	0%
Food: Dairy products	7	10	70	**87**	13	46%
Food: Rice, processed	3	10	110	**123**	18	15%
Food: Sugar	7	50	177	**234**	35	1%
Food: Food, other	17	44	475	**536**	80	33%
Food: Beverages	13	10	45	**68**	10	90%
Food: Fish products	3	3	29	**35**	5	80%
Total	**143**	**341**	**1,881**	**2,366**	**355**	**43%**

Based on the balanced mass flows of resource inputs, products and emission outputs in the CREEA model, a quantitative illustration of the product system relating to the world's food consumption is created. Only the activities involved in agriculture, fishery, food industries and food consumption are shown. The actual modelled product system includes 166 activities in total. The product system is presented in Figure 2.

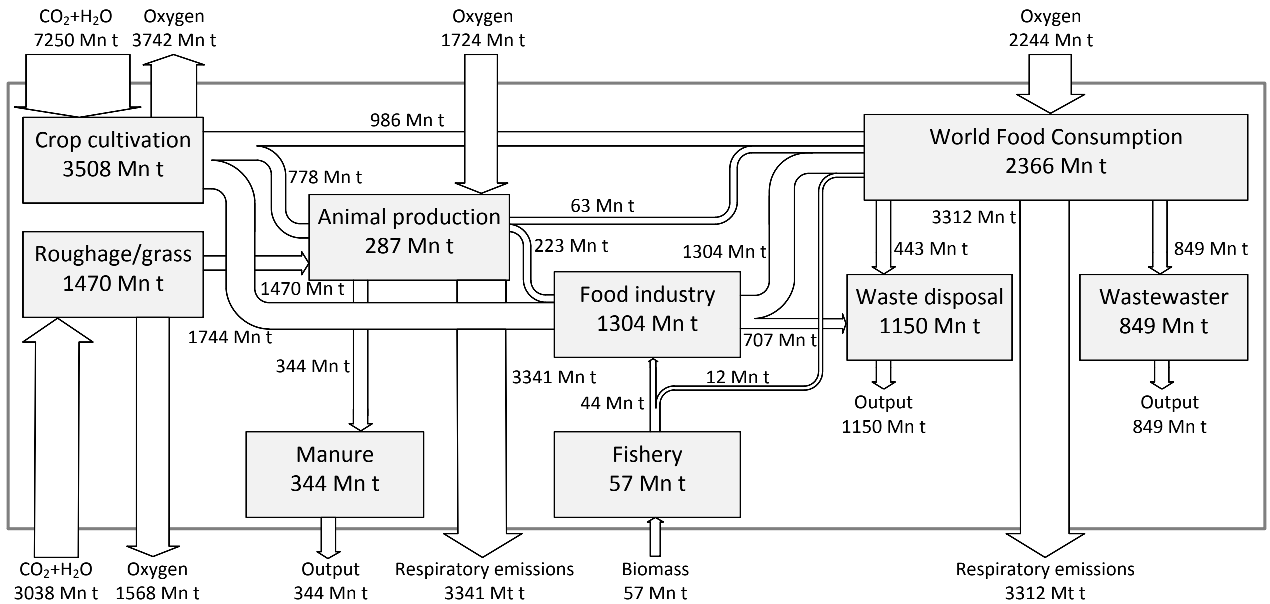

Figure 2. Mass balanced product system relating to the functional unit: the world's food consumption. The boxes represent activities, the arrows represent flows, and the grey borderline illustrates the system boundary. The numbers in the boxes show the total product output from the activities. All flows are given in million tonne (Mn t) dry matter.

It appears from Figure 2, that the largest flows on the input side were crop cultivation and roughage/grass. Of the total plant material produced, the largest share was used as animal feed; 45% of all plant material was used as input for animal production, and the remaining plant material was crops to food industry (35%), and to food consuming activities (20%). The largest share of cultivated crops were inputs to the food industry; 50%. The remaining crops were used as animal feed (22%), and directly for food consumption (28%). Waste or materials for treatment flows occurred in animal production (manure), food industry (food waste), and in the food consuming activities (food waste to disposal and faeces/urine to wastewater). The largest material for treatment flow was the faeces/urine to wastewater (849 million tonne). Another major material for treatment flow occurred in the food industry (707 million tonne), but also large quantities of food wastes occurred in the consumption activity (443 million tonne). It should be noticed that most of the materials for treatment in the industry are utilized for various purposes. However these materials for treatment or by-products are currently not modelled in detail in the Exiobase v2 model.

The most remarkable highlights from Figure 2 are:

- Of the total plant material produced/extracted for food purposes at 4978 million tonne, only 48% (2366 million tonne) ended up as an input to the food consuming activities. And further in the food consuming activities, additional 443 million tonne was food waste. Hence, only 39% of the raw material for food ended up being consumed.
- Almost half (45%) of all the plant material produced/extracted was used as animal food, while animal products only account for 15% of the input of food to the food consuming activities (see Table 1).

3.2. Life cycle impact assessment (LCIA)

This section presents the life cycle impact assessment of the world's food consumption. The results are shown as GWP100 for GHG-emissions (IPCC 2007) and in addition the land-use (occupation) is also described. Global GHG-emissions, measured as GWP100, in 2004 were around 50,000 million tonne CO_2-eq. (IPCC 2007).

Equivalent data for 2007, which was the basis year for the LCA, have not been identified. This will likely be published as part of IPPC's fifth assessment report in 2014. Therefore, when comparing the food consumption related emissions with global emissions, reference is not made to the same year, and hence these comparisons should be interpreted with care since the GHG-emissions in 2007 would be higher than 2004.

The LCA showed that the total impact on GHG-emissions from food consumption in 2007 was **25,370 million tonne CO_2-eq.** Compared to global GHG-emissions in 2004, food consumption in 2007 accounted for approximately 50% of all GHG-emissions. When also including the contribution from indirect land-use changes (iLUC), the emissions increased by 16% to **29,450 million tonne CO2-eq.** This corresponds to almost 60% of global GHG-emissions in 2004. The total land-use was **4,900 million ha** which corresponds to 38% of the global land area. This was distributed on 25% cropland, 7% roughage/intensive grass and 69% extensive pastures (grassland).

Two different contribution analyses are presented: In Figure 3, the overall result (without iLUC) at 25,370 million tonne CO2-eq. is broken down in a contribution analysis which shows the contributions in terms of the impact of inputs to the food consumption activities (canteens, restaurants, and households). Figure 4 breaks down the overall result in terms of the direct emissions by each activity in the product system.

It appears from Figure 3 that 36% of the total impact was related to the inputs of meat. When including also other animal products (dairy, egg), then this increased to 51%. The use of processed food accounted for 22% and non-processed food (raw food) for 8%. The contribution from energy (8%) relates to the electricity and fuels used for storing, preparing and dish washing in the food consuming activities. Waste disposal (5%) relates to the impacts from the food and waste water generated in the food consuming activities only. The impact from upstream food waste was included in the results for the input of food products to the consuming activities.

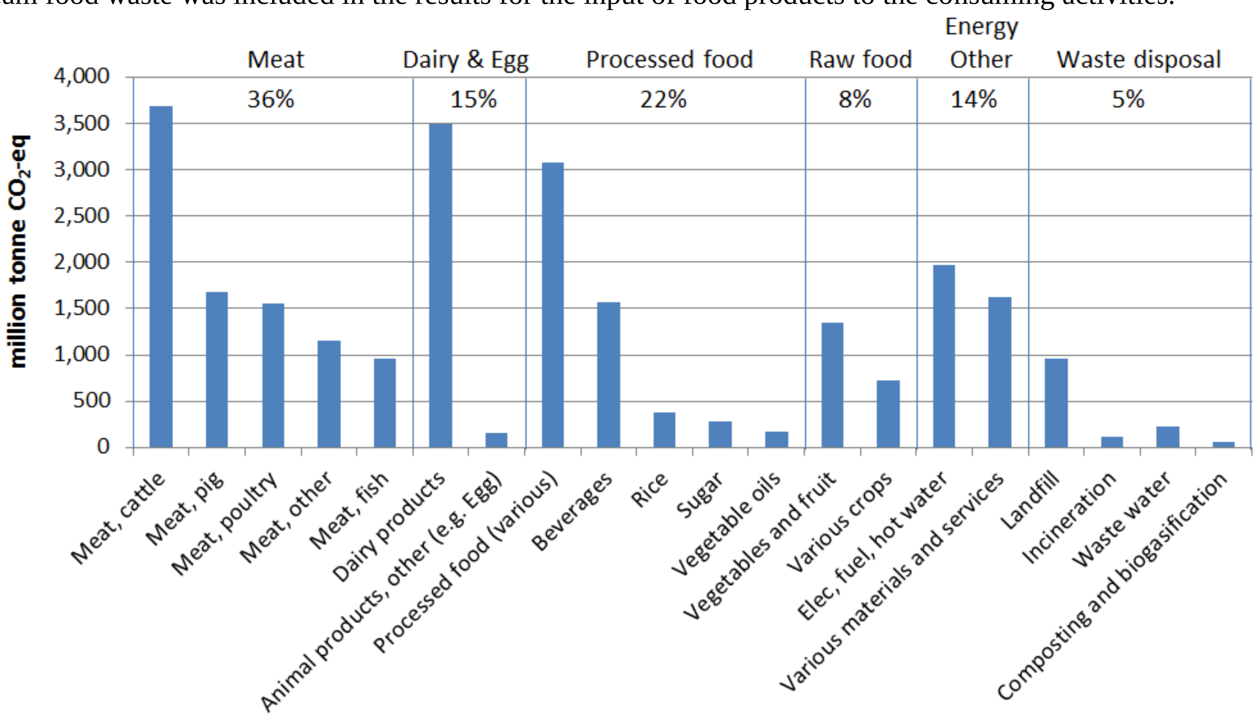

Figure 3. Contribution analysis based on the direct inputs to the food consuming activities. The results do not include the contribution from iLUC.

Figure 4 shows that 32% of the total emissions at 25,370 million tonne CO2-eq. took place in the animal producing activities in agriculture. Note that the cultivation and maintenance of roughage and grass areas were included in the animal activities. 7% of the GHG-emissions took place in crop production. It also appears from Figure 4 that energy was a hotspot in the food system. Around 14% of all food related emissions took place in activities where fuels are produced, converted to energy or transmitted to the energy user. Fertiliser production accounted for 6% and 2% were emitted in the food processing industries. The latter included combustion of fuels and process emissions (e.g. CH_4 from palm oil mill effluent treatment). 7% of the emissions took place in waste treatment activities. The remaining 32% 'other' relates to the production of packaging, machinery, transport, wholesale and retail etc.

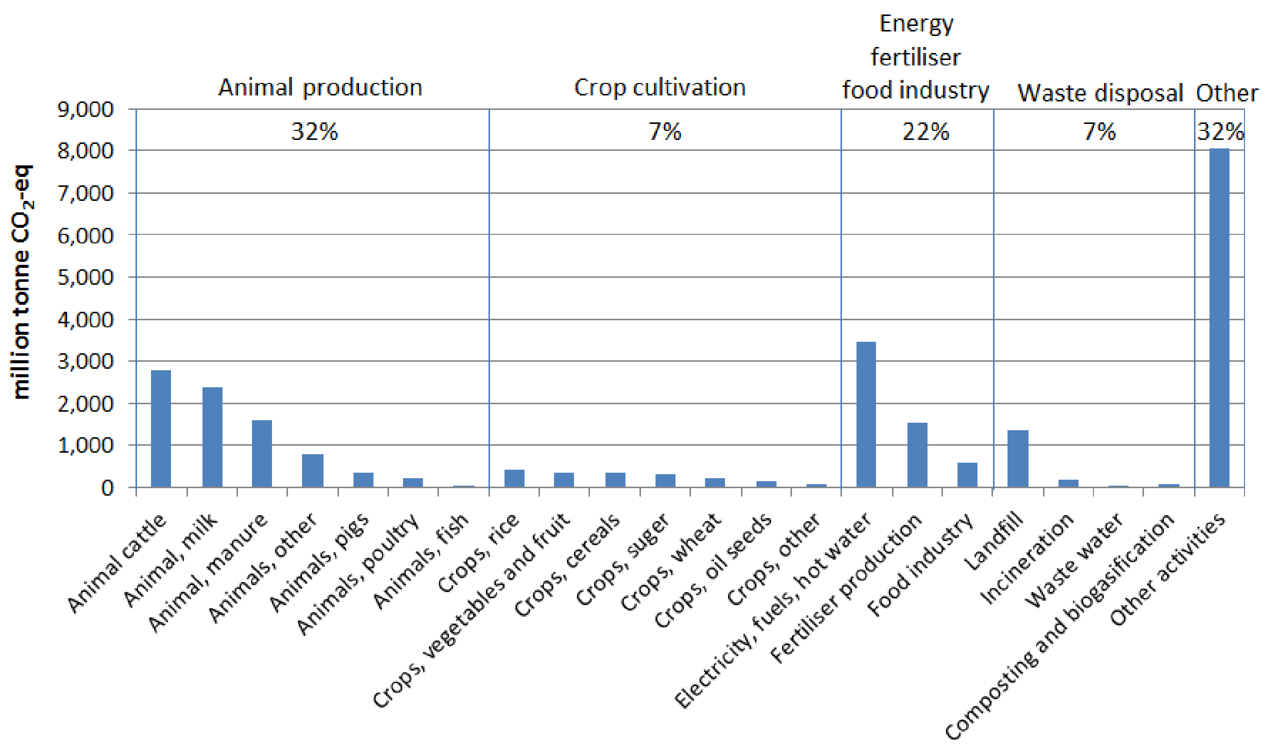

Figure 4. Contribution analysis based on direct emissions of individual processes in the product system. The results do not include the contribution from iLUC.

Figure 5 shows the GHG-emissions per kg dry matter of food product – without and with iLUC. The figure clearly shows that the impacts from animal products were significant higher than non-meat products. The reason is that animals need 4-40 kg dry matter feed per kg dry matter animal product depending on the type of animal. The most feed-to-product efficient animals are poultry, pigs, and fish, while meat production in the cattle and sheep systems (ruminants) is much less efficient. Milk production is somewhere in between. In addition to the relative low feed-to-product efficiencies of animal system compared to non-animal systems, the animals also produce emissions themselves; especially ruminants where methane from enteric fermentation is high. It can also be seen in Figure 5 that processed food was associated with higher impacts than non-processed food. The difference was related to losses of food waste in the processing as well as energy inputs. When including iLUC, the GHG-emissions increase by approximately 40-50% for crops, 10-30% for animals (smaller for fish), and 10-30% for processed food.

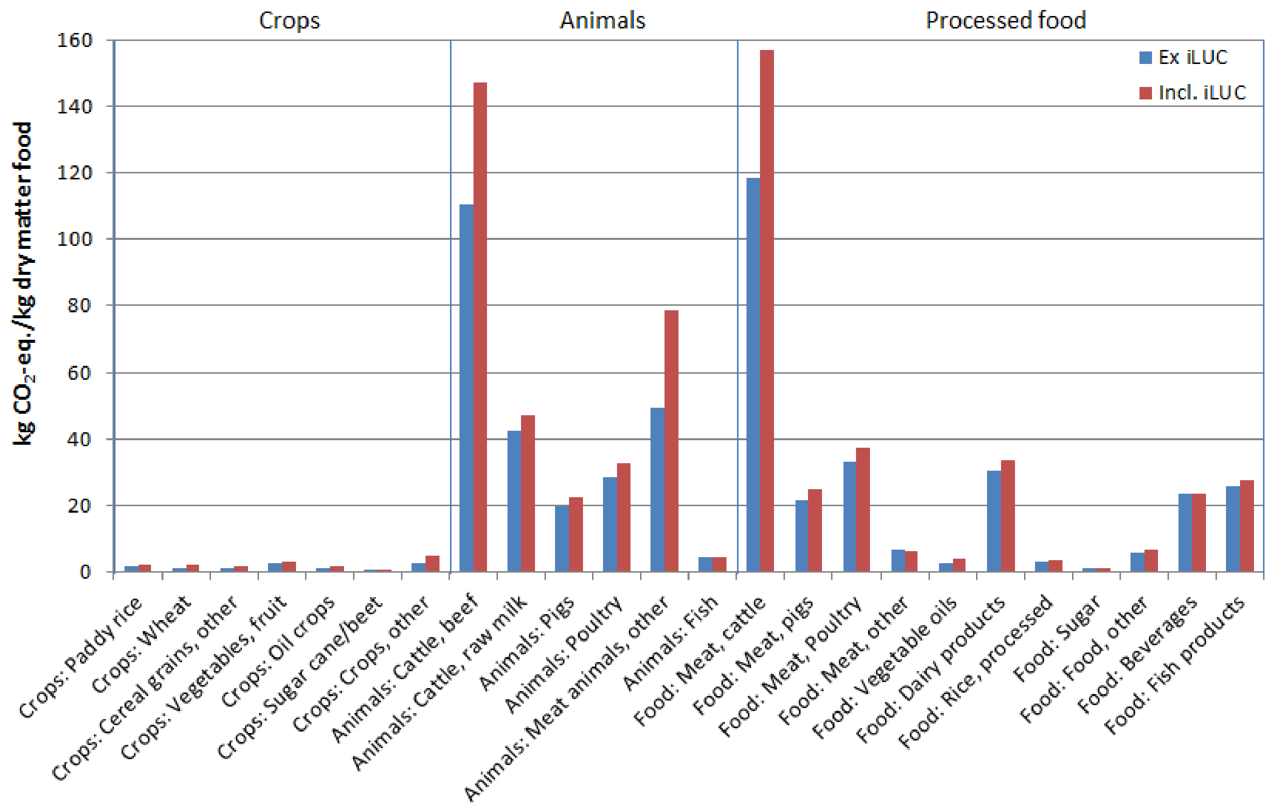

Figure 5. GHG-emissions per kg dry matter product. The results are shown with and without the contribution from indirect land-use changes (iLUC).

4. Discussion

This paper presented the use of a new model to create a detailed mass flow analysis and LCA of the world's food consumption. Since the model was based on several inherent mass balances, the level of consistency and accuracy of the results are regarded as being high. However, the presented results were based on a preliminary version of the Exiobase v2 model. Therefore, the final revisions of the model may also lead to changes in the results presented in this paper.

Since the model has a global scope and a national level of detail, it is very useful for analyzing various consumption groups at different levels (national, regional, global) as well as specific products or industries. The integration of mass flow analysis and input-output life cycle modeling in a hybrid unit database also show advantages; the mass unit of products in the database makes it look very much like a traditional process database in LCA software. Further, the mass flow data are useful for creating mass balanced product systems, and to obtain national and global scale overview of industries or consumption groups. Also, the combination with monetary input-output models ensures that emissions and product flows from all activities in economy are included.

The presented results were on a global scale, and at the level of detail which was allowed from the product classification in the Exiobase v2 model. The model immediately allows for similar analysis at the national level, and with some limited additional effort, it is possible to achieve a higher level of detail in terms of included food product categories to any desirable level. Further, similar analyses can also be carried out for any other consumption group than food, e.g. paper, electronics, waste etc. Hence, this article only represents an initial glimpse of the opportunities for analyses with the Exiobase v2 model.

5. Conclusion

The purpose of this paper was to carry out a mass flow analysis and an LCA of the world's food consumption. For this purpose a preliminary version of the novel model Exiobase v2 was used. As an add-on to the Exiobase model, a model of indirect land use changes (iLUC) was integrated with the Exiobase v2 model. The results were shown without and with the contribution from iLUC. The total food consumption in 2007 was 2366 million tonne (dry matter). 10% of the food was meat (beef, pig, poultry, fish and other), 5% was other animal products (milk, egg etc.), and 85% was non-meat. 6% of the world's food was eaten in canteens (industry, schools, at sport events etc.), 14% in restaurants, and 80% in households. The total plant material produced/extracted for food purposes was 4978 million tonne. Of this only 48% (2366 million tonne) ended up as an input to the food consuming activities. And further in the food consuming activities, additional 443 million tonne was food waste. Hence, only 39% of the raw material for food ended up being consumed. Almost half (45%) of all the plant material produced/extracted was used as animal food, while animal products only accounted for 15% of the input of food to the food consuming activities.

The LCA showed that the total impact on GHG-emissions from food consumption in 2007 was 25,370 million tonne CO_2-eq. Compared to global GHG-emissions in 2004, food consumption in 2007 accounted for approximately 50% of all GHG-emissions. When also including the contribution from indirect land-use changes (iLUC), the emissions increased by 16% to 29,450 million tonne CO2-eq. The total land-use was 4,900 million ha*year which corresponds to 38% of the global land area. This was distributed on 25% cropland, 7% roughage/intensive rotation grass and 69% extensive pastures (grassland). Of the total impact at impact at 25,370 million tonne CO_2-eq. (excluding iLUC), 36% was related to the inputs of meat. When including also other animal products (dairy, egg), then this increased to 51%. The use of processed food accounted for 22% of the GHG-emissions and non-processed food (raw food) 8%. The contribution from energy related to the electricity and fuels used for storing, preparing and dish washing in the food consuming activities accounted for 8%. Waste treatment of the food waste generated in the food consuming activities accounted for 5%. The remaining 6% related to domestic machinery, cleaning chemicals etc. As for the mass flow analysis, the LCA also revealed remarkable impacts related to meat and animal product consumption; while animal products only accounted for 9% of the food input to food consuming activities, the GHG-emissions from these animal products accounted for 51% of the food related GHG-emissions.

ABSTRACT

A Life Cycle Sustainability Assessment of dairy production system at the Grignon farm is presented. Two systems are studied, corresponding to the feed mix used before 2008, and the feed mix used thereafter, including a higher share of corn silage, alfalfa, locally produced rape meal and grazing; the functional unit is 1 kg standard FPCM at the farm gate. An innovative approach to assess impacts on biodiversity and soil quality is included, next to relevant environmental LCA impact categories, including water use and land use, as well as social and economic sustainability indicators. Comparison between previous and current diet shows a reduction in global warming potential and cumulative energy demand, two main objectives of the farm. Benefits and trade-offs with regard to other impact categories are presented and discussed, and recommendations are derived for further optimization.

Keywords: Life Cycle Sustainability Assessment, Dairy, Biodiversity,

1. Introduction

1.1. Overview and Context

The experimental farm of Grignon is a mixed crop-livestock farm. It is located at a distance of 40 km from Paris. The farm hosts 120 Prim'Holstein dairy cows with a 30 liter average daily milk production, in two milking times, which represents ca. 1,100,100 liter production every year on the farm. The agricultural net area of the Grignon farm exceeds 500 ha. This surface is dedicated to pasturelands and fodder and cereal production. The main crops are wheat, fodder barley, beer barley, canola, corn, horse bean, alfalfa, and meadows.

In order to reduce the farm's energy consumption and GHG emissions, there has been a change in the feed for dairy cows around the year 2008, which affected the composition of the feed mix. In the following, the new feed composition used since then will be referred to as 'current diet', whereas the alternative feed composition will be referred to as 'previous diet '.

In line with the objectives of the farm there is a need to investigate the consequences of this change in diet on greenhouse gas emissions and energy consumption but also in other potential impacts on sustainability in a wider context, encompassing environmental, social and economic aspects. Therefore, the farm and BASF have conducted together a Life Cycle Sustainability Assessment (LCSA) based on the AgBalance methodology created by BASF (Schoeneboom et al. 2012)

The present study hence quantifies and compares the sustainability performance (based on Life Cycle Assessment and additional sustainability criteria) of dairy (milk) production at the Grignon farm based on the current and the previous dairy cow feed mix.

A critical review has been carried out by a panel of interested parties, represented by external experts.

1.2. Objectives of the Study

The main objective of the study is to investigate sustainability performance of dairy production system at the Grignon farm by quantifying key environmental, social and economic performance characteristics (indicators). Due to the farm's objectives, the focus is on climate change impact and energy consumption.

Sub goal is to investigate the sustainability impact of the feed composition used at Grignon farm, specifically the effect of a change from the feed composition around the year 2008 (previous diet) to the feed used since then (current diet).

The intended audiences of the study include stakeholders of the farm and other interested parties, including the general public.

2. Methods

2.1. Studied Systems and Functional Unit Definition

The systems chosen for this comparative analysis are the dairy cow production system at the Grignon farm with the typical feed composition in the period since 2009, referred to as ‘current diet’, and the dairy cow production system based on the feed composition before 2008, referred to as ‘previous diet’, respectively.

Table 1. Diet composition of current and previous diet for one dairy cow life in absolute quantities (dry weight)

Feed component	System 1: Current diet Quantities [kg dw / cow life]	System 2: Previous diet Quantities [kg dw / cow life]	Origin
Maize silage	10,214	3,815	Grignon farm
Beet pulp	2,818	4,419	market
Alfalfa silage	1,916	0	Grignon farm
Rape meal from Grignon	4,428	0	Grignon farm
Alfalfa hay	3,252	0	Grignon farm
Grain maize	1,929	4,134	Grignon farm
Hay	2,499	2,593	Grignon farm
Molasses	1,851	2,451	market
Grazed grass	1,855	347	Grignon farm
Rape meal, industrial	1,421	3,186	market
Orange skin	243	307	market
Minerals (CaCO3 + NaCl)	618	1,192	market
Wheat straw	437	1,610	Grignon farm
Dried distillers grain	352	560	market
Humid distillers grain	0	1,470	market
Dehydrated alfalfa	4	1,662	market
Horsebean	0	881	market
other	1,140	2,252	market

Table 1 lists the composition of the feed mix for both systems, giving totals of each feed component aggregated over all growing stages of the cows’ life (veils, heifers, dairy cows). The comparison shows that the dominating component in the current diet is by far maize silage (44%) produced on the farm. On the other hand side, previous diet is composed by 24% of sugar beet pulp (purchased from a supplier) and 20% maize silage. ‘Rape meal industrial’ use was reduced significantly in the current diet and is now just 45% of the previous diet (compare Table 1). Rape meal industrial refers to the residual by-product of rapeseed oil pressing, which is purchased by Grignon from the general market. In the current diet, a new type of rape meal was introduced. This rape meal is obtained from a local oil mill, that uses oilseeds from rape produced at the Grignon farm, and has higher residual oil content than the industrial rape meal. Herein, we will refer to this new type of rape meal as "Rape meal from Grignon". The rape meal from Grignon replaces industrial rape meal in the current diet to a large extent; the remaining fraction of industrial rape meal comes from the ready-mixed feed products which are still used in the current diet. Another difference between the systems is the amount of grazed grass which increased by 300% in the current diet.

Dairy cow systems provide several functions: milk, veil (for fattening), manure, and the products derived from slaughter of the cows. The relevant function of the system considered herein is the provision of milk. Allocation is used to resolve multi-functionality (see below).

The functional unit provides a basis for comparing all life cycle components on a common basis and allows direct comparisons among the product systems in question. The systems are compared based on the functional unit of 1000 kg standard fat and protein corrected milk (FPCM).

A simplified representation of the processes considered in the present study is shown in Figure 1. Although not shown, the calculation considers all activities ‘upstream’ from the extraction of raw materials to manufacturing of basic intermediate products etc. and including transportation. The study considers process up to the farm gate; further activities 'downstream' as distribution, consumption and end-of-life of the milk are not taken into account. This is usually referred to as "cradle-to-gate" study.

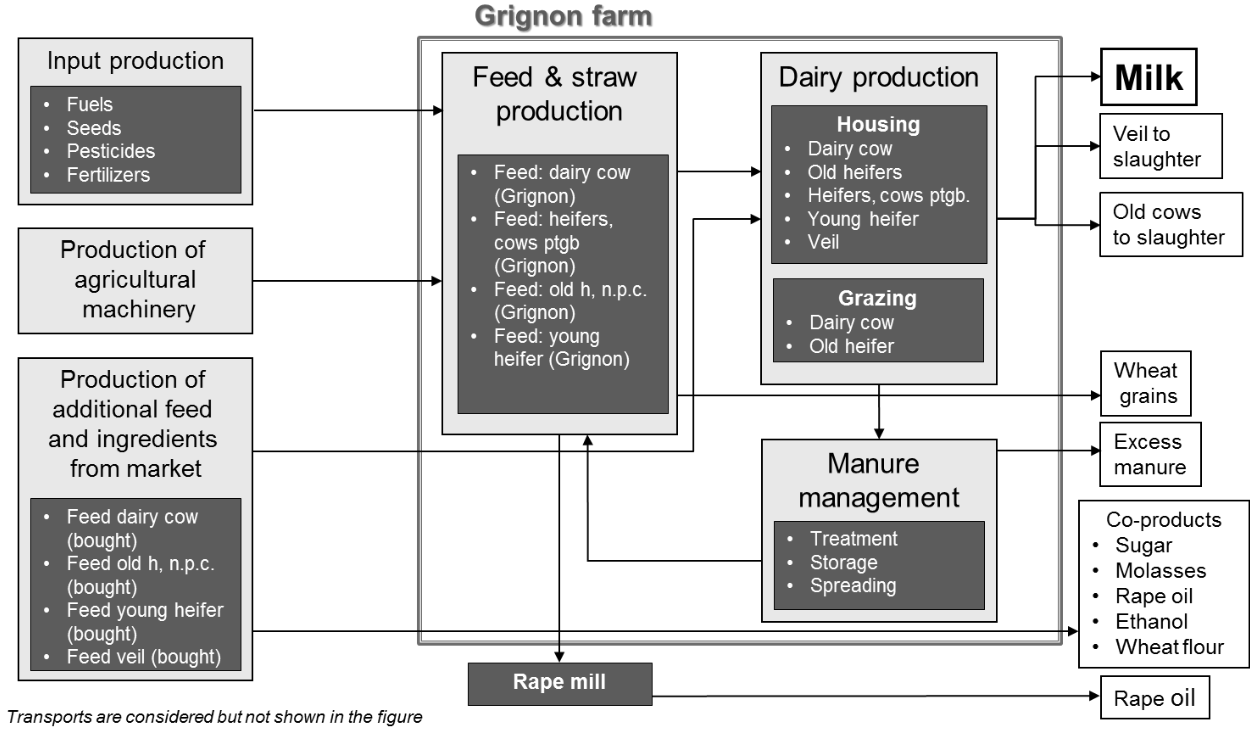

Figure 1. Generic system boundary diagram for current and previous diet.

2.2. Inventory Methods and Assumptions

To achieve the objective of the study attributional life cycle inventory method is used. A consequential LCA was considered to be not necessary for the objectives and intended use of the study, because it is aimed at a retrospective or descriptive comparison of milk production, the system is thus modeled as it was; average or generic data is used. Conclusions of this study do not serve as a basis for long-term policy decision making.

Feed components:

All relevant feed components have been considered, either by collecting data from the Grignon farm, or by consulting relevant databases for appropriate life cycle inventory datasets (see below). Feed components where data was not readily available were neglected when their estimated impact falls below 1% of the total system.

For the feed components which are purchased from an external supplier, life cycle inventory data from the ecoinvent database (version 2.2) was used (ECOINVENT 2007). In a few cases, for example in the case of dehydrated alfalfa and orange skin, an equivalent inventory was not available, and an approximation was taken instead. The datasets for inputs needed to model the production activities at the Grignon farm have all been taken from the ecoinvent database (version 2.2).

Primary data for feed components produced on the Grignon farm, as well as for the dairy cow farming and manure management was collected in a dedicated data collection sheet. The social data for the other processes, i.e., all activities not carried out on the farm, are derived from statistical data for industry sectors (Kölsch et al. 2008). The economic costs are calculated at the production step of the milk, i.e., from the perspective of the farm. Therefore, cost data has only been raised from the Grignon farm; no costs therefore had to be obtained for upstream processes.

The multi-output system 'dairy cows' produces milk, excess veil, dairy cows to slaughtering, and excess manure. Both economic allocation as well as the procedure proposed by International Dairy Federation (IDF 2010) for allocation were tested and lead to identical allocation factor for milk of 87%. To ensure consistency between ecoinvent and Grignon specific feed component datasets the same allocation factors are used. For the following multi-output processes economic allocation was applied (allocation factor to co-products derived from ecoinvent documentation in brackets): Feed components: co-products include rape meal (25.7%), beet pulp (3.8%), distillers grain (2.3%) and straw (7.5%).

Excess manure produced by the livestock and not used within the system (for arable production of fodder crops) was treated as substituting an equivalent amount of N, P_2O_5 and K_2O from a mineral fertilizer production process.

Emissions:

CH_4 emissions from enteric fermentation as well as from manure management are calculated based on IPCC 2006, according to the 'tier 3' approach. N_2O, NH_3 and NO emissions from manure management are calculated based on IPCC 2006, according to the 'tier 2' approach.

Emission factors for direct and indirect field emissions of N_2O and CO_2 are taken from IPCC 2006 (tier 1). CO_2 emissions due to land use change (according to IPCC 2006) are not considered because no production area was converted to arable land in the past 20 years.

Water:

The inventory includes consumption of water over the complete product system. Water used in the cow housing system is considered to be 100% consumptive because this water is either diverted to milk, to slurry and manure or consumed otherwise by the animals. The fraction of water applied to agricultural fields with slurry is considered to be transferred to other watersheds and lost through evapotranspiration. In crop production, all forage crops are non-irrigated. Water consumption in industrial manufacturing of fertilizers was modeled based on the following assumptions: 1% of cooling water is considered consumptive (99% returned to the river), based on actual data of the BASF Ludwigshafen production site. As for the water consumption of other water resources we followed the recent study of De Boer et al 2013; these authors included consumptive water use based on ecoinvent: sea water and turbine water (in-stream use) were excluded from the inventory. All other water sources (lake, river, well, unspecified) were assumed to be consumptive. The results were taken from this study and amount to the following numbers: 4 L per L Diesel, 1.3 L per kWh electricity, 4.6 L per ton of concentrate produced at the feed mill, 0.652 L per ton-km road transport, 0.16 L per ton-km for inland ship transport, 0.029 L per ton-km transoceanic ship transport.

In line with the goals of the present study, which are to compare the sustainability of the feed compositions and the contribution of the feed composition to the overall impact, several parameters were assumed to be identical in both product systems: (i) the same milk productivity is assumed for both product systems (10.475 litres per lactation period); (ii) technical itineraries and yields for crop production are assumed to be identical in both systems; (iii) prices for inputs (e.g. fertilizers, pesticides) were held constant for both systems, to average 2012 prices.

2.3. Life Cycle Impact Assessment Method

The environmental assessment is based on established life-cycle impact assessment (LCIA) mid-point indicators as used also in Eco-Efficiency Analysis (Saling et al. 2002) and a wide range of other LCA approaches. Environmental impact categories are: abiotic resource depletion (Saling et al. 2002), climate change (IPCC 2007), acidification (CML), photochemical ozone creation (CML), fresh water eutrophication (Goedkoop et al. 2013), marine eutrophication (Goedkoop et al. 2013), water use related to water scarcity (Pfister et al. 2009), ecotoxicity (Rosenbaum et al. 2008), land use (EDP; Köllner and Scholz 2007, Köllner and Scholz 2008). Primary energy consumption (Saling et al. 2002) was assessed to meet the farm's objective to measure and reduce energy demand.

Additionally, environmental indicators addressing the specific impacts of agricultural activity on biodiversity in agricultural areas, and on soil health and conservation, have been incorporated into the methodology (see Schoeneboom et al, 2012 and references therein). The potential impact on biodiversity is assessed using eight indicators relating to the state of biodiversity, crop management practice (e.g. crop rotation, ecotoxicity potential of crop protection products, nitrogen surplus) and the environmental policy context (e.g. availability of protected areas or agri-environmental schemes). The impact category of soil health is comprised of indicators assessing soil organic matter balance, soil erosion, soil compaction and the nutrient balances of N, P, K.

In terms of economic assessment, both production costs as well as economic performance are taken into account. Production costs are grouped into variable and fixed costs and quantified using an overall total cost of ownership for the defined functional unit (Kicherer et al. 2007). Economic performance is assessed using indicators for farm profitability as the central criterion for economic sustainability, subsidies which may excert distorting economic effects and productivity as measured as the production value of agricultural goods per hectare weighted by the contribution of the agricultural sector to the national GDP.

The social assessment in AgBalance is derived from the SEEBALANCE method for social LCA, which was developed in 2005 by Universities of Karlsruhe and Jena, the Öko-Institut (Institute for Applied Ecology) Freiburg e.V., and BASF (Schmidt et al. 2005, Kölsch et al. 2008). Based on the UNEP-SETAC guidelines for social LCA of products 5 stakeholder categories were defined: Farmer, consumer, local community, internal community and future generations. The SEEBALANCE indicators and data sources are employed to assess the social impacts of industrial up- and downstream processes. For the agricultural activities in the life cycle, a set of adapted social impact indicators was integrated into the AgBalance method which was designed to match closely the same social sustainability topics addressed in the assessment of the upstream and downstream processes.

3. Results

3.1. Environmental Impact Assessment

The contribution analysis of the environmental impacts below makes use of the following category definitions:

(i) emissions from manure management

(ii) emissions from livestock enteric fermentation

(iii) ancillary input for cow housing: contains among others diesel (production and combustion) needed for supplying and distributing the feed to the cattle on the farm (e.g. extraction of silages from the silo and on farm transports). Furthermore electricity for lighting, pumping of slurry etc. is included. Other materials combined in this category are: consumed blue water, wheat straw for bedding and farm infrastructure (milking parlour and housing system)

(iv) feed production: aggregated impacts due to production of agricultural inputs and field emissions from fodder crop production

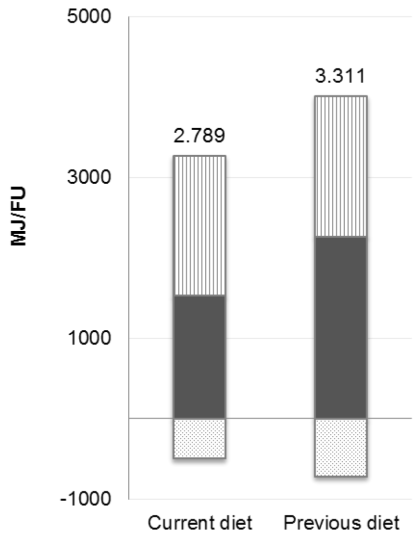
(v) avoided fertilizer production: Excess manure produced by dairy cows and not used within the system (for arable production of fodder crops) was treated as substituting an equivalent amount of N, P_2O_5 and K_2O from mineral fertilizer production processes. This contribution appears as a negative impact in the graphs.

Because the objectives of the farm are to reduce energy consumption and greenhouse gas emissions, we focus on these two impact indicators first.

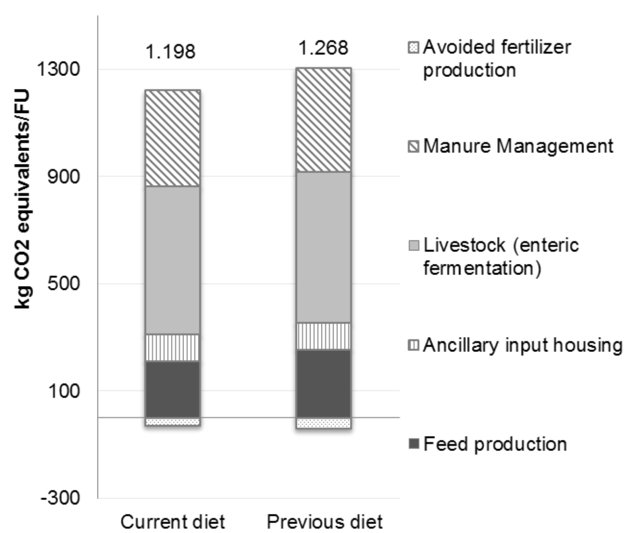
Figure 2 shows the primary energy consumption (excluding biomass feedstock energy for feed) for the current and previous diet calculated excluding biomass feedstock energy in feed. Primary energy consumption of the milk production for 1000 kg FPCM with the current feed mix is 2.8 GJ and 16% reduced in relation to the previous diet. The dominating contributions arise from the diesel and electricity use in housing and the feed production. This in turn is dominated by fuel and mineral fertilizer production and use.

It is noted that the current diet is associated with a higher input of biomass total matter (cf. Table 1), mainly of maize silage from the Grignon farm. If the biomass feedstock energy of the fodder is taken into account (which stems from sun energy), the current diet system exhibits a significantly higher energy consumption of 14 GJ/FU.

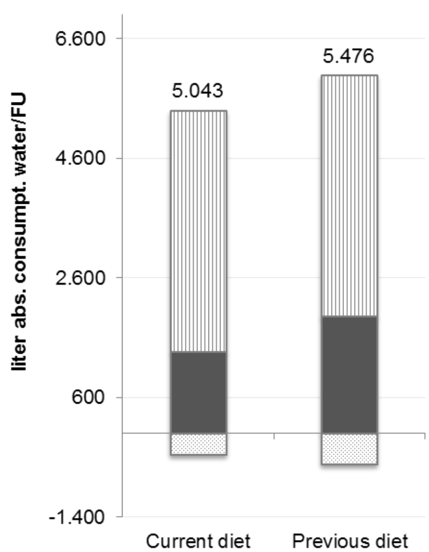
The global warming potential for both systems is shown on the right side of Figure 2. The current diet exhibits a 5.8% lower global warming potential (GWP) compared to the previous diet. The largest contribution to this improvement in GWP of the new diet (i.e., the difference between both systems) comes from the feed production: there is a significantly lower GWP associated with the feed in system ‘current diet’ than in system ‘previous diet’ (current: 214 kg CO_2e/FU, previous: 257 kg CO_2e/FU, 17% reduction). In more detail, this difference from feed production can be attributed particularly to the dairy cow feed. In sum, the GWP attributed to dairy cow feed is reduced from 223 kg CO_2e/FU in system ‘previous diet’ to 175 kg CO_2e/FU in system ‘current diet’. This net reduction in GWP is because of the comparably low GWP impact of the production of the new feed components, particularly those produced on the Grignon farm. An inspection of the corresponding input data of these inventories (not shown here) reveals that in oilseed rape, maize, and hay production at Grignon, mixed organic and mineral fertilization is applied, thus reducing mineral fertilizer use. Furthermore, alfalfa, a leguminous (N-fixing) crop, is grown without any addition of mineral N-fertilizer.



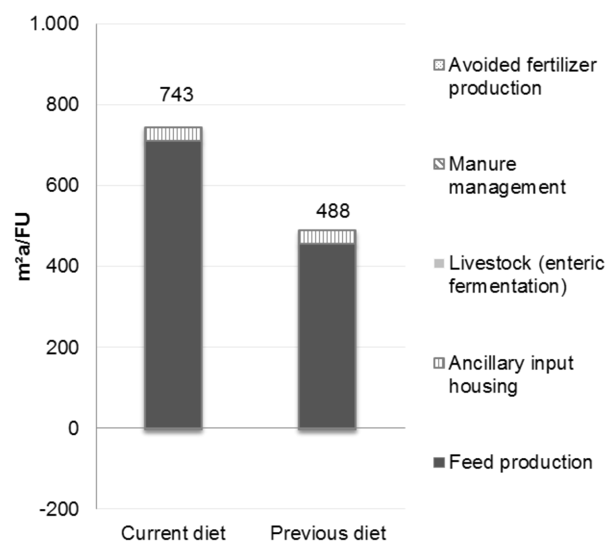
Primary energy consumption excluding biomass feedstock energy of feed



Climate Change impact



Water use impact related to water scarcity



Land use impact (EDP)

Figure 2. Primary energy consumption excluding biomass feedstock energy of feed (left) and climate change impact (right) of the current and previous diet.

The second largest contribution to the reduction in GWP with the current feed is due to changes in methane emissions from manure management. With the 'current diet', older heifers and dairy cows are fed in a mixed housing (liquid/slurry and solid manure storage) and grazing (pasture) system, whereas the 'previous diet' system used exclusively housing (liquid/slurry and solid manure storage). The decisive factor in the present IPCC modeling approach is the 'methane conversion factor' for each manure management system (MCF). This factor is more favorable for pasture, than for solid manure storage, and much more favorable than liquid/slurry storage. In simpler words, the higher the share of pasture in the feed system is, the lower the methane emissions from manure management are.

Analyzing the contribution of each aspect to the total GWP of each system, it is apparent from Figure 2 that livestock emissions of methane from enteric fermentation represent the highest share, followed by methane emissions from manure management. Feed production then itself makes the third largest contribution to the total GWP

Water Use: The impact of water consumption related to freshwater deprivation (water scarcity) is assessed over the cradle-to-gate life cycle of the milk. Forage crop production in the present study does not make use of irrigation; therefore the main contribution comes from the water consumed directly as drinking and cleaning water for the animals. The category 'ancillary input housing' moreover also includes impacts due to use of Diesel fuel and electricity. The impacts of the feed are mostly due to the use of mineral fertilizers. The total volumetric amount of consumptive water per kg of FPCM is 5.0 to 5.5 L in our study; the result of the impact assessment is 1.5 to 1.6 L-eq. per kg FPCM. The amount of water used for drinking / cleaning is 4.0 L in the present system.

The rank order of the two systems appears robust as the "previous diet" product system (with the higher impact) might actually include irrigation in crop production of some feed ingredients purchased from suppliers.

Land Use: System 'current diet' has a 34% higher land use impact compared to system 'previous diet'. Main contributions are due to the use of arable land for feed production at the Grignon farm for the dairy cows as well as the older heifers and non-productive cows (maize -silage and grains-, alfalfa, pasture and oilseed rape). By contrast, sugar beet pulp, which makes up a larger fraction in the previous diet, has a comparably low profile in terms of land occupation. The rather low land occupation of beet pulp is due to being a co-product of sugar production of sugar beet. We applied an allocation factor of 3.8% for beet pulp (91.7% are allocated to sugar and 4.5% to molasses).

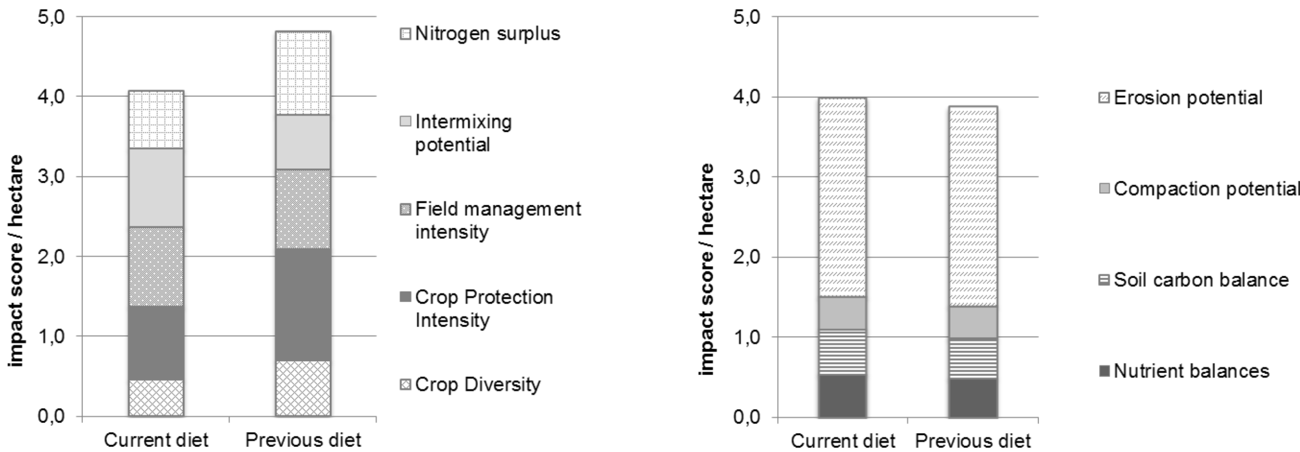
We also assessed other environmental impacts. The results for abiotic resource depletion and marine eutrophication likewise show an improvement for the current diet system relative to the previous diet system. Some other impact indicators show insignificant differences for the two systems, e.g. eco-toxicity potential, acidification potential and photochemical ozone creation potential. The fresh water eutrophication potential shows a worse performance of the current diet system. However, this result is strongly influenced by the contribution from avoided phosphate mineral fertilizer production.

3.2. Farm specific Biodiversity and Soil Assessment

Evaluation of biodiversity and soil indicators was carried out specifically for the agricultural area at the Grignon farm dedicated to the forage crop production (corn, alfalfa, oilseed rape, grassland and pasture, wheat). Wheat is included because wheat straw serves as an input for the cow bed and also as a minor feed component. Other areas, which are not associated with the fodder crops, were not considered.

Biodiversity (figure 3): Except for the indicator intermixing potential, system 'current diet' performs equal or better concerning all indicators. The previous diet performs better concerning the intermixing potential due to the inclusion of oilseed rape as a forage crop. Oilseed rape has a higher intermixing potential with the natural vegetation compared to the other crops. The indicators performing better for the current diet are the nitrogen surplus, the field management intensity, crop protection intensity and crop diversity. The indicator conservation area is determined by location and remains unchanged between both systems (not shown). Agri-environmental schemes were not implemented on the farm.

The evaluation of management indicators related to soil showed only minor differences between both systems.



Biodiversity　　Soil quality and conservation

Figure 3. Weighted impacts on biodiversity in agricultural areas (left) and soil quality and conservation (right) of the current and previous diet on agricultural areas for forage crop production at the Grignon farm.

3.3. Socio-Economic Impact Assessment

In this comparative assessment, the basic socio-economic figures of the farm remained were assumed to remain unchanged, to focus the comparison on the effects of the change in feed composition. The resulting impacts – both positive and negative indicators – attributed to system 'current diet' are generally higher at the Grignon farm, and lower for the farm-external activities. This is related to the higher amount of feedstuff produced on farm in system 'current diet' compared to system 'previous diet', where more feed was bought from the market. Hence Grignon farmers/farm employees, and local community potentially benefit from the new feed system in so far as potentially more labor activities are carried out on the farm itself, meaning that e.g., more wages, employment opportunities, and social security provisions are attributed to the milk production. On the other hand, the need for more land to produce the feed poses additional needs for productive area, with consequences for the land market and potential future restrictions in access to land.

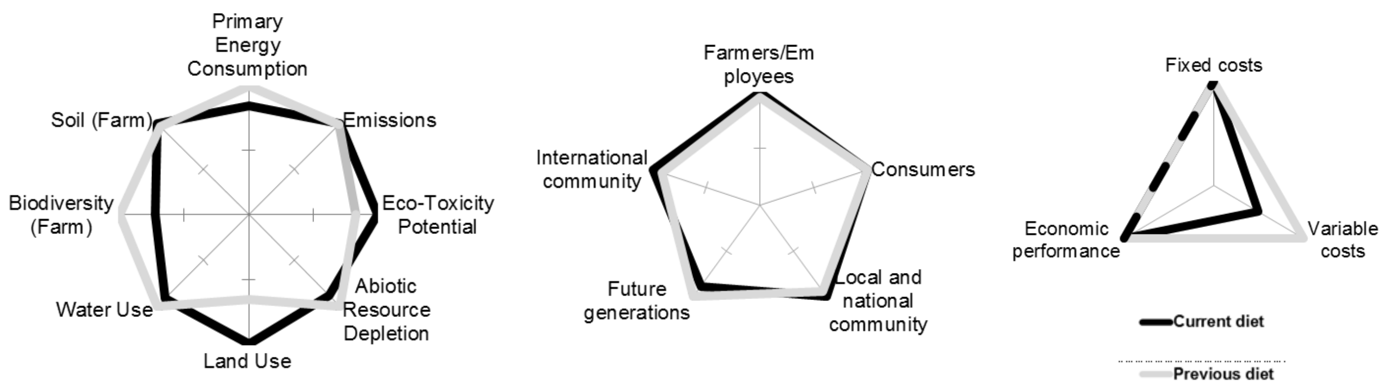
The economic assessment showed that the new feed (current diet) can potentially contribute to cost reductions for the farm. Direct costs to produce the higher amount of feed on the farm in the current diet are lower than the purchasing costs for the substituted components of the previous diet. The overall costs for use of fixed assets and total farm profits are unchanged in the two systems.

3.4. Sensitivity Analysis

Sensitivity analyses on multiple relevant methodological choices (allocation factors, milk productivity, emission factors) showed that allocation factors chosen for by-products (e.g. sugar beet pulp, distillers grain or rape meal), milk-meat allocation factor, milk productivity as well as the methane conversion factor for the manure management system have a significant influence on the absolute indicator results. The absolute deviations in GWP amounted to 20%, the standard deviation is 10%. The relative ranking of the alternative systems is however hardly affected, therefore, the conclusions drawn above remain valid.

3.4. Aggregated Results and Trade-off Analysis

Normalized and aggregated results are shown in Figure 4 to give a concise representation of the individual indicator results discussed in the preceding sections.



Environmental fingerprint | Social fingerprint | Economic fingerprint

Figure 4. Relative results obtained by internal normalization to the highest impact. Smaller figures indicate better performance. Dark line: system 'current diet'; grey line: system 'previous diet'. Social indicators for the stakeholder group 'Consumers' have not been evaluated in the present study.

The environmental fingerprint shows advantages of the new feed composition in the current diet related to a lower cumulative energy demand, abiotic resource depletion and the biodiversity potential of the agricultural area at the farm. The global warming potential is considered as part of the aggregated category emissions, and is lower for the current diet. The category emissions further contains the impact categories: acidification potential (AP), photochemical ozone creation potential (POCP), ozone depletion potential (ODP), and impact on water quality. The previous diet (old feed mix) has advantages related to a lower land use. The difference in eco-toxicity potential falls within the uncertainty of the USEtox impact assessment methodology. The higher impacts from land use in the current diet primarily are due to a higher land occupation on the farm itself. As shown in Figure 3, the biodiversity indicators related to on site management of the production area at the Grignon farm indicate an improvement (indicator 'Specific Impacts on Biodiversity in Agricultural Areas') with the current diet, and therefore the higher land use is balanced by a higher biodiversity potential on the farm area.

The social fingerprint shows that at the level of stakeholder categories, the impacts aggregated over the life-cycle lead to negligible differences between the two alternative systems.

4. Conclusions and Recommendations

The main objective of the farm is to reduce the climate change impacts and energy consumption of its produce. The present results clearly show that this objective was met with the introduction of the new cattle feed (current diet). Dairy cow feed crops produced at the Grignon farm contribute to lower GWP impacts of the current diet. However, the absolute GWP impacts foremost are due to emissions from livestock, which contribute with more than two-thirds to overall emissions. This underlines the relevance of investigating mitigation options of GWP impacts from livestock emissions. Mitigation strategies for CH_4 from enteric fermentation could be based on optimizing the feed mix for higher digestibility and usage of fat sources with reduction potential concerning methanogen bacteria. Regarding the manure management system, storage time and storing conditions (e.g. type of cover, temperature) are important parameters for reducing methane emissions. Furthermore, biogas plants provide excellent options for reduction of these emissions. Gastight covered biogas plants usually emit about 1 % of the CH_4 forming potential. In contrast to this, the liquid manure management system considered in this study leads to emissions in the dimension of 20% of the CH_4 forming potential. Additionally the energy produced by the biogas plant can substitute fossil fuels.

Few trade-offs between environmental consequences of introducing the new feed composition exist. The higher land use associated with the current diet is – at least to same extent – balanced by a higher biodiversity potential on the farm area. This may be further supported on the farm through targeted implementation of agri-environmental schemes, for example, flowering strips. The higher land use in system 'current diet' could also lead to a higher risk for indirect land use change. This has not been considered in the present study due to high uncertainty associated with such evaluations. Nevertheless this could be assessed in a further step for a better understanding of global environmental consequences of the two systems.

ABSTRACT

Assomela, the Italian Association of apple Producers Organizations (POs), has financed the Life Cycle Assessment (LCA) of the average apple produced in Italy. A study was carried out with the aim of providing an EPD certification and understanding the contribution of the different production phases to the carbon (C) footprint. For the cultivation phase data from several farms were sampled taking into account eight geographical areas and four main apple varieties cultivated in Italy. Data about the apples storage, processing, packaging and distribution phases were then collected from the POs. Four impact categories were considered: Global Warming Potential (GWP), Photochemical Ozone Creation Potential (POCP), Acidification Potential (AP) and Eutrophication Potential (AP).Results show that 1 kg of apple, in a cradle to retailer perspective, have a GWP of 0.20 kg CO_2 eq., a POCP of 0.18 g C_2H_4-eq., a AP of 1.12 g SO_2-eq and a EP of 0.62 g PO_4^{3-}-eq. The main contributor of the C footprint during the cultivation phase was the consumption of fuel for machinery, which significantly changed according to the distance from the farm center and the field size.

Keywords: Environmental product declaration, carbon footprint, fuel consumption

1. Introduction

Assomela, the Italian Association of apple Producers' Organizations (POs) representing 80% of the national production, promoted a project for the certification of the environmental impact of apple production in Italy. Assomela brings together VOG (Marlene), VI.P and VOG-Products in the province of Bolzano, Melinda and La Trentina in the province of Trento, COZ and Nord Est in the region Veneto, Melapiù in the region Emilia Romagna, Rivoira and Lagnasco in the region Piemonte and Melavì in the region Lombardia (Table 1).

Table 1. Main characteristics of the Producers' Organization (POs) involved in the study

POs	Head office	Apple production (t year^{-1})	Cultivated land (ha)
La Trentina	Trento	100,000	1,800
Melinda	Cles	330,000	6,500
VI.P	Laces	330,000	5,100
VOG	Terlano	660,000	10,600
Lagnasco	Lagnasco	15,000	348
Melavì	Ponte in Valtellina	26,000	NA
OP NordEst	Verona	15,000	400
Rivoira	Verzuolo	30,000	600

Several varieties are cultivated in the area under study but for the LCA only the main four (that together represent the 76% of the total production) were considered (table 2).

Table 2. Varieties cultivated by the 8 Producers Organizations (POs)

Variety	Percentage on the total production
Golden Delicious	44%
Gala	14%
Red Delicious	11%
Fuji	7%
Granny Smith	5%
Other varieties	19%

Objectives of the study were 1) to assess the environmental impacts of the apple production chain in Italy following the *Product Category Rules* for *Fruits and nuts* of the International EPD System and 2) to characterize the processes occurring during the cultivation phase that most affect the carbon footprint of the main apple variety.

2. Methods

2.1. Functional unit

The functional unit of the study is 1 kg of apples intended for fresh consumption, delivered at the retailer.

2.2. System boundaries

The considered system includes all the activities carried for the agricultural production, the storage, the processing and the distribution. According to the PCR the nursery phase has not been considered since the average orchard duration may exceed 25 years and thus the impacts of this phase can be considered negligible.

The main factors considered for the field phase are the use of oil, water, pesticides and fertilizers (see also table 4).

After the harvest, apples are stored in controlled atmosphere (where they stay in cool chambers at low oxygen concentration), until they are requested by the market. Then they are packed and finally delivered.

The distribution of apples occurs both in Italy and abroad, mainly through land transport by truck even if a small percentage is shipped by sea.

2.3. Treatment of data

The informations presented refer to eight of the ten Producer Organizations associated to Assomela, operating in the regions of Trentino Alto Adige, Piemonte, Lombardia and Veneto. Since the goal of this declaration is to provide information typical of the whole association, the data have been processed in a way that allows to create different averages between the POs participating to the project, using weighting factors based on production volumes. In detail, the average has been organized in three different levels:

- (M1): the average for each variety cultivated by each PO;
- (M2): the overall Assomela average for each variety, calculated by using the single variety production quantity of each PO as weighing element;
- (M3): the overall average for all the apples produced by the POs associated to Assomela.

2.4. Main assumption of the LCA approach in the four production phases

Cultivation

Consumption of water and diesel oil was estimated according to the real consumption of the selected farms. Data on other consumption (fertilizers and pesticides) have been obtained by the production specifications of the areas interested and then validated with specific information.

Data about yields were calculated considering the average age of the trees and the production volume. Data about produced waste were collected by APOT, the fruit and vegetable organization of Trentino. The land use change was not included in the calculation, since almost all the orchards are in the studied areas last for more than 20 years.

The global warming potential caused by the cultivation phase was additionally assessed by considering an average “Golden delicious” apple orchard managed according to the integrated fruit production guidelines of South Tyrol, yielding 62 t ha^{-1} y^{-1} (Mazzetto et al., 2012).

To investigate the role of the farm structure on the carbon footprint of apples, simulations about fuel consumption in scenarios with different field sizes and field distances from the farm center were carried out. A farm with a total surface of 3.9 ha, entirely cultivated with apple trees, representative of many farms in Trentino Alto-Adige, was selected as model for the simulations. The total farm surface was split into 15 fields with an average size of 0.26 ha and a distance from the farm center ranging from 200 to 1200 m.

Processing

In this phase electric energy consumptions, water consumption and waste production both for processing and for storage have been considered.

Data were collected from a sample of plants.

Packaging

The presented data refer to the selling apples considering the use of 1 plastic bag for 1 kg of apples.

Distribution

The impacts referred to the transportation phase have been calculated considering an average transport of 850 km by truck and 250 km by ship, which takes into account the Italian and European markets, as well as smaller amounts distributed overseas, in the Asian and North African markets.

3. Results and discussion

The main results of the LCA approach are shown in Table 3 and Figure 2.

Table 3. Environmental impacts of the apple production chain in the four considered impact categories. Data are referred to 1 kg of apples commercialized in a plastic bag.

Potential impact	**Cultivation**	**Processing**	**Packaging production**	**Transportation**	**Total**	
Global Warming Potential	0.04	0.06	0.01	0.09	0.20	kg CO_2 eq
Photochemical Ozone Creation Potential	0.06	0.02	0.03	0.07	0.18	g C_2H_4
Acidification Potential	0.31	0.22	0.04	0.55	1.12	g SO_2 eq
Eutrophication Potential	0.41	0.08	0.01	0.12	0.62	g PO_4-eq

Transportation had the highest impact on the Global Warming Potential, followed by processing, cultivation and packaging production (Figure 1).

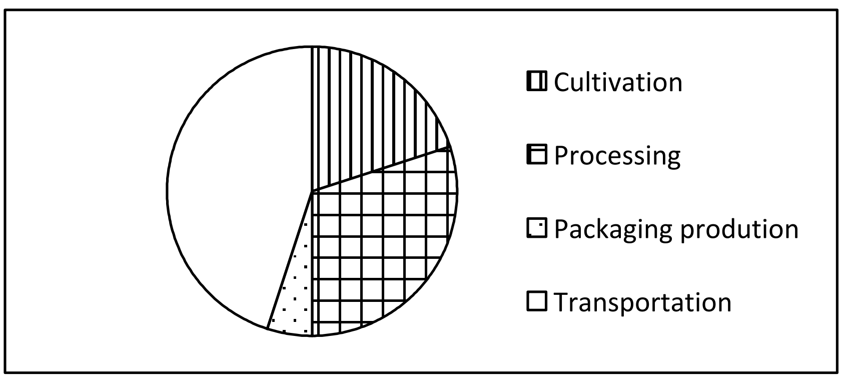

Figure 1. Contribution of the different production phases to the Global Warming Potential impact category.

Transportation has a high GWP because it occurs mainly by trucks. Transport by sea or railway could be a solution to decrease these emissions (Blanke and Burdik, 2005). Processing has also a high relevance because in this phase cool storage is included and it is a process that requires a significant amount of electric energy.

Cultivation is the third contributor in terms of GWP. The main impacts in this phase are due to the amount of diesel for machinery and to production and use of fertilizers (table 4)

Table 4. Carbon footprint of the Golden delicious apple during the cultivation (cradle to gate) phase (data from Mazzetto et al., 2012).

Source of emission		CO_2 emissions (GWP)	
		kg CO_2 eq kg^{-1}	%
Infrastructure	Buildings	0.002	4
	Machinery	0.013	25
	Planting scaffold	0.001	2
	Irrigating system	0.007	14
	Plant material	0.001	2
Annual management	Fertilizers	0.006	12
	Herbicides	0.002	4
	Pesticides	0.003	6
	Labour	0.001	2
	Fuel	0.015	29
TOTAL		0.051	100

As reported by Zanotelli et al.(2014), the total value of C footprint for the cultivation phase of apple is relatively low when compared with other fruit cultivation (data expressed in MJ kg^{-1} of primary energy use) also due to the high yields reached by modern apple orchard that allow a good use efficiency of external resources. Fuel consumption resulted to be among the most important impact factors also in apple produced in other countries, and in other fruit production chain like olive and grape (Zanotelli et al., 2014).

The sensitivity analysis carried out for the cultivation phase with the analytical approach, quantifies the linear increase of fuel consumption observed by increasing the distance of the fields from the farm center (Table 5). The consumption due to the machines transfer can reach 50% of the total when the fields (with an average size of 0.26 ha) are located at more than 1500 m from the farm (Tab 5). The simulation reported in table 5 has been carried out considering an average apple production of 60 t ha^{-1}.

Table 5. Simulation of changes in fuel consumption for machinery (as total yearly amount and as % due to the transfer of machinery) due to the increasing distance of the apple orchard from the farm-center.

Distance farm center -field	Fuel consumption	% of fuel consumption due to the transfer of machinery
m	kg ha^{-1}	%
200	294	10
500	341	26
1000	426	36
1500	503	45
2000	581	52
4000	906	67

A second simulation aimed to assess the variation in fuel consumption when the apple fields, 1000 m far from the farm center and yielding 60 t ha^{-1} of apples, varies their size from 0.26 to 8 ha. Results show that there is a sharp decline in fuel consumption at increasing field size (Tab. 6).

Table 6. Simulation of changes in fuel consumption for machinery (as total yearly amount and as % due to the transfer of machinery) due to the increasing size of the fields. An average yield production of 60 t ha^{-1} and a distance of the fields to the farm center of 1000 m was considered in the sensitivity analysis.

Field surface	Fuel consumption	% of fuel consumption due to the transfer of machinery
ha	kg ha^{-1}	%
0.25	426	36
0.5	358	30
1	306	23
2	277	19
4	261	17
8	254	17

4. Conclusions

Considering the difficulties in performing an LCA study at a country level, especially due to the adoption of a good sampling strategy, we believe that the approach used in this study reconciles feasibility of data collection and statistical significance.

The carbon footprint of the whole apple production chain is dominated by the emission occurring in the transport phase from the storehouse to the final market. The use of more efficient transportation means with respect to truck should be explored in the future.

The good level of apple yield per hectare reached by modern orchard (approx. 60 t ha^{-1}) indicated a good use efficiency of external resources which is reflected in a relatively low C footprint of the apple cultivation phase (0.04 - 0.05 kg CO_2-eq). Anyway a better farm organization in terms of field distance from the farm center and average field size could further diminish the current C footprint value.

This analysis contributed to increase the awareness of environmental impacts of apple production and constitute a scientific basis for improving the sustainability of the whole apple production chain.

ABSTRACT
Labeling is an important tool for consumer's perception of sustainability and quality of a product. Focusing on measuring the impact of sustainability labeling (seal and/or indication of Organic, Origin and Quality, and Sustainable Agriculture) in purchase intention and quality perception of products labeled by the quality and sustainability criteria, this study aimed to investigate dark chocolate (pack-1 kg) with six different percentage of cocoa, with and without such labeling. A blind test was carried out in the first evaluation session, in which the samples 1, 2 and 6 were better accepted by consumers. In the second session, all judges were able to see the percentage of cocoa and the label of each sample, and the chocolates 1 and 2 obtained the highest acceptance scores. It is possible to conclude that labeling had a positive impact on purchase intention and quality perception of dark chocolates.

Keywords: Sensory analysis, Purchase intention, Dark chocolate, Labeling, Sustainability

1. Introduction

Cacao cultivation is an important agricultural activity in areas of hot-humid climates. In 2009/2010, according to the International Cocoa Organization (ICCO, 2010), Brazil was the sixth largest producer of cocoa in the world and occupied the fifth position on processing cocoa for obtaining the main derivatives used the chocolate industry (liquor / cocoa mass and cocoa butter).

Brazil is the third largest producer of chocolate in the world; in 2012 the chocolate production has increased by 3.1% over 2011, with 732 000 tons. The country remains the fourth largest consumer of chocolate in the whole world, with per capita consumption of 2.2 kg per year, showing an optimistic scenario for the coming years, since three years ago this number corresponded to 1.65 kg. According to a balance sheet released by the Brazilian Association of the Chocolate, Cocoa, Peanut, Candy and Derivatives (ABICAB), there was also an increase in apparent consumption of 3.7%, with 717 000 tons (ABICAB, 2014).

These data evidence the economic and social importance of cacao cultivation. Brazil is the only country with the complete production chain, with a significant production, cacao processing, and high consumption of chocolates.

The sectors of cocoa cultivation and chocolate production have developed several projects related to sustainability around the world. Two certifications have focused on sustainability in the development of cocoa / chocolate: as organic chocolate and products with designation of origin, for example with Rainforest Alliance Certified seal. In Europe and in the United States, there is an increase in the organic sector, thus companies have been establishing some guidelines for its manufacture. According to the Organic Trade Association, consumers buy organic products not only for their nutritional benefits, but also to avoid the consumption of pesticides and additives, in addition to maintaining the environment and promote sustainability. This customer profile is very concerned about the social and environmental aspects of food, and possibly will keep brand loyalty if the product provides positive social and environmental impacts, despite the costs may be higher. Origin cocoa is a trend in the chocolate segment, since the characteristics of each region, such as climate and soil conditions influence the cocoa quality and can provide good results on cocoa liquor and chocolate flavor. As with wine and coffee, the place of origin of cocoa production is taken into account due to the different flavor notes peculiar to the region or farm that cultivates the fruit. In addition, proper farming, environmentally correct handling and processing allow obtaining better quality products, which also promotes sustainable regional development. The concept of origin cocoa considers not only the place of production, but also the environmentally management, with a focus on fruit quality and social concern for producers (SADAHIRA, 2010).

The role project aims to apply the Ecodesign (ISO/TR 14062, 2002) methodology in the production chain of cocoa in Brazil. The objective is evaluate the impact of sustainability labeling to contribute for the development of chocolates with focus on sustainability, in a Brazilian industry that export to over 30 countries and is one of the topping leading manufacturers in Latin America (HARALD, 2014). In the scope of the project are chocolates with high cocoa content (>50%), business-to-business packs (>1kg), from "cradle to grave" LCA (ISO 14040, 2006; ISO 14044, 2006) (cocoa and sugar producer, packing, chocolate manufacturing and consumption). A research data collection at supermarkets identified two kinds of certification focused on sustainability in the development of cocoa/chocolate: certification of agricultural practices as organic cocoa and cocoa with designation of origin (without any seal or with Rainforest Alliance seal). The chocolates were produced and sensory evaluated by 126 consumers without restriction of age or sex.

This paper, a part of Ecodesign Project, aims to characterize by sensory analysis the profile of Brazilian consumers as the impact of labels and certification of organic, origin and quality or sustainable agriculture (Rainforest) on the acceptance and purchase intention of chocolates.

2. Methods

2.1. Manufacturing process

A research data collection was carried out at different supermarkets in the city of Campinas-SP to identify the organic chocolates and those with designation of origin or with Rainforest Alliance Certified Seal, from national manufacturers. Then, six dark chocolates containing different percentages of cocoa were selected for molding and demolding steps (Table 1).

Table 1: Chocolate samples selected in the Brazilian market, with label or indication of organic, with designation of origin and quality or with Rainforest Alliance Certified seal.

Samples (Chocolates)					
1*	2*	3*	4*	5**	6**
53% Origin and *Rainforest*	63% Origin and Quality	70% Organic from Amazon	75% Organic from Bahia	70% cocoa	45% Dark

Samples 1: 53% origin cocoa and with Rainforest Alliance Certified seal; 2: 63% origin cocoa with quality indication "*Salon du Chocolat* Award Winner"; 3: 70% organic cocoa from Amazon-Brazil; 4: 75% organic cocoa from Bahia-Brazil; 5: 70% cocoa; 6: 45% dark chocolate; *seal and/or indication of Organic, Origin and Quality or Sustainable Agriculture (*Rainforest*); ** without seal and/or indication of Organic, Origin and Quality, or Sustainable Agriculture.

The six chocolate samples were melted and submitted to tempering, molding, cooling and packaging. Then, the samples were melted in a microwave and subjected to the tempering step performed manually on a marble table. The chocolate mass was warmed to 50 ± 1.0 ° C and then cooled to 29 ± 1.0 ° C under constant movement at a rate of 2 °C / min. The pre-crystallization was monitored by a temper meter considering the tempering index between 4.0 and 6.0. The chocolate was dispensed manually into preheated polypropylene rectangle-shaped molds. Then, the molds were subjected to vibration to remove air bubbles, and the samples were cooled in cooling tunnel. The chocolates were demolded, packaged in aluminum foil and stored in a chamber at 18 °C.

2.2. Sensory Analysis

The impact of labeling on the acceptance and purchase intention of consumers was carried out with 126 consumers of dark chocolate, in the Sensory Analysis Lab, Department of Food Technology (DTA / FEA/UNICAMP) and Laboratory of Sensory Analysis of Cereal & Chocolate Research Center (Food Technology Institute - ITAL). The chocolates were evaluated by consumer acceptance test with consumers of dark chocolate (STONE & SIDEL, 2004).

The sensory evaluation of chocolates was performed according to a randomized complete block design, with no restrictions on age, gender and social class. The test was divided into two sessions, with a blind test performed in the first session, without revealing the origin or the certification seals.

In the second session, after the blind test, the assessors were informed about Organic and *Rainforest* seals, certificates of origin, and then the origin and/or certification of each chocolate sample was revealed, followed by the purchase intention and sensory acceptance analysis.

In both sessions, the samples were evaluated for the attributes aroma and chocolate flavor, chocolate melting in the mouth, bitterness, acidity, hardness or force required to break the chocolate, and overall impression, through a 9-point scale anchored as follows: 9 "like extremely"; 8 "liked"; 7 "liked moderately"; 6 "liked slightly"; 5 "neither liked nor disliked"; 4 "dislike somewhat"; 3 "dislike moderately"; 2 "dislike very much"; and 1 "dislike extremely". The purchase intent was assessed using a 5-point scale: 1 "definitely would buy"; 2 "probably buy"; 3 "I doubt if I would buy"; 4 "probably would not buy"; and 5 " definitely would not buy." The data were subjected to analysis of variance (ANOVA) and means were compared by Tukey's test at 5% significance level.

3. Results

Table 2 presents the results of the blind acceptance test in the first session with 126 consumers.

Table 2. Blind acceptance test of six different samples

Chocolate samples	Attributes						
	Flavor	Bitterness	Acidity	Aroma	Hardness	Melting	Overall impression
1 53% Origin and *Rainforest*	6.64 a	5.97 a	5.38 ab	5.98 a	6.12 ab	6.71 a	6.65 a
2 63% Origin and Quality	6.38 ab	5.86 a	4.96 ab	6.12 a	6.06 ab	6.39 ab	6.21 ab
3 70% Organic from Amazon	5.88 bc	5.89 a	4.75 b	6.22 a	6.07 ab	5.95 b	5.73 bc
4 75% Organic from Bahia	2.96 d	3.87 b	2.93 c	4.79 b	5.14 c	4.75 d	2.87 d
5 70% cocoa	5.53 c	5.24 a	5.12 ab	6.11 a	5.66 bc	5.36 c	5.60 c
6 45% Dark	6.15 abc	5.27 a	5.58 a	6.01 a	6.28 a	6.54 a	6.32 ab

Averages in the same column followed by the same letter are not significantly different by Tukey test ($p \geq 0.05$).

Although the sample 1 was more accepted by consumers, with a mean score lying in the category "moderately liked" for the attribute overall impression, it was not significant ($p \leq 0.05$) different from the samples 2 and 6, with a mean score lying in "slightly liked ".

With respect to the attribute chocolate flavor, sample 1 had the highest acceptance score in the category "moderately like", but did not differ ($p \leq 0.05$) from the samples 2 and 6, with a mean score lying in "slightly liked".

Concerning the bitter taste, despite the samples 1, 3, and 2 had the highest scores in the category "slightly liked", it did not differ statistically from the samples 5 and 6, which scored in "neither liked nor disliked".

As the attribute acidity, sample 6 was the most widely accepted, lying in the category " slightly liked ", but did not differ at a significance level of 5% from the samples 1, 2 and 5 that scored in "neither liked nor disliked".

The low acceptance of the sample 4 when compared to the other samples is mainly due to the attributes flavor, bitterness, acidity, aroma and melting which have received lower mean scores and influenced the overall impression. The results also indicate that Brazilian consumers enjoy chocolate containing low levels of cocoa than chocolates with high cocoa content.

Table 3 presents the purchase intention in the blind test.

Table 3. Purchase intention of chocolates in the blind test.

Purchase intention	Samples (blind test)					
	1 53% Origin and *Rainforest*	2 63% Origin and Quality	3 70% Organic from Amazon	4 75% Organic from Bahia	5 70% cocoa	6 45% Dark
Definitely would buy	41.27%	36.51%	26.19%	3.97%	26.19%	39.68%
Probably buy	42.06%	36.51%	25.40%	3.97%	28.57%	29.37%
I doubt if I would buy	9.52%	16.67%	29.37%	13.49%	22.22%	19.84%
Probably would not buy	5.56%	8.73%	12.70%	34.92%	18.25%	7.14%
Definitely would not buy	1.59%	1.59%	6.35%	43.65%	4.76%	3.97%

In general, samples 1, 2 and 6 had the highest scores in the purchase intention test. In contrast, sample 4 had the highest scores in the category "certainly would not buy", with over 40% intentions, demonstrating that the flavor has influenced purchase intention in the blind test.

Table 4 shows the results of the acceptance test after the information of the samples with or without labeling.

Table 4. Acceptance test of the samples with or without labeling

Samples	Attributes (with or without labeling)						
	Flavor	Bitterness	Acidity	Aroma	Hardness	Melting	Overall impression
1 53% Origin and *Rainforest*	7.01 a	6.37 a	5.62 a	6.55 ab	6.41 a	6.84 a	6.87 a
2 63% Origin and quality	6.85 ab	6.27 a	5.56 a	6.67 a	6.49 a	6.75 ab	6.90 a
3 70% Organic from Amazon	6.13 c	6.03 ab	4.84 b	6.37 abc	6.26 ab	6.30 b	6.11 bc
4 75% Organic from Bahia	3.20 d	3.96 c	3.02 c	5.01 d	5.32 c	5.02 d	3.03 d
5 70% cocoa	5.71 c	5.53 b	5.34 ab	6.09 bc	5.80 bc	5.60 c	5.60 c
6 45% Dark	6.30 bc	5.50 b	5.65 a	5.94 c	6.40 a	6.55 ab	6.28 b

Averages in the same column followed by the same letter are not significantly different by Tukey test ($p \geq 0.05$).

In the second session, the samples containing the seals were presented to the assessors. Both samples 2 and 1 were the most accepted by consumers, with a mean score lying in "like moderately" for the overall impression, with no significant differences at 5% level.

The blind test showed that chocolate 1, 2, and 6 were the most accepted for the majority of the attributes. However, in the second session where the assessors knew the cocoa content and the seals of each sample, samples 2 and 1 were the most accepted and received higher scores than those in the blind test, showing that the labeling with seals had an impact on the overall acceptance of chocolates.

For the attribute flavor, the sample 1 had the highest score lying in the category "like moderately", followed by the sample 2 with a mean score also in the category "like moderately".

Samples 1, 2 and 3 had the highest scores for the attribute bitter taste in the category "liked slightly", and differed statistically from the samples 5 and 6.

Again, the sample 4 was less accepted by consumers for flavor, bitterness, acidity, aroma and melting attributes at a significance level of 5%, with a mean score on the overall impression lying in the category "dislike moderately".

Even after the information of the organic seal, the chocolate 4 remained less accepted than the other chocolates, demonstrating that the taste was the most important factor for consumers.

As shown in Table 4, after the revelation of the seals, the acceptance scores increased for samples 1, 2 and 3. The sample 2 contained an origin cocoa with quality flavor indication, as twice winning the award for best chocolate flavor at the *Salon du Chocolat* in Paris, France. The sample 1 contained the sustainable agriculture *Rainforest* seal, and the sample 3 contained the declaration of organic cocoa from Amazon-Brazil.

It is verified in the second session that the samples were separated into groups, once the samples 2 and 1 received the highest acceptance scores for almost all attributes, and did not differ at a 5% significance level. On the other hand, samples 3, 5 and 6 formed the second group receiving the highest acceptance scores, and did not differ at a significance level of 5% for the attributes evaluated.

In general, it is possible to say that the labeling influenced the sensory acceptance of chocolates after the second session, when the assessors knew the percentage of cocoa and the seals of each sample. Samples 1, 2 and 3 received the highest scores from one test to another, and no changes were observed for the sample 5, evidencing the positive impact of labeling.

Table 5 presents the results of consumer purchase intent after the information about labeling of chocolates.

Table 5. Purchase intention in the second session after information about labeling.

Purchase intention	Samples					
	1 53% Origin *Rainforest*	2 63% Origin and quality	3 70% Organic from Amazon	4 75% Organic from Bahia	5 70% cocoa	6 45% Dark
Definitely would buy	51.6%	50.0%	29.4%	6.3%	24.6%	42.9%
Probably buy	36.5%	33.3%	35.7%	7.1%	34.1	27.0%
I doubt if I would buy	9.5%	12.7%	19.0%	18.3%	20.6%	19.8%
Probably would not buy	2.4%	3.2%	11.9%	26.2%	14.3%	7.9%
Definitely would not buy	0.0%	0.8%	4.0%	42.1%	6.3%	2.4%

Again, the chocolate 1, when compared with the blind test, obtained the largest percentage of purchase intention with 51.6%, followed by samples 2 and 6.

It is noticed that after revealing the information of the samples to consumers, the positive effect on purchase intention increased and the negative effect decreased, except for the sample 5. Regarding the sample 4, the uncertainty regarding the purchase intention increased, thus showing the seal and / or indications may have impacts on the sensory acceptance and purchase intention by consumers.

4. Discussion

Johansson et al. (1999) found an impact of labeling on the form of production (conventional and organic) in the sensory preference of tomato consumers. After informing about the cultivation techniques, the authors observed that the labeled organic samples increased the preference scores, but that information was less important when the tomatoes were sweeter and had more intense taste when compared with those grown ecologically and presenting high acid taste.

Levin and Gaeth (1988) studied the effect of labeling on the perception of four sensory attributes of meat. The judges were informed that a sample contained "75% lean ground beef" and the other contained "25% fat ground beef". Although both samples contained the same fat content, information was passed differently for the judges. The results showed that the 75% lean beef was evaluated as low fat with better quality than the sample labeled 25% fat beef.

In this study, it was observed that the labeling had an impact on the consumer acceptance and purchase intention, once those samples containing quality seals presented the highest sensory scores when compared with those chocolates without such labels.

5. Conclusion

It was possible to observe that the consumer's behavior changed when quality and sustainability labels have been informed, since the sensory acceptance and purchase intention increased for the samples containing the seals. Moreover, it appears that the sensory attributes were also important for Brazilian consumers, once among the samples with seals, the chocolates with lower cocoa content were more accepted in both sessions.

The authors would like to thank Fapesp (12/24472-6) for the financial support, CNPq for the PIBIC scholarship, and Harald Food Commerce and Industry for the partnership.

ABSTRACT

To describe a more sustainable food sector, a supply chain approach is needed. Changing supply chains inevitably means that a range of attributes of the product and its system will change. This project will take on this challenge and deliver detailed descriptions of supply chains of six commodities from a Swedish region in 2012; Milk, cheese, beef, pork, chicken and bread. The set-up of the project was that experts on production along the supply chain design environmentally improved systems. The next step was to challenge the improvements considering their possible consequences on products and systems from different perspectives: food safety, sensory qualities, animal welfare, and consumer appreciation and (only for primary production) costs. The final supply chains were quantified by life cycle assessment (LCA), and they were again assessed from the perspectives mentioned above. Results will be generated during August 2014 and comprise both single-product LCA and region-wide impacts of the future scenarios.

Keywords: Sustainable food chains, Food system scenarios

1. Introduction

To design a more sustainable food production we need to look at the whole supply chain, from the primary production and its inputs, to the consumers. This is obvious for the LCA community and is being embraced by a growing part of the society. LCA research and case studies are critical for understanding the impact profile of products and systems. Most studies aiming at proposing and analyzing food production systems with improved sustainability performance use an aggregated approach for identifying improvement potentials in different steps of the life cycle, where improvement potentials are based on general assumptions on possibilities in each step separately. This is a useful approach to identify and quantify the possibilities and may work as a "semi back-casting exercise" as it provides a more realistic future state that can be used as a starting point for focusing research and development on how to implement improvements. However, such an approach is less valuable for practical information on relevant actions needed by food chain actors (farmers, industry, retailers, consumers and various public decision-makers).

To move LCA research closer to more hands-on decision making, novel approaches are needed. In order to design environmentally improved supply chains on a more detailed level than what is usually accomplished by LCA there is a need for new working methods that combine the systems perspective from LCA with deeper and more detailed knowledge about production systems.

Another extremely important aspect of food systems is the broad range of food related aspects, such as food safety, food quality and animal welfare. Consumer reactions are also critical when new solutions for the food supply chain are introduced. Furthermore, overall economic viability is a condition to be met. Changing food supply chains inevitably means that a range of these attributes of the product and its system will change, and neglecting this in studies will seriously hamper the interest from stakeholders and delay or stop necessary improvements in environmental performance.

The aim of the whole project was to present solutions for specific food supply chains with improved sustainability performance that are realistic and concrete enough for food chain stakeholders to use in their decision-making. The focus is on improved production in a short-term perspective; whereas changes in consumption patterns are beyond the scope of the project. A second aim was to develop and apply an integrated working process involving different disciplines and synthesizing their knowledge.

The objectives are to:

- define present and detailed descriptions of supply chains of six commodities from the county Västra Götaland in Sweden in 2012; Milk, cheese, beef, pork, chicken and bread
- describe future scenarios for these supply chains, producing the same amount of commodity as in 2012, where the environmental performance is improved while important attributes mentioned above (e.g. product safety and quality) are improved or kept at present levels
- quantify the environmental impact of these supply chains and compare them with the present situation as reference using LCA
- quantify the costs in primary production for scenarios and the reference, based on present cost levels.

This paper describes parts of the project, namely the supply chain for smoked, sliced ham, which includes animal production, feed production, industrial processing, packaging and distribution. Description will be presented to highlight the processes as well as solutions. During early autumn 2014 these solutions will be evaluated by LCA and presented at the conference.

2. Methods

The set-up of the project was that experts on production along the supply chain (agronomists, animal scientists, food engineers, packaging and supply chain management experts) designed a reference production system (in the following text referred to as "reference"), reflecting the present system. Three environmentally improved systems for each product chain were developed by the experts using literature and their own expertise combined with expertise on environmental impact of food supply chains. The close cooperation between different food chain experts and also with experts representing different "attributes" (food safety, animal welfare, food quality etc.) ensured overall improved supply chains, so called solution scenarios. To avoid trade-offs between environmental impacts within a particular system, the solution scenarios were designed in three versions in order to improve the performance of three "goal scenarios", corresponding to clusters of usually compatible environmental objectives for Swedish conditions. Finally the solution scenarios for the supply chains will be quantified using LCA and cost calculations (only agriculture). The general working process is described in Figure 1.

The time frame for implementation of improvements was five to ten years, so it basically meant gathering available knowledge to functioning supply chains. The primary production part included the entire animal- and/or crop production system within the specified region (beef, dairy, pig, chicken and bread grain production) while beyond primary production and primary processing (slaughter, milling) specific products were studied (smoked ham, frozen chicken fillets, sirloin steak, aged cheese, drinking milk and bread). The reason for limiting the later stages of the chain to just one single product is the existence of a huge diversity of products in later stages; a farmer delivers one product, the slaughter pig, while the meat processor delivers hundreds of products through a number of distribution channels. Of course the farming system is very complex, with numerous inputs and connections between parts, but the products are much fewer so it is possible to follow the total flow. This approach means that we will deliver LCA results for the entire primary production for the region studied, but only case study results for the chain beyond primary production. The retail and consumption stage is not included; the system boundary is set at the retail intake. The products were selected using criteria such as market volume and potential challenges to one or more attributes.

The approach also included interactions between the different agricultural systems. Hence, the crop production part of the chains, where each production system produced an important part of the feed required, and the manure management, with the intention to use the manure at the farm, functioned as the common space for this interaction. Feed can be, and often is, produced and traded between different farms. The total need for feed, quantified by animal nutrition experts aiming at high production efficiency and low environmental impact from feed raw materials corresponding to the different "goal scenarios", decided the design of crop rotations at the different types of farms. As a starting point, possible rations were assessed using emission factors from a feed database developed at SIK. In addition, wheat for bread production was also to be produced by the farm, in particular by specialized crop farms. Through discussions, the feed ration formulations were adjusted to better facilitate improvements in crop production, including manure management, in order to find compromises between optimal feeding and optimal crop production systems. Throughout the process the work was guided by food LCA experts that supported in decision-making, ensured the collection of relevant data in an appropriate format and facilitated discussions between expert groups.

The next step was to challenge the improvements considering their possible consequences on products and systems from different perspectives: food safety, sensory qualities, animal welfare, and consumer appreciation and costs for primary production. All scenarios were assessed, mainly qualitatively, and modified using an iterative process in order to take all perspectives into account at the same time in the final supply chains.

The finalized supply chains will be quantified by LCA and by cost calculations for primary production part of the chain. Furthermore, they will be assessed for possible consequences mentioned above.

The functional units for the primary production were the total production volumes for year 2012, one kg of product at farm gate, and, for the post-farm stage, one kg of packed product of the specific type chosen at the point of reception at retail. Results will be generated during Q3 and Q4 2014 and comprise both single-product LCA and region-wide environmental impacts and resource use for the future scenarios.

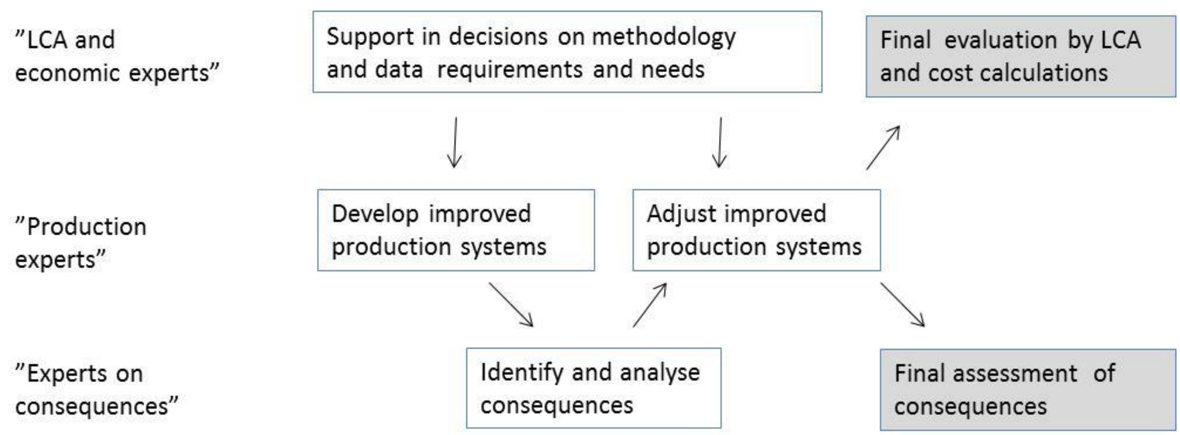

Figure 1. Principal description of the working process in the project, shaded boxes are not included in this article

3. Results

3.1. Goal scenarios

First, the generally most critical environmental impacts were identified using literature (Rockström et al., 2009, SEPA, 2013 (Sweden’s official environmental goals)). The next step was to “match” these environmental impacts with the full list of impact categories in LCA as defined in ReCiPe (Goodkoep et al., 2009) and identify impact categories where food production has an important role. This was made using published LCA and normalization. Based on this a priority list of impact categories was developed, where the highest priority was given to impacts where food systems have a large impact and the impact itself were identified as globally and nationally important (Table 1).

Table 1. List of Mid-point impact categories in ReCiPe, priority based on 1) global importance of category and 2) how important food systems are to total impacts (project internal assessment).

Impact category	Priority	Activity in the food sector contributing to the specific impact category
Marine eutrophication	1	Nitrogen turnover, use of phosphorous
Freshwater eutrophication	1	Nitrogen turnover, use of phosphorous, organic matter from soil
Freshwater ecotoxicity	1	Pesticides, Nitrogen turnover use of phosphorous, antibiotics, detergents in agriculture and industry
Biodiversity	1	Pesticides, agricultural practices general, crop rotations, management, Nitrogen turnover, use of phosphorous
Climate Change	1	Energy use, transports, nitrogen turnover, manure management, ruminants, soil, carbon flows, deforestation, refrigerants
Agricultural land occupation	1	Feed use, yields for crops
Minerals consumption	1	Use of phosphorous and sulphur, Metals used in machinery and equipment
Terrestrial acidification	1-2	Nitrogen turnover and manure (NH_3), transports, energy use, fertilizers
Terrestrial ecotoxicity	2	Pesticides, heavy metals e.g. in fertilizers
Natural land transformation	2	Feed use, yields for crops
Fossil fuel consumption	2	Production of chemical fertilizers, transports, energy use
Water consumption	2	Irrigation, cleaning (agriculture, industry)
Ozone depletion	2	Refrigerants, N_2O from nitrogen turnover
Human toxicity	2	Heavy metals, pesticides, antibiotics and natural toxins in foods
Photo-Chem. ozone formation	2	Transports, energy use, methane (from manure and ruminants)
Particulates	2-3	Transports, energy use
Urban land occupation	3	Infrastructure for industrial production, distribution and retail
Marine ecotoxicity	3	
Radiation	3	Electricity use (nuclear power)

A grouping was made where impact categories corresponding to environmental objectives that rarely are in conflict with each other were put in the same group. This was based on previous studies and experiences of food LCA. Furthermore impact categories corresponding to potentially conflicting goals were put in different groups (based on a large number of LCA studies). This resulted in three goal scenarios, presented in Table 2. The goal scenarios were then used as “compasses” for the development of the solution scenarios. Several measures were applicable in more than one solution scenario, but this kind of overlap is not a flaw to the method since they are accounted for only once in each solution scenario. The use of goal scenarios was a support for making decisions in cases there were measures that would lead to conflicts between environmental goals but still were interesting for one of the goals. For the post-farm chain it became evident that most improvement measures fell into scenario three. Hence only one solution scenario per product was developed for this part of the supply chain.

Table 2. Goal scenarios developed in the project

Goal scenario	Impact categories that will be addressed in solution scenarios	Examples of measures and connections to the production system
1. Reduced local impact on ecosystems. Maintain and develop ecosystems	• Eutrophication • Biodiversity • Eco-toxicological impact • Land use	Crop rotations, plant protection, management and utilization of bio-diverse semi-natural pastures, manure management, plant nutrient supply, local field management, feed rations
2. Optimize plant nutrient use and supply	• Eutrophication • Acidification • Use of minerals (phosphorous) • Land use	Manure management, plant nutrient supply, crop yields, feed rations
3. Reduced climate impact	• Climate change • Use of fossil fuels • Land use (less land use give space for e.g. bioenergy production).	Energy use, plant nutrient supply (e.g. use of recirculated nutrients), transports, manure management, feed rations, crop yields

3.2. Solution scenarios

Using the goal scenarios above, solutions for each part of the supply chain were developed, so called solution scenarios. For pig production, the most important aspects are feed efficiency, feed composition, production efficiency and manure management. For the post-farm chain the possible improvements are smaller, but include less wastage in industry and distribution, reduced energy use and shifting to bioenergy. Also optimized transports can be of interest. In the project all details are described and quantified, but due to space limitations we only present the most prominent changes for each scenario. Below, the solution scenarios for the pork supply chain are presented, using the reference scenario as a basis. We should keep in mind that solutions should be possible to implement within a ten year time frame, which limits the possibilities to include more drastic changes.

3.2.1. Solution scenarios for the animal production system

Results for the animal production part of the pork chain are presented in Table 3. As can be seen in Table 3 there are many similarities between the three solution scenarios (for other agricultural products there are more differences between scenarios). This is a result of that there are no conflicts between the goal scenarios in this particular part of the production system. The only main difference between scenarios is the feed composition. In all scenarios the basis is grains (wheat, barley, and oats). In the reference scenario the protein feed is mainly soy bean meal and some rape seed meal, in Scenario 1 the protein feed consists of rape seed meal and faba beans. Scenario 2 uses mainly rapeseed meal and some soy bean meal and in Scenario 3 faba beans is the main protein feed, complemented with some rape seed meal. In all three solutions scenarios the use of synthetic amino acid is increased.

A factor that is not changed from the reference is the housing, which is a conventional indoor production with partly slatted floor for fattening pigs and lactating sows, and deep litter bedding for dry sows. Alternative systems as e.g. keeping the animals outdoor might have advantages for some goal scenario, but the short time frame for implementation disqualified such a solution. Also the pig's breed is assumed to be the same in all scenarios.

As explained in the "Methods" section, the description of future scenarios was done by production experts in collaboration with experts on animal welfare, product safety, product quality and economy; hence the solutions scenarios are realistic and based on literature and expert judgments.

Table 3. Solution scenarios for the primary pig production for the reference scenario and the three different goal scenarios developed in the project

	Reference – situation of year 2012	**Scenarios 1,2 and 3**
Surviving piglets per sow and year	23.8	30
Recruitment sows (% replaced annually)	52.5	46
Mortality fattening pigs (30-115 kg live weight), %	1.8	1.2
Carcass meat percentage slaughtered pigs	58.2	60.2
Feed intake sow (incl. recruitment), kg/year	1619	1649
Feed intake, kg per piglet (up to 30 kg/animal)	43	39
Feed intake, kg per fattening pig (30-115 kg live weight)	238	209
Total feed use in the region Västra Götaland (ktons/year)	160	135
Manure management, dry sows	Deep litter	Deep litter
Manure management lactating sows	Slurry, partly slatted floor	Slurry, partly slatted floor
Manure management fattening pigs	Slurry, partly slatted floor	Slurry, partly slatted floor

Since the functional unit in this case was production volumes of pig meat in the region studied, Västra Götaland, for the year 2012, the following changes and consequences were introduced in the animal production in all the solution scenarios;

1. More piglets per sow and lower recruitment of sows lead to lower number of sows needed.
2. Higher meat percentage lead to fewer fattening pigs for the same total meat volume, hence less sows and piglets are needed.
3. Less feed use per fattening pig and more piglets per sow with just a small increase in sow feed leads to a reduced overall feed need.
4. Lower mortality of pig lead to lower number of sows needed.
5. Less nitrogen and phosphorous in manure due to higher feed efficiency (use of synthetic amino acids and phytase for increased phosphorous uptake)

Together, these changes lead to a significantly reduced need for feed, hence arable land, and less plant nutrients in the manure. This gives consequences for the crop production part of the system (below), and is also reduced resource use as such.

3.2.2. Solution scenarios for the feed crop production

The crop production system is connected to all animal production systems in the project (dairy, poultry, beef and pork) as well as to the bread production. Crop production farms produce feed crops that will be used for all animal types, and animal farms can produce a surplus of feed crops to be used at other farms. Our approach was to define type farms for the different production systems; dairy, beef, pork, poultry and crop farming. In the region studied, there are two main types of production areas; plains district with large fields and intensive agriculture, and forest district with smaller and scattered fields and more extensive farming. As a reflection of todays' situation, we assumed the poultry, pork and crop production farming take place in the intensively farmed region, beef production in the more extensive region and dairy in both.

Below, only results for farms producing feed for pigs as well as pigs are presented, a selection made due to space limitations. Actually, some pig feed raw materials come from crop producing farms or is being imported to the region. The main measures in crop production concern crop rotations and use of manure and other plant nutrient supply. Use of pesticides is important for solution scenario 1, as well as farm management options to support biodiversity, such as elements that break up monotonous landscapes, e.g. hedges. Generally, varied crop rotations, with leys and other non-cereal crops, give possibilities to reduce the need for plant protection and facilitate mechanical weeding, as well as reduce the need for mineral fertilizers. Catch crops are introduced as much as possible to reduce nutrient losses and clover/grass ley for green manure. In solution scenarios 2 and 3 the same crop rotation is applied, as well as farm management and plant protection. The reason is that efficient nutrient management and reduced climate impact demand similar solutions. In Table 4 the results for the feed crop production part of the pork chain are presented.

Table 4. Solution scenarios (combination of crop rotation and management measures) for the feed crop production on pig producing farms for the three different goal scenarios developed in the project.

	Reference – situation of year 2012	**Scenario 1 - Reduced local impact on ecosystems**	**Scenario 2 - Optimize plant nutrient use and supply**	**Scenario 3 - Reduced climate impact**

3.2.3. Solution scenarios for manure management

Manure management identified solutions for housing, storage and treatment as well as optimizing manure use in crop rotations. In the reference scenario manure was stored in lagoons covered with a natural crust and spread on grain crops. Scenario 1 had essentially the same handling system as the reference and changed only spreading application rates. Ammonia and greenhouse gas emissions were drastically reduced in Scenario 2 with a housing ventilation filtering system, a tightly covered roof over the storage lagoon, and by acidifying the slurry during spreading. Solutions for scenario 3 centered on anaerobic digestion of manure to produce biogas; which in turn increased the amount of plant available nitrogen and decreased losses to the environment. Furthermore, digestate was acidified to avoid methane and ammonia losses during storage and spreading. For manure application, solution scenarios were restricted to equal crop demands, although scenario 1 and 3 were allowed to apply phosphorus in buffer doses for the next year’s crops. Timing of application was also identified as a feasible measure to reduce losses and was included in the solution scenarios.

3.2.4. Solution scenarios for the post-farm supply chain

This part of the supply chain was divided in four parts; processing, transport and distribution, packaging and by-product management. Some measures needed to be coordinated in order to avoid sub-optimization. One overlapping aspect is the wastage along the supply chain, where all parts contribute, and where actions taken in one part affects wastage at other parts. The issue of wastage is addressed separately. For the post-farm supply chain, few improvement measures involved conflicts between goal scenarios; hence one solution scenario was developed. The only exception was for byproduct management, where different solutions met goal scenario 2 and 3.

For processing it was concluded that major improvements on energy use often requires new investments and possibly new ways of producing. Considering the short time frame applied in the project we focused on incremental changes. The energy savings for the actual slaughter and meat processing was considered to be in the range 20-30% as a food industry average.

For transport and distribution two end-points were included, one large supermarket in a large city and one small grocery shop in a small rural town. The present system is relatively well optimized; hence there were limited improvements for the logistics. However, some minor improvements as fuel efficient trucks and fuel efficient driving were identified which lead to fuel savings in the order of 5%. It is also possible to use biodiesel to reduce greenhouse gas emissions.

For the packaging it was necessary to consider both the function of the packaging (to protect the product to maintain quality and also avoid wastage), how space-efficient the packaged product is in the distribution and finally the environmental impact of the packaging material itself (including waste management). In the reference scenario the smoked and sliced ham was packed in a plastic tray and modified atmosphere was used, 70% nitrogen and 30% oxygen). The pack size was 180 g. In the solution scenario a wallet packaging is used instead, using the same modified atmosphere. The gain is reduced volume per kg product while maintaining the shelf life. This facilitates higher transport efficiency and less use of secondary packaging.

Wastage of raw materials as well as finished products constitutes a large share of post-farm environmental impacts. The causes of wastage are often interconnected with processing, distribution, storage and packaging. On average, 3% of products are lost in the Swedish food industry (excluding retail and households), but variations are large, between companies but also within the same company (Lindbom et al., 2013). The flow of information from retailers to producers is not sufficient and the time before products go out of date is short. This, in combination with less flexible production units within industry lead to overproduction and large storage in industry in order to avoid lack of products when the order comes (empty shelves at the supermarket is not accepted, neither by retailers, nor consumers). Moreover, the food supply chain is a “push-system” in a short time frame, meaning that the primary production cannot adjust its production volumes on short notice; the pigs are growing regardless if there is a demand for pork products the coming week, which adds on to the complexity. Based on a detailed analysis of possible measures to reduce wastage in the food industry (Lindbom et al., 2013) we assume that the wastage can be reduced by 50%, from the present level of 3%.

Food processing generates large volumes of by-products, especially meat processing. Out of a live pig, only around 35% of the live weight of the slaughtered pig ends up as meat and processed meat products (the “Carcass meat percentage” mentioned in table 3 includes bones etc., hence the difference). The possibilities for using these large flows are restricted by the European Directive of Animal Byproducts (European Commission, 2002) laying down health rules concerning animal by-products not intended for human consumption), focusing entirely on safety issues. In the directive animal by-products are classified in three groups: high risk, medium risk and low risk. High risk waste accounts for around 2% of total by-products from pig slaughter, medium risk waste for 13% and low risk waste the remaining 85%. The high risk by-product is presently treated by incineration, and no changes are possible. The medium risk by-product is presently mainly treated as high risk by-products, but a small share is anaerobically digested without recirculation of residues to farmland. Due to regulations and certification systems in Sweden this will not be changed in the solution scenarios. For the low risk by-product, solution scenario 2 and 3 assumes anaerobic digestion and use of residual slurry as fertilizer on farmland.

3.3. Analyses of consequences of solution scenarios

Since the project works with hypothetical systems it was not possible to use experimentally based methods, so the analyses of consequences were theoretical studies based on available knowledge and also mainly of qualitative nature. The consequences included in this part of the project were; product safety (microbiological), animal welfare and product sensory qualities. Throughout the project the design of the solution scenarios were scrutinized by consequence analyses experts, who gave advice how to avoid problems. Finally a short report for each area of consequence was compiled.

For product sensory quality, the impact of a number of aspects was assessed; feed, breed and possible castration of male pigs, stress during live animal transports, reception and waiting at the slaughterhouse and killing were assessed. For the pig meat, impacts of processing, recipes, packaging and distribution were included. Findings included that a change to medical castration instead of surgical will lead to less risk of boar taint and lower fat content, which is considered positive for the sensory quality.

The microbiological food safety was approached using HACCP (Hazard Analysis Critical Control Point) for the identification of critical points and corrective measures, and predictive modeling for calculation of bacterial concentrations along processing and storage. Six processing lines for pork and smoked, sliced ham were evaluated: ordinary slaughter and deboning of pork, automated slaughter, cold deboning, hot deboning, and processing and storage of smoked ham. Some critical changes were found between the reference scenario and the solution scenarios. The identified effects on microbial safety and quality can be controlled by applying relevant control measures. The optimization of heat processing must be related to the microbial quality of the raw material and the extent and likelihood of post processing contamination.

As animal housing did not change much between scenarios, the animal health and welfare was not judged to be much affected in the solution scenarios compared to the reference. However, one thing was that less straw was used for dry sows in all solution scenarios, which might have a negative impact on animal welfare. This can be managed by better knowledge among animal keepers, if straw is used more strategically, as it has been shown in studies.

The cost for primary production is obviously an important consequence of changed production systems. The cost aspect has been included in discussions on choices of farm sizes, animal husbandry systems (e.g. no outdoor production of pigs), possible feeds to use and crop rotations (these need to deliver decent yields over the cycle). In the next phase of the project (Q3-4 2014), costs for primary production will be quantified along with LCA calculations.

4. Discussion

The overall approach in the project, integrating expert competence from various fields of food and agricultural sciences, was extremely beneficial in terms of developing the solution scenarios. By combining expertise on production systems with LCA competence, detailed production systems that maintained the systems perspective of LCA could be designed. The involvement of experts on consequences on products and systems added very valuable insights in how the design affected e.g. food safety and animal welfare, and what measures could be suggested without jeopardizing these critical constraints. The broad competences also enhance our credibility among stakeholders, since the project group as a whole really understands the limitations of and possibilities for food production in a broad sense. Working in such an integrated and synthesizing manner is a novel approach, and it brought about needs for new ways of working and interacting between researchers in different fields. Efficient communication and organization of the project proved to be most important, together with mindset of individuals in the project group.

Not many critical consequences were identified, partly due to the short time horizon that was applied in the project, but also to the close interaction between researchers that eliminated questionable solutions at an early stage. If the time horizon had been longer, hence open up for more radical changes, the role of consequence assessments would have been prominent.

The ambition was to avoid value-based choices in the project. This was partly accomplished by the structured method, including the definition of goal scenarios and the iterative working process. However, it is impossible to be fully objective - some choices need to be made. One example is the presumption that improved production efficiency is favorable for all goal scenarios, which was based on experience from a number of previous LCA studies and also on the fact that globally arable land is a limited resource and that increased productivity is crucial for global food security. However, this presumption could still be contested. Our assertion on full transparency on all choices made throughout the project will not resolve this issue, but will facilitate fruitful discussions about the results.

The trade-off between “reasonable” solutions and optimized ones is also an issue. On the one hand, stakeholder-relevance in the short term calls for known solutions, but on the other hand, substantial improvements often call for more radical changes. This balance is provided by open-minded thinking on radical changes while maintaining a sound realism.

Finally, a broad approach generally implies new challenges to researchers and to project management. With a large number of highly qualified experts, each with limited overview over the entire project, project goals in each sub-project were vital. For the success of the project it was critical to maintain focus and interest among all project members. Therefore, during the more intensive parts of the project, frequent but short meetings between each sub-group and the project management were scheduled in order to keep up the pace and make the information flow efficiently and, not the least important, in both directions.

5. Conclusion

- The working approach applied in the project was successful in integrating LCA research with food system production expertise in order to deliver results that are relevant to decision makers in the supply chain.
- The consequence assessments brought large value to the project, guiding the design of solution scenarios efficiently and preventing solutions that are unrealistic and counterproductive. Examples are a low yield milk system that was abandoned due to poor competitiveness, and reduced cooling at slaughter, that was left out for product safety reasons. The consequence assessment also gave the results higher credibility among stakeholders in the supply chain.
- The issue of value-based choices is important and needs to be managed and communicated in a transparent way.
- Working multi-disciplinary in such an integrated way puts large demands on project management and communication skills.

ABSTRACT

This study aims to incorporate a life cycle assessment (LCA) technique with multi-objective linear programming (MOLP) into practice through a case study of a rice packaging system in Thailand. The flexible packaging system chosen for the study is a CPP/LLDPE (cast polypropylene/linear low density polyethylene) bag of rice. The incorporated model is intended to determine an optimal usage of raw materials for rice package manufacturing. The decisions were as the consequence of minimization of two trade-off objectives: total cost and global warming potential. The results gained from this study show that the developed model could be used as a decision-support tool to yield a solution that is a compromise between cost and environmental considerations based on the manufacturer's preference and constraints. The optimal value of total cost and global warming potential are $US 6012.23 (equivalent to 192391.34 THB; $US 1 = 32 THB) and 2791 kg CO_2 eq, respectively. To this end, the slight improvement of lowering total cost and decreasing global warming potential at 0.1% and 1.5%, respectively, is below their typical values incurred in actual production.

Keywords: flexible packaging, total cost, global warming potential, life cycle assessment, multi-objective linear programming

1. Introduction

The basic functions of food packaging are not only to contain the food and provide consumers with information on ingredient and nutrition, but also to protect and preserve food products from outside influences and damages. Presently, there are many innovative packaging materials that are used for food products. However, plastic has gained more attention as the most common packaging material. This is because plastics can have various forms and applications, such as films and sheets, bags, pouches, and bottles. Plastics in flexible form are inexpensive and light-weight with a wide range of characteristics, including flexibility, heat sealability, and ease of print, and can be integrated into production processes where the package is formed, filled and sealed in the same production line (Marsh and Bugusu 2007). More than 90% of flexible packaging is made of plastics, compared to only 17% of rigid packaging (Raheem 2012). In Thailand, demand on the flexible packaging industry is expected to grow in response to the continuous expansion of the food industry, as flexible packaging is increasingly used to replace rigid packaging (Plastics Institute of Thailand 2012).

The environmental impact of packaging has become an important issue of society. This is due to a drastic accumulation of packaging waste becoming a major disturbance for life today. Directives and regulations for packaging wastes have been intensively enacted in an attempt to alleviate the environmental problems and thus inevitably being barred in many countries. As a result, manufacturers have gone on a quest for a good packaging solution for their products. One plausible action contrived on a technological development and innovation movement purposely depleted resource consumption but conversely elevated pollutants in the environment. Also, subduing environmental problems with this innovation may subsequently cause manufacturers relevant costs to increase and that can hurt business competition and profit achievement as a whole. This conflict of interest lead to manufacturer difficulties in decision making where simultaneous goals of economic and environmental aspects are being taken into account and the best alternative is not yet clearly determined (Pieragostini et al. 2011).

Life cycle assessment (LCA) is a technique used for identifying and quantifying the environmental performance of a product or process throughout its life cycle (cradle-to-grave) (Azapagic and Clift 1999). Several studies have employed LCA as a tool for determining appropriate packaging used in different applications. These include a comparative study on environmental impact generated by retort sterilization for glass jars, over the aseptic process for plastic containers (Humbert et al. 2009), and an environmental analysis of the entire life cycle of coffee and butter packed in flexible packaging systems (Büsser et al. 2009). Others are an evaluation of environmental impact of packaging systems for canned tuna meat (Poovarodom et al. 2011); a comparative study on environmental impact of strawberry packaging systems: bio-based polylactic acid (PLA) and petroleum-based polyethylene terephthalate (PET) and polystyrene (PS) clamshell containers (Madival et al. 2009). In addition, the single use thermoform boxes made from PS, PLA and PLA/starch was also studied (Suwanmanee et al. 2012).

Normally, the relationship between inventory data and impact category indicators of LCA methodology is linearly expressed by characterization factors, as follows:

$$E_j = \sum_i Q_{ij} m_i \qquad \text{Eq. 1}$$

where E_j is the indicator for impact category j; m_i is the quantity of emission pollutants i; Q_{ij} is the characterization factor that links emission pollutants i to impact category j (Pennington et al. 2004). However, this technique is based on unconstrained human economic activities, such as market demand, material availability and production capacities (Azapagic and Clift 1998). Therefore, the lack of information on economic effect is a major shortcoming of LCA.

As mentioned, decision-making incorporating environmental consciousness with economic cost for packaging solutions should be considered. An appropriate solution, comprising both environmental and economic aspects, in a packaging system can lead to manufacturer satisfaction. The objective of this study is to present the developed model incorporating life cycle assessment (LCA) technique and multi-objective linear programming (MOLP) for a rice packaging system in Thailand as a case study, aimed at combining two objectives: low total cost and decreased global warming potential.

Linear programming (LP) is based on a linear relationship subject to constraint models. This technique is usually used for solving economic problems and is formulated as follows:

$$Min\ Z = \sum_{j=1}^{J} c_j x_j \qquad \text{Eq. 2}$$

$$s.t. \sum_{j=1}^{J} a_{ij} x_j = or \geq or \leq b_i \qquad \mathrm{i = 1, 2, \ldots, I} \qquad \text{Eq. 3}$$

$$and\ x_j \geq 0 \qquad \mathrm{j = 1, 2, \ldots, J} \qquad \text{Eq. 4}$$

where Eq. 2 represents an objective function and Eq. 3-4 are linear equality or inequality constraints in the system. The objective function Z is a value of overall measure of performance (e.g. total cost); variable x_j is a level of activity j; coefficients c_j are the constant values of performance resulting from activity j; coefficient a_{ij} is the amount of resource i consumed by each unit of activity j; coefficient b_i is the right hand side or limitation of resource i that is available for allocation to activities (Azapagic and Clift 1998; Hillier and Lieberman 2001).

Multi-objective linear programming (MOLP) is the LP problem involving multiple objective functions. Thus, MOLP allows the problem where more than one optimization criteria needs to be satisfied (Ragsdale 2007).

2. Methods

2.1. LCA model

The goal of this study is to develop a multi-objective linear programming (MOLP) model by incorporating a life cycle assessment (LCA) technique. Optimality the use of raw materials for rice package manufacturing is determined as a decision considering variables that are the consequence of a trade-off between two objectives. Minimization of total cost for production and minimization of global warming potential are considered two such objectives.

The model system boundary (as shown in Figure 1) involves the acquisition of raw materials, transportation of raw materials and manufacture of the packaging (cradle-to-gate). In addition, packaging materials, including paper core, oriented polypropylene (OPP) tape and polyethylene (PE) film wrap that are required for packing processes are included in the study.

The flexible packaging system chosen for this study is a multi-layer of cast polypropylene/linear low density polyethylene (CPP/LLDPE) bag of rice. A 5 kg package size is used due to it being the most common size of rice products in Thailand. Finished packaging is in the form of bags on a roll (as shown in Figure 2) where the package can be formed, filled and sealed in the same automatic machine. Thus the functional unit is specified as 12,000 m of bags on a roll (a minimum quantity of production).

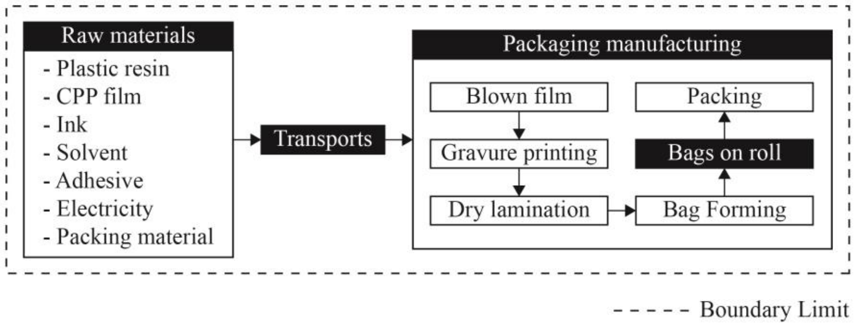

Figure 1. System boundary of the MOLP model.

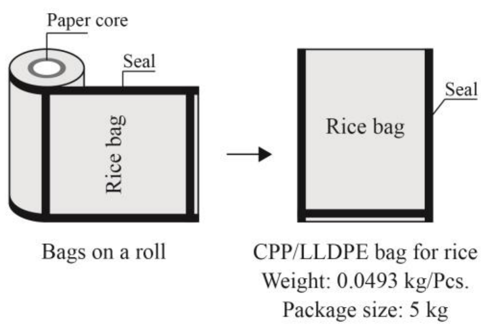

Figure 2. Feature of bags on a roll.

LCA is the most widely acceptable method to assess the environmental impact of a product or process throughout its life span, from cradle-to-gate or cradle-to-grave (Suwanmanee et al. 2012). This study is carried out using life cycle methodology in compliance with ISO 14040 (2006): Environmental management - life cycle assessment - principles and framework.

Life cycle inventory (LCI) data of CPP/LLDPE rice bags was collected from packaging manufacturers. Primary data of input materials, energy consumption, output products, as well as waste generated were collected for each main activity in the production line. The production process includes film blowing, printing, laminating, bag forming and packing. The transportation distance, including vehicle type, for the raw materials is provided (as shown in Table 1). In this study, an assumption on one-way transportation with 100% loading is made for the delivery of raw materials to the packaging manufacturer.

Table 1. Transportation data of raw materials for packaging production

Raw material	Vehicle type	Distance (km)
Plastic resin type A-D	Truck (6 wheels)	130
Plastic resin type E	Truck (6 wheels)	40
Printing cylinder	Truck (4 wheels)	100
CPP film	Truck (6 wheels)	110
CMYK ink	Truck (6 wheels)	100
Other ink	Truck (4 wheels)	50
Solvent	Truck (6 wheels)	50
Adhesive	Truck (4 wheels)	80
Paper core	Truck (4 wheels)	20
OPP tape	Truck (4 wheels)	50
PE film wrap	Truck (4 wheels)	20

Impact assessment is an important phase in LCA framework (ISO 14040 2006) for evaluating the significance of potential environmental impact based on the results of LCI. In this study, impact category of global warming potential (GWP) is chosen as it is relevant to the environmentally important emissions from the production of flexible packaging. The life cycle impact assessment was performed using the CML 2 Baseline 2000 method. Secondary data for emission factor was obtained from the supplier, Thai national LCI database (Thailand Greenhouse Gas Management Organization 2013) and peer-reviewed literature - namely, emission factor of printing cylinder (Ponnak 2011).

In this study, manufacturing cost is classified into four categories: direct raw material cost, direct labor cost, overhead cost and transportation cost. Primary data of direct raw materials cost, machine capability and overhead cost - for example, indirect raw material, indirect labor, depreciation of machine and building, electricity, and others, are approximated and provided by the packaging manufacturer. Direct labor cost is based on the secondary data of minimum wage (Ministry of Labor 2013) and the primary data of number of laborers in each activity of the production line and was obtained from the packaging manufacturer. In addition, secondary data of transportation cost was obtained from the database of cost for freight truck (Department of Land Transport 2009).

A number of constraints can be defined according to LCI as well as specification data of each activity in the production line. First, mass balance is carried out to define the mass balance constraints. This step is normally done in the LCI phase. Second, raw material usage for the CPP/LLDPE rice bags in each activity is limited in compliance with the production capability and performance. Therefore, these constraints can be defined as either equality or inequality. Lastly, the output products in each activity are limited by the functional unit of this study.

2.2. MOLP model

The MOLP model is incorporated with the life cycle assessment (LCA) technique to enable a workable combination of two objectives: minimized total cost for production and minimized global warming potential. The main steps to develop the MOLP model are (Ragsdale 2007)

- Implementing the MOLP model;
- Determining target value for the objectives;
- Determining weighted percentage deviation for the objectives;
- Defining the MINIMAX objective;
- Implementing the revised model and solving.

From the collected data, as discussed in section 2.1, the mathematical model of this study can be formulated as the following.

The raw material usage in each activity of the production line is defined as a decision variable, where the variable x_{ij} represents the quantity of raw material type i in activity j (kg or rolls); i = 1, 2, …, I and j = 1, 2, …, J (as shown in Table 2). In addition, the maximum of weight percentage deviation from target values (Q) is defined as the additional decision variable.

Table 2. List of raw material and activity.

j	Activity	x_{ij}	Raw material
1	Film blowing	x_{11}	Plastic resin type A
		x_{21}	Plastic resin type B
		x_{31}	Plastic resin type C
		x_{41}	Plastic resin type D
		x_{51}	Plastic resin type E
2	Printing	x_{12}	Printing cylinder
		x_{22}	CPP film
		x_{32}	CMYK ink
		x_{42}	Other ink
		x_{52}	Solvent type A
		x_{62}	Solvent type B
		x_{72}	Solvent type C
3	Laminating	x_{13}	Adhesive component A
		x_{23}	Adhesive component B
		x_{33}	Solvent type C
4	Bag forming	x_{14}	Paper core
		x_{24}	OPP tape
5	Packing	x_{15}	PE film wrap

Two objective functions, including minimized total cost and minimized global warming potential can be formulated as follows:

$$Min\ Z_1 = \sum_{j=1}^{J} c_{ij} x_{ij} \quad \text{Eq. 5}$$

$$Min\ Z_2 = \sum_{j=1}^{J} e_{ij} x_{ij} \quad \text{Eq. 6}$$

where Z_1 is the optimal value of minimized total cost ($US); c_{ij} is the unit cost of raw material ($US/kg), labor ($US/hr) or overhead ($US/hr) resulting from raw material type i in activity j; Z_2 is the optimal value of minimized global warming potential (kg CO_2 eq); e_{ij} is the emission factor of raw material (kg CO_2 eq/kg), electricity (kg CO_2 eq/kWh) or transportation (kg CO_2 eq/ton.km) resulting from raw material type i in activity j. However, it is important to note that these objective functions are subsequently are transformed according to the additional constraints of weighted percentage deviation from target values. Thus the MINIMAX objective function will be defined as a new objective function of MOLP model:

$$Min\ Q \quad \text{Eq. 7}$$

$$w_1 \left(\frac{Z_1 - t_1}{t_1} \right) \leq Q \quad \text{Eq. 8}$$

$$w_2 \left(\frac{Z_2 - t_2}{t_2} \right) \leq Q \quad \text{Eq. 9}$$

where Eq. 7 represents an objective function and Eq. 8-9 are additional constraints of weighted percentage deviation from target values. Q is the maximum of weight percentage deviation from target values; the target value t_1 is the optimal value of minimized total cost obtained in single-objective optimization ($US); w_1 is importance weight of minimized total cost; the target value t_2 is the optimal value of minimized global warming potential that is obtained in a single-objective optimization (kg CO_2 eq); and w_2 is importance weight of minimized global warming potential. The weight factors are based on the manufacturer satisfaction. First, weighting factors equal to one are used to yield the same importance of minimized total cost and minimized global warming potential. Later, different relative relevance is considered by adjusting these factors (Pieragostini et al. 2011). In this case, the weight of importance of minimized total cost and minimized global warming potential are defined as 4.6 and 2.4, respectively.

The constraints maintain the mass balance in each activity of the production line. Thus, the sum of all input raw materials must be equal to the total output products, as follows:

$$\left(\sum_{j=1}^{J} x_{ij} \right) - b_j = 0 \quad \text{Eq. 10}$$

where b_j is the output products from activity j (kg).

This constraint maintains the performance of output products in each activity of the production line. The limitations of raw material usage are defined as equality and inequality constraints, as follows:

$$x_{ij} \geq a_{ij} \left(\sum_{j-1}^{J} x_{ij} \right) \quad \text{Eq. 11}$$

$$x_{ij} = d_{ij} \quad \text{Eq. 12}$$

An inequality constraint of raw materials that can be optimized by the MOLP model is expressed in Eq. 11. An equality constraint of printing cylinder, CPP film and packing materials that cannot be optimized by the MOLP model are expressed in Eq.12. In addition, a_{ij} is the minimum percentage of raw material type i in activity j (%), and d_{ij} is the constant quantity of raw material type i in activity j per functional unit (kg).

This constraint maintains the relationship of output products and the functional unit of this study. The limitation of output products can be formulated as follows:

$$b_j = f_j \qquad \text{Eq. 13}$$

where f_j is the limitation of output products from activity j (kg).

The mathematical model is formulated on excel spreadsheets with the addition of solver add-ins (Excel's Solver). The optimality of raw material usage as decision variables for the CPP/LLDPE of rice bag manufacturing is determined as the consequence of the trade-off relationship between two objectives: minimized total cost for production and minimized global warming potential.

3. Results

According to the developed MOLP model, economic cost and global warming potential were calculated for each activity in the production of CPP/LLDPE rice bag to identify feasible usage of raw material while simultaneously minimizing total cost and global warming potential. The optimal solution obtained can serve as a basis to affect the improvement of packaging production.

First, the results of objective functions (Eq. 5-6) are obtained and then normalized to the optimal values of each objective. This can be done by a single optimization of one objective function while neglecting the other. Thus the target values of the two objectives - total cost and global warming potential - are found to be $US 6000.39 and 2780 kg CO_2 eq, respectively. However, it should be noticed here that when the total cost decreases to reach the feasibly minimum value of $US 6000.39, the global warming potential is 0.5% above its target value. Similarly, when the global warming potential decreases to reach the feasibly minimum value of 2780 kg CO_2 eq, the total cost is 1.2% above its target value. These two objectives are in direct conflict with each other. That is, reaching lower levels of global warming potential is associated with incurring greater levels of total cost for the production (Figure 3).

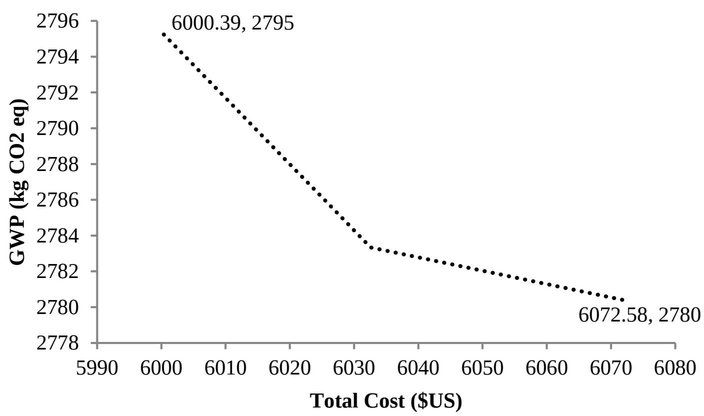

Figure 3. Trade-off relationship between GWP and total cost.

Therefore, the MINIMAX objective is applied to explore the loci on the edge of the feasible region where both objectives can compromise. In the case of the same weight factor (equal to 1) being applied to each objective, to indicate the same level of importance, the result of the MOLP model shows a slight increase in both objectives, approximately 0.3% above the target values. The optimal values of total cost and global warming potential are found to be $US 6018.27 and 2789 kg CO_2 eq, respectively (Table 3). However, it is not usual for industry to consider the cost issue to be of less importance to the decision-making process than the environmental impact. Thus, the weight importance factors of both total cost and global warming potential in this study are adjusted to 4.6 and 2.4, respectively. According to these weights, the optimal value of total cost and global warming potential are shifted to $US 6012.23 and 2791 kg CO_2 eq, respectively. Moreover, the optimal value of total cost shows a lower deviation at 0.2% above its target value. In contrast, the optimal value of global warming potential shows a higher deviation at 0.4% above its target value. This means the manufacturer satisfaction is dependent on how much of one objective they are prepared to give up in order to gain in another.

Although total cost may decrease when more global warming potential is generated, the quantity of raw material usage, as the consequence of the trade-off between these two objectives suggests is the best compromise solution, as is shown in Table 4. Among the five types of plastic resin in film blowing activity, plastic resin type B is found to be increased compared to its typical quantity. This is because it has lower cost and less greenhouse gas (GHG) emissions than the other types of plastic resin. In addition, although the cost of CMYK ink is higher than other solvents used in printing, it is found to increase as compared to its typical quantity because of the limitation in solvents usage. Due to lower GHG emissions there is an increase of adhesive component type B in laminating activity. As a result, the model output suggests that above raw materials should be increased in response to the trade-off relationship between the two objectives. On the other hand, the usage of other raw materials is decreased, subject to their constraints.

Table 3. Optimal values of two objective functions.

Objective function	Weight importance factor	Unit	Optimal value	Maximum of weight percentage deviation from target values (Q)
Minimized total cost	$w_1 = 1.0$	$US	$Z_1 = 6018.27$	0.0030
Minimized GWP	$w_2 = 1.0$	kg CO_2 eq	$Z_2 = 2789$	
Minimized total cost	$w_1 = 4.6$	$US	$Z_1 = 6012.23$	0.0091
Minimized GWP	$w_2 = 2.4$	kg CO_2 eq	$Z_2 = 2791$	

Table 4. Best compromise solution between two objective functions in case of $w_1 = 4.6$ and $w_2 = 2.4$.

Activity	Raw material	Unit	Usage	Compare with typical quantity[a]
Film blowing	Plastic resin type A	kg	198.00	Decrease
	Plastic resin type B	kg	270.00	Increase
	Plastic resin type C	kg	198.00	Decrease
	Plastic resin type D	kg	117.00	Decrease
	Plastic resin type E	kg	117.00	Decrease
Printing	Printing cylinder	Rolls	6.00	Constant
	CPP film	kg	132.00	Constant
	CMYK ink	kg	18.34	Increase
	Other ink	kg	0.47	Decrease
	Solvent type A	kg	1.88	Decrease
	Solvent type B	kg	1.88	Decrease
	Solvent type C	kg	0.94	Decrease
Laminating	Adhesive component A	kg	8.10	Decrease
	Adhesive component B	kg	27.10	Increase
	Solvent type C	kg	45.79	Decrease
Bag forming	Paper core	kg	19.29	Constant
	OPP tape	kg	0.03	Constant
Packing	PE film wrap	kg	1.63	Constant

[a] The typical quantity represents the quantity of raw material which incurred during the real production.

4. Discussion

As the best compromise solution, the optimal values of total cost and global warming potential are found to be $US 6012.23 and 2791 kg CO_2 eq, respectively. Therefore the sensitivity analysis of this MOLP model shows a slight improvement in the optimal value of total cost and global warming potential at 0.1% and 1.5% below their typical values that occur during actual production. However, the system boundary of the model and data availability also implies several limitations. For example, this study focuses on the main activity in the production line of CPP/LLDPE rice bag, but due to a limit of data availability, does not cover the production of CPP film. Likewise some of the data, including labor cost, transportation cost and emission factor is obtained from secondary data. The constraints of raw material usage can be adjusted according to the manufacturer preference.

Thus, there is an opportunity for further improvement in each objective for the minimization of total cost and lowering of global warming potential.

5. Conclusion

Integration of MOLP and LCA can be used to incorporate two aspects concerning economic and environmental issues. The model we developed is applied to determine the optimality of raw material usage for manufacturing the CPP/LLDPE rice bag as a consequence of the trade-off between two objective functions: minimized total cost and minimized global warming potential. According to the results gained from the MOLP model, the best solution shows a slight improvement in the optimal values of total cost and global warming potential at 0.1% and 1.5% respectively, below their typical values incurred in actual production. The compromise solution obtained can identify opportunities to affect production improvement. To this end, the developed model can be used as a decision-support tool to determine a compromise solution to both objectives based on the manufacturer preference and constraints. Also, the model can be used as model prototype for other flexible packaging systems for rice, such as Nylon/LLDPE and PET/LLDPE (polyethylene terephthalate/linear low density polyethylene) in the future.

Losses in the supply chain of Swedish lettuce – wasted amounts and their carbon footprint at primary production, whole sale and retail

Ingrid Strid*, Mattias Eriksson

Department of Energy and Technology, Swedish University of Agricultural Sciences, Uppsala, Sweden
* Corresponding author. E-mail: *ingrid.strid@slu.se*

ABSTRACT

The waste flow of Swedish iceberg lettuce was followed through the value chain from field to retail shelf. The study also included estimations of the carbon footprint of the waste at the different stages. At the farm level 3 tons of high quality lettuce heads were wasted per ha and year (compared to 19 tons harvested), corresponding to ca 1100 tons CO_2-e per year at a national level. Ca 50% of the lettuce sold in Swedish retail stores is domestically produced and 50% imported. The carbon footprint of the wasted Swedish iceberg lettuce at retail level was estimated to 1500 tons CO_2-e per year at a national level. The conclusion was that the losses at the retail stage were of higher importance than the losses occurring during primary production for the lettuce supply chain, and that measures therefore should be targeted primarily to the retail sector.

Keywords: carbon footprint, food supply chain, food wastage, horticultural production

1. Introduction

1.1. Background

The Swedish National Food Agency has an official assignment to act for reduced food wastage in the Swedish food supply chain. As part of the background material for a new proposed environmental target on reduction of food waste, the Swedish Board of Agriculture initiated a study on the losses, and their carbon footprint (CF), during primary production of lettuce. The current paper highlights the main results of the study (Strid et al., 2014), which also includes the whole sale stage, and merges these results with findings from a study of the retail stage (Eriksson, 2012). The losses of lettuce in retail stores, and their carbon footprint, were studied by the authors in a previous project. By combining these studies, the flow of lettuce can be followed through the value chain from field to retail shelf, and the carbon footprint of the waste can be estimated at the different stages. This type of supply chain study, where the losses are quantified and environmentally evaluated, is likely to be of importance in the policy making for reduced food waste.

1.2. Swedish production and distribution of iceberg lettuce

This subject is described in detail in the background report: Wastage of iceberg lettuce during primary production and whole sale in Sweden (Strid et al., 2014), whereas some highlights are presented here. Iceberg lettuce is mainly produced in southern Sweden, amounting 2012 to 33 400 tons/year. Normally, two or three harvests can be taken each season. Packing can be done either directly at the field - by picking, quality checking, wrapping in plastic bags and packing in cardboard boxes placed on a slowly moving tractor in front of the workers – or at packing tables at the farm center. In the first case, outer leaves and rejected heads are dropped on the field and eventually ploughed down, whereas in the second case the rejected heads are sorted out at the table, and later brought back to the field as compost. The boxes with lettuce are usually continuously moved to a cold storage and then transported away from the farm the same day. At the whole sale distribution center the lettuce is normally loaded on trucks for further transport within a day. The supply chain can schematically be described as in Figure 1.

1.3. Purpose of the study

The present study aims at describing the waste flow of Swedish iceberg lettuce through the value chain from field to retail shelf. The study also aims at estimating the carbon footprint of the waste at the different stages, taking into account that the remaining product flow shrinks as losses occur along the supply chain.

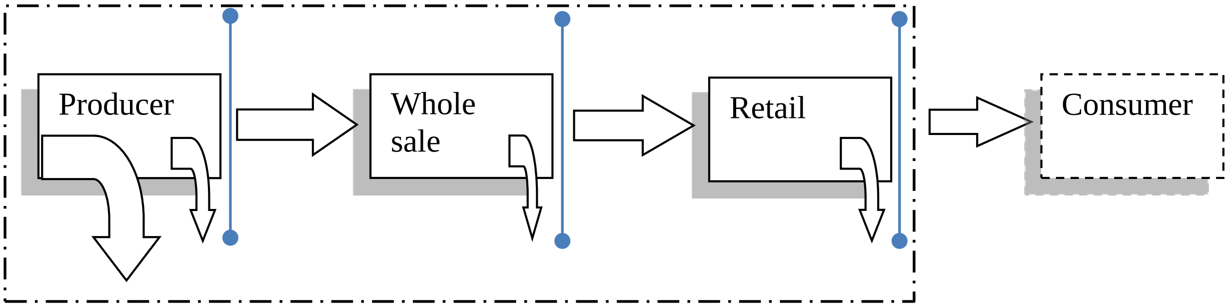

Figure 1. Schematic illustration of the supply chain of Swedish iceberg lettuce, and the system boundaries of the study. The fat waste flow represents un-harvested biomass, and the thinner, losses of prime heads. The vertical lines represent the CF check point belonging to the different stages: Ex-farm, Ex-whole sale and Ex-retail.

1.4. Scope of the study

The study covers primary production of iceberg lettuce, distribution to and waste at whole sale distribution center and distribution to and waste at retail stores, as illustrated in Fig. 1. At the farm, only the waste of high quality heads was considered, and not the type of waste occurring at the field during harvest (e.g., peeled off outer leaves and damaged heads left on the field), since this was defined as production losses instead of food waste. This type of waste can, however, be of interest in other studies, looking at valorization options for the produced biomass. At the whole sale and retail stages, all discarded lettuce was considered. The waste occurring in the households was not addressed in this paper. The study follows the lettuce produced in Sweden as this moves forward in the supply chain. About 50 % of the lettuce sold in Sweden is domestically produced and 50 % imported each year. The normal route for the imported lettuce is via the large distribution centers, and then further to, among others, retail stores. The flow of imported lettuce is not included in this study, but would roughly double the wasted amounts and thereby the CF of the whole sale and retail stages, if it was.

2. Methods

This paper merged and scaled up to national level the results from two studies on iceberg lettuce waste (Strid et al., 2014 and Eriksson, 2012), giving an overview of the losses in the value chain from primary production to retail shelf. The losses were also assessed for their carbon footprint, allowing the different stages of the supply chain to be compared. This was done by applying the product flow's CF at each stage to the wasted amount, thereby answering the research question: "How much extra environmental burden is caused by the losses, assuming that the lost lettuce is replaced by other lettuce produced under the same conditions?"

Each part of the study is described below. The methods used in the two waste inventory studies are briefly described in section 2.1, 2.2 and 2.3; for a full description of the methods, see the original studies.

2.1. Waste during primary production (Strid et al., 2014)

The method used for the study on losses during primary production was a combination of a field study on 5 farms in southern Sweden during the harvest period 2013, and an interview study with the same farmers. The farms practiced direct packing on the field as their harvest method. The biomass left on a number of test squares at the harvested fields was weighted one hour after harvest. During the interview it was explained that 10-20 % of the fields usually are never harvested, mainly due to mismatching orders (if the lettuce gets to old it loses quality and cannot be sold). The losses during primary production was hence accounted as 15 % (mean of 10-20 %) of high quality lettuce ready for harvest, but never harvested. The hectare harvest before dismissing part of the fields was on average 22 tons/ha, thus leading to 18.7 tons actual harvested heads and 3.3 tons not harvested heads. The total biomass left on the fields after harvest was 34 tons/ha, of which 3.3 consisted of the un-harvested heads, and the rest of outer leaves, malformed or damaged heads.

2.2. Waste during whole sale (Strid et al., 2014)

For the whole sale stage, some of the main whole sale organizations were interviewed. The waste was of two kinds: some smaller losses during the normal handling at the whole sale storage and some larger as a result of the quality control of the incoming lettuce, i.e., rejections to the producer, but physically a waste at the whole sale stage. The waste level used for the study was 3.0 %, of which 2.7 % was due to rejections and 0.3 % was due to in-storage losses.

2.3. Waste during retail (Eriksson, 2012)

The waste during the retail stage was based on a Swedish research project on retail food wastage (www.slu.se/foodwastage), which has access to a database covering weekly sales and waste of perishable products during 2010-2012, per item, for 6 stores belonging to one of the larger retail chains in Sweden. In this study both in-store and pre-store waste were assessed, representing the products lost at the retail shelf and those lost already when the products are subject to quality control at delivery. The waste of lettuce was recorded as 10.7 % of the incoming flow, of which 7.3 % was pre-store waste and 3.4 % in-store waste, as documented by Eriksson (2012).

2.4. Up scaling to national level

For the primary production stage, the wasted 3.3 tons of ready heads in relation to 18.7 harvested heads per ha was scaled up to national level according to the mean national harvest 2012, which was 33 400 tons. This led to that 5900 tons per year of produced lettuce never left the farms.

For the whole sale stage, it was assumed that all iceberg lettuce produced in Sweden passes the whole sale stage, and that 3 % of this falls out as waste. 3 % of 33 400 tons equals 1000 tons of lost lettuce, and implies that 32 400 continues to the retail stage.

About 50 % of the lettuce sold in Swedish stores is domestically produced and 50 % imported each year. For the retail stage it was assumed that all domestically produced iceberg lettuce passing the whole sale stage also passed the retail stage. This led to a waste of lettuce by 10.7 % of 32 400 tons, i.e., 3500 tons wasted per year for the retail stage, and 28 900 tons passing on to customers.

2.5. Carbon footprint of losses

The last part of the study was to estimate the CF of the losses occurring at each stage. This was done by keeping track of the CF of the outgoing product flow at each stage and multiply this with the wasted amount at the same stage. It was assumed in this study that the wasted lettuce did not have any other offset, e.g., no biogas was produced from the waste. On the other hand, the energy use for transporting the lettuce to waste management facilities at the whole sale and retail stages were not included either. For simplification, these two factors were assumed to even out each other.

2.5.1 Input data used for Carbon footprint calculations

For the carbon footprint data on lettuce production, a Swedish study on emissions of greenhouse gases from production of 17 horticultural products up to and including retail stores were used (Davis et al., 2011). In this, the greenhouse gas emissions at the different stages of lettuce production and distribution were assessed (see Figure 2).

	Fertiliser production	Cultivation	Packaging	Transport	Retail	Total
N2O	0,02	0,05	0,00	0,00	0,00	0,07
CO2	0,02	0,06	0,12	0,08	0,01	0,28

Figure 2. Carbon footprint data of Swedish iceberg lettuce used as input data in the present study. Source: Davis et al., 2011.

However, in this study the waste levels were lower than those found in the more explicit waste studies by Strid et al. (2014) and Eriksson (2012). The waste levels during primary production in Davis et al.'s study were based on questionnaires, where the growers were asked questions about harvest residues and storage losses per hectare. The losses were stated to be 1 ton per ha, in relation to the harvest of 23 tons per ha, and the loss was assumed to be composted and returned to the field. This gives a waste ratio of 4.2 %. There was no question about the share of un-harvested fields, as in the study by Strid et al. (2014), which may have underestimated the actual losses. The waste level during whole sale was not assessed (thus assumed 0 %), but the waste level at the retail stores was included, and derived from Gustafsson, 2010. In Gustafsson's study, the waste at retail stores was obtained from interviews with the store owners, and was assessed to 1.9 % for iceberg lettuce. It is likely that the store managers only regarded the amount that is sorted out and discarded of the in-store products, and not also included the incoming lettuce that was rejected. In a study of Eriksson et al., 2012, it was however concluded that for assessing retail wastage accurate, it is necessary to include both pre-store and in-store wastage. Due to higher confidence in the specific waste studies, new CF values were calculated to reflect these higher loss ratios. The new CF values and the assumptions behind these are described below in section 3.

3. Results

3.1. Adjusting the Carbon footprint values to the assumed product flow

For the cultivation stage, the harvest was assumed to be 19.6 tons instead of 23 tons/ha, taking away the 15 % harvest loss not accounted for. This altered the CF Ex cultivation from 0.15 kg CO_2-e/kg lettuce to 0.18 kg CO_2-e/kg lettuce. Lettuce lost after cultivation, but before packaging, was ascribed this value. For the next stage (Whole sale), the burden from plastic packaging was added, 0.12 kg CO_2-e per kg lettuce, and ¼ of the transport burden, 0.02 kg CO_2-e. This sum was then ascribed to the 97 % of the lettuce making it through the whole sale stage, giving a new Ex whole sale CF of 0.33 kg CO_2-e. For the last stage (Retail), the remaining ¾ of transport, 0.06 kg CO_2-e, was added to the value coming out of Whole sale, and then ascribed to the 89.7 % of lettuce leaving the retail stage for the consumer stage, thus giving a new Ex retail CF of 0.43 kg CO_2-e. The resulting new CF for each stage is listed in Table 1.

Table 1. Calculated carbon footprints per kg lettuce for the different stages of the supply chain

Stage of supply chain	Carbon footprint [kg CO_2-e per kg lettuce] according to Davis et al. 2011	Product flow according to Davis et al. 2011	Product flow in the present study	Carbon footprint [kg CO_2-e per kg lettuce] adjusted to the product flow in the present study
Ex cultivation	0.15	23 tons/ha leaving farm	19.6 tons/ha leaving farm	0.18
Ex whole sale	0.29	23 tons/ha leaving distribution center	19.0 tons/ha leaving distribution center	0.33
Ex retail	0.35	22.6 ton/ha leaving retail	16.9 tons/ha leaving retail	0.43

3.2. Lost amounts and CF of the losses at different stages of the lettuce supply chain

Table 2 gives an overview of the study, describing the relative and absolute waste levels and CF at the different stages of the supply chain. In the last column, the estimated CF of the losses at each stage is shown. The largest losses on a mass-basis occurred during primary production, whereas the largest carbon footprint was associated with the losses at the retail stage.

Table 2. Lost amounts and CF of the losses at the different stages of the domestic supply chain

Stage of supply chain	Loss percentage	CF of lettuce at different stages [kg CO_2-e per kg product]	Lost amount of lettuce at national level [ton per yr]	CF of losses at a national level [ton CO_2-e per year]
Primary production	15 %	0.18	5900	1060
Whole sale	3 %	0.33	1000	330
Retail	11 %	0.43	3500	1500
Total CF of losses				2900

4. Discussion

Contrary to many other agricultural products (tomatoes, broccoli, milk, meat, etc), but similar to other open field crops, the emissions at the production stage of iceberg lettuce is relatively small, leading to that the packaging and transport instead is relatively large; although the absolute value of the product is small. This explains why the smaller amount wasted at the retail stage still can be more important for impact on climate change than the larger amounts wasted at the farms.

When comparing the results with a life cycle assessment study on British and Spanish lettuce production (Hospido et al., 2009), data on losses or waste could unfortunately not be found. The harvest levels were between 15-27 tons of lettuce per ha for open field production, thereby comparable with both the yield without losses (23 tons/ha) and the yield after losses (20 tons/ha) of the present study. The global warming potential was in the study of Hospido et al. estimated to 0.33 kg CO_2-e/kg lettuce for the domestic UK open field production up to a regional distribution center. This can be compared to the CF at the whole sale stage in the present study, which also was 0.33 kg CO_2-e/kg lettuce. In the UK study some parts were different from the Swedish study: postharvest cooling was included, but packaging was excluded.

For mitigation of the environmental impact caused by lettuce waste, the retail stage is the most important stage to target of the stages covered in this study, and within the retail stage the pre-store waste causes the largest volumes of waste. As described by Eriksson et al. (2012), the pre-store waste occurs when the produce arrives at the store. Since the products are formally rejected, the retail store does not have to pay for them. Rejecting a possibly not perfect product already when it arrives is economically favorable compared to be forced to discard it later. This creates economic incentives for pushing products to pre-store waste. Economic feedback systems, such as lower purchase prices if the store keeps a low pre-store waste pattern, might stimulate the development of creative routines and solutions for keeping the waste low..

The pattern of pushing the cost of waste back to the supplier was also found at the whole-sale stage, where more waste was created as rejections, than from handling of the products at the storage (see section 2.2). For the grower, there is no stage earlier to push the waste to. At farm level, development of other market channels for the lettuce that could not be sold to the primary buyer might be a possible solution for reduced wastage at farms.

For comparison, lettuce wasted at household level was in a British study (WRAP, 2014) around 38 % of purchased volumes (64 000 ton wasted of 170 000 ton purchased), thus being more important than all the earlier stages together, if these figures also holds for Sweden. The household waste is not only larger in volume, but also in its carbon footprint, since more impact has been accumulated. If the CF of Swedish household lettuce waste is estimated to 0.5 kg CO_2e/kg (the earlier 0.43 kg CO_2e/kg + home transport and fridge storage), and 38 % of 28 900 tons yr^{-1} leaving retail is wasted, a rough estimate would give that the CF of Swedish household lettuce waste corresponds to 5500 ton CO_2e per year.

5. Conclusion

The main outcome from this study was the indication on to what extent lettuce is wasted at the different stages of the Swedish supply chain of iceberg lettuce up to and including retail. The largest losses on a mass-basis occurred during primary production, followed by the retail stage and last the whole sale stage. The global warming potentials associated with these losses were highest for the retail stage, followed by the primary production stage and last the whole sale stage. Since the retail stage was responsible for the largest contribution to global warming, reduction measures should be targeted to this sector. Within the retail stage the pre-store waste caused the largest volumes of waste. Investigating the root causes behind the retail pre-store waste would give valuable information for reducing the impact of lettuce waste in a food chain perspective. Also, the amount and causes of household waste need to be investigated in future studies.

ABSTRACT

In the framework of the French research program AGRIBALYSE®, Life Cycle Inventories of 12 annual crops have been worked out. Specific developments were required to establish the LCI of these crops. Firstly, as cropping management and environmental conditions vary both in space and time, emissions modelling at a national scale is a complex task and induced methodological challenges. Secondly, environmental assessment of a single crop requires taking into account the whole cropping rotation, in particular to assess nitrate leaching emission and allocate nutrient burdens between crops. Hence, a specific work, based on statistical data, was done to develop a nitrate model and to take into consideration fertilization practices into whole rotations. These developments provide a framework to assess emissions at a national scale in consistency with average agricultural practices and field observations. Availability of data can be a limiting factor and determine choices made for agricultural LCA-making. The nitrate model and the allocation method developed for AGRIBALYSE® are two examples of structured and simplified methods based on and parameterized with national statistical data and provide consistent results.

Keywords: annual crops, allocation, LCI, nitrate, rotation

1. Introduction

AGRIBALYSE is a French research program (2010-2013) launched by ADEME and aimed to produce public Life Cycle Inventories (LCI) of agricultural products. It pursuits two purposes: i) build an LCI database to provide data for the environmental labeling of food products and ii) share the data to enable the agricultural and food industries to assess the production chain and reduce environmental impacts (Colomb et al., 2014; Koch P.; Salou T., 2013). In the framework of this program, Life Cycle Inventories (LCI) of 25 product groups have been produced, whereof 12 are referring to annual crops, as cereals, leguminous, oleaginous and industrial crops,. A common methodological framework has been established for all the plant production inventories to ensure a homogeneous database. But at the same time, the crop diversity (annual / perennial, field / greenhouse, French / tropical crops) required specific choices to model at the best the different productions. LCA of crops induce different challenges:

(1) *Data collection:* for French cereals, leguminous, oleaginous and industrial crops, detailed and representative statistical production related data are available by crop for the main production systems from national administration or technical institutes. However, this is not the case for organic production. Moreover, few data on soil and climate conditions are available in these surveys.
(2) *Allocation of inputs and direct emissions between crops:* emissions depend on practices managed on the whole crop rotation and not only on one crop. For instance, fertilization to one crop may benefit following crops too. Moreover, the emissions of some environmental flows vary in function of the management and features of one crop but also of the preceding or following crops. In particular, nitrate leaching due to the nitrogen fertilization of one crop depends on the quantity applied but also on the intercrop management and on the following crop. Hence, environmental assessment on single crops requires taking into account the whole crop rotation. But statistical data are rarely available on a crop rotation level.
(3) *Calculation of direct emissions*: the estimation of an average value for some emissions, as nitrate, for a given crop at the national scale is difficult as the emissions greatly vary depending on agricultural practices, type of soil and climatic conditions.

The main methodological choices and the database as well as a result analysis for annual crops are described in two other contributions to the LCA Food 2014 (Colomb et al., 2014, Willmann et al. 2014). This article describes the main specific choices and methodological developments that have undertaken to cope the features of

French annual crops and agronomic specificities. The first part discusses the modelling framework. Specific developments for nitrate leaching assessment and nutrients burdens allocations are presented in the two following parts.

2. Modelling framework

For a complete and detailed information on methodological choices, we here refer to the AGRIBALYSE methodological report (Koch and Salou, 2014). For a general description about the modelling framework, system boundaries and the quality control, see Colomb et al. (2014).

2.1. Main methodological framework

LCI for 12 cereals, leguminous, oleaginous and industrial crops have been established. Several production systems for the same product have been described to distinguish different productions in function of their quality or of the mode of production (Table 1). The system boundaries considered in AGRIBALYSE are from cradle to field gate.

Table 1. AGRIBALYSE inventories for cereals, leguminous and oleaginous and main sources for description of production systems

Product groups	Inventories	Main source for description of production systems
Barley	Barley, conventional, malting quality, national average	[1]
	Forage barley, conventional, national average	[1]
Durum wheat	Durum wheat grain, conventional, national average	[1]
Soft wheat	3 Soft wheat grain, conventional LCI: breadmaking quality, 15% moisture / protein improved quality, 15% moisture / national average	[1]
	2 Soft wheat grain, organic (model type), Central Region LCI: after Alfalfa / after fava beans	[2]
Triticale	Triticale grain, conventional, national average	[5]
	Triticale grain, organic (model type), Central region	[2]
Grain maize	Grain maize, conventional, 28% moisture, national average	[1]
Silage maize	Silage maize, conventional, national average	[1]
Rapeseed	Rapeseed, conventional, 9% moisture, national average	[3]
Sunflowers	Sunflower, conventional, 9% moisture, national average	[3]
Faba beans	Faba beans, conventional, national average	[5]
	Spring faba beans, conventional, reduced protection	[5]
	Faba beans, organic (model type), Central Region	[2]
Peas	Winter pea, conventional, 15% moisture	[1]
	Spring pea, conventional, 15% moisture	[1]
Potatoes	4 ware potato, conventional LCI: for industrial use / for fresh market, firm flesh varieties / for fresh market, other varieties / variety mix, national average	[1]
	Starch potato, conventional, national average	[1]
Sugar beet	Sugar beet roots, conventional, national average	[4]

[1] survey on agricultural practices of the French agricultural administration managed in 2006 (2006 SSP farming practices survey), [2] RotAB: project for organic arable crop systems without livestock (http://www.itab.asso.fr), [3] survey of CETIOM, [4] survey of ITB, [5] according to expert opinion

As for most of the production systems, detailed and representative statistical data about agricultural practices are globally available by crop from surveys of national administration or technical institutes, these data were used by preference (Table 1). With the exception of organic production and of some conventional produced crops (faba beans, triticale), those provide detailed information about the different crop operations and applied inputs from the harvest of the preceding crop to the harvest of the surveyed crops and the harvest. If necessary, these data were completed by expert opinions in particular to distinguish agricultural practices in function of their quality and to adjust data to be representative for the period 2005-2009. On the other hand, no data on soil and climate conditions were available in these surveys. In the absence of representative statistical data, study cases from the project RotAB have been used to establish LCI for organic productions. So, the aim of these inventories is not to represent the French organic production but to provide an order of magnitude for one example of organic arable system production without livestock.

Emissions associated with inputs are based on existing data, mainly from the database Ecoinvent® V2.2. Some input references have been adapted to French specificity when possible as for example fuel consumption by tractors during field work, transport of inputs and fertilizer product.

2.2. Identification of models for the calculation of the direct emissions

The substances quantified have been selected following international standard recommendations, knowledge about the contribution of the substance emitted by agricultural activities on environmental impacts and the existence of valid models. Each flow was calculated with a specific model chosen as the most suitable according to the objectives and limits of the program. Such models should not require input data that are too difficult to collect, and should be validated for France and recognized internationally. We also considered whether models simulate the effect of agricultural practices on emissions.

For some flows, different models used for LCA, national inventories, agronomical research or development have been identified in particular for NO_3^-, N_2O or NH_3 emission assessment. Mechanistic models allow the assessment of evolving changes in farmer practices but are often applied to a relatively small geographical region, assuming a homogeneous environment with respect to soil and climate. Their application at a larger scale is difficult as input data to models, including cropping management and environmental conditions, can vary both in space and time. In the meantime, no or few data on soil and climate conditions were available in the surveys on farming practices. Hence, models used to assess N_2O or NH_3 emission for national inventories (IPCC 2006b Tier 1; EMEP/EEA 2006, 2009 Tier 2) were finally chosen. For NO_3^- emission, a specific empirical model has been developed based on a risk analysis approach (see 3. Nitrate leaching modelling).

Only one model meeting AGRIBALYSE requirements was identified for some flows as phosphorus (SALCA-P), heavy metals (SALCA-ETM) or eroded soils (RUSLE). The application of these models for AGRIBALYSE required some adaptations, in particular taking into account French production conditions and using them at a national scale, while they have been established for applications at field scale. Hence, some parameters have been adapted when possible. For instance, average soil and climate parameters at regional scale have been assessed basing on INRA soil and metrological database to implement RUSLE. However, as data were missing, it appeared that the adaptation of SALCA-P to the French context was not possible. Some parameters related to plots, as slope, have been assessed by expert judgment. To assess the relevance of this model on French situation, a specific work was done to compare results to experimental data (Willmann et al., 2014).

Some flows were not assessed as no valid model has been identified. It is the case of particulate emissions other than ammonia, as the data currently available in France and Europe was considered to be insufficient to take satisfactory account of these emissions. Among the various NOx gases only NO was considered for direct flows, owing to the lack of appropriate models for the other gases.

3. Nitrate leaching modelling

3.1. The aim of the model

Different mechanistic field-models have been identified to assess either only NO_3^- emission (eg: the model DEAC, described in Cariolle 2002 and Cohan et al., 2011; or SALCA-NO3, described in Richner et al. 2006), or NO_3^-, NH_3 and N_2O emissions (the model STICS, described in Brisson et al. 1998 and Syst'N, being published). In the meantime, their application at region scale is difficult. Schnebelen et al. (2004) developed and assessed an upscaling approach of STICS to model nitrate leaching at regional scale. This approach has been proven effective at the scale of a small agricultural area (i.e; 526 km2) but is likely to introduce additional errors, as it is based on assumption of homogeneous crop and soil parameters on simulation units. Moreover, the application of this approach at the French national scale is a lengthy and data-intensive process.

Very simple models that estimate nitrate leaching as a fraction of applied fertilizer (IPCC 2007; Miller et al. 2006; Powers 2007) are too crude to compare production systems or assess effects of changes in farmers' practices. Bentrup et al. (2000) estimated nitrate leaching on the basis of estimated post-harvest soil mineral nitrogen content, but some input data for the model (nitrogen mineralization and immobilization in the soil) are difficult to quantify at large scales. Basset Mens et al. (2006) developed a method combining a risk analysis approach, based on the risk analysis proposed by Cattin et al. (2002), with regional leaching data. In this study, a model was specifically designed to assess some production systems in the Brittany region in western France, and the method therefore is not valid outside this region. However, this approach has been proven efficient at providing an average estimation of nitrate leaching for a specific region and it is based on easily available data regarding farmers' practices and soil parameters. This method could therefore be applied at a national scale after specific development.

3.2. General principles of the model

The COMIFER model proposed by Cattin et al. (2002) is a qualitative simplified approach that is applicable at a plot scale to qualify the risk of leaching. It takes account a "crop risk" and an "environment risk" (depending on the quantity of water percolating through the soil and the mineralization conditions).

Concerning the "crop risk", the COMIFER model classifies conditions according to the following criteria, in order of importance.

1. Period without presence of vegetation able to absorb nitrogen (depending on the following crop and the sowing of an intermediate crop)
2. Capacity of the following crop to absorb nitrogen in the fall (depending on the following crop)
3. Application of organic fertilizer in the fall (C:N ratio < 8)
4. Quantity of nitrogen provided by crop residues (depending on the crop studied and the management of residues)

The COMIFER model defines the "environment risk" by the combination of two criteria: i) the soil drainage index and ii) the organic matter content of the mineralizing soil layer.

Then, it classifies the risk according to various "crop risk" x "environment risk" combinations.

3.3. Specific developments

ARVALIS managed different developments based on this model for its implementation in AGRIBALYSE:

1. A weighting system for the different classification criteria was drawn up by expert opinion on the basis of the model to estimate the risks for crop conditions not covered in the COMIFER classification.
2. The COMIFER provides a risk classification according to the crop and environment risks. Each level has been associated with a nitrate leaching amount, based on expert opinion.

Table 2. Nitrate leaching amount (kg $N\text{-}NO_3^-$/ha) according to the crop and environment risks.

		« crop risk »				
		1	**2**	**3**	**4**	**5**
« soil risk »	**1**	5	10	20	25	30
	2	10	15	25	30	40
	3	15	20	30	40	50
	4	20	30	40	55	60
	5	30	40	40	60	80

3. The balance between nitrogen supply and the crop requirements is not a parameter used in the COMIFER model. This was based on the assumption that there was no excessive nitrogen fertilization on the previous crop which could generate an excessive increase in the nitrogen content of residues. On the one hand, many studies (Chaney, 1990; Richards et al., 1996; Machet et al., 1997) have shown that when N inputs are lower than the crop requirement, the N application has a very little effect on the nitrate amount that is available after harvest

and potentially leachable. On the other hand, excessive N inputs can potentially increase the amounts of N leached. These depends on cropping practices, soil type and climate conditions (Lacroix et al., 2006).

First, the effect of the excessive N inputs (N inputs minus crop N requirements) on the residual soil mineral nitrogen content (SMN) after harvest has been assessed from the relationship established by the COMIFER (1997), based on 400 measures. Then, the surplus amount of nitrate leaching was assessed, based on the supplementary SMN and parameters on leaching fraction. As the effect of excessive N-fertilization was merely assessed on the experimental sites, these fractioning parameters have been established for each "environment risk" by expert opinion (Table 3).

Table 3. Fractioning parameters to assess the effect of excessive N-fertilization from the increase of SMN and nitrate leaching results for an excess of 50 kg N/ha

		Soil risk				
		1	**2**	**3**	**4**	**5**
% of the supplementary SMN that is leached		0.5	0.6	0.7	0.8	0.9
Supplementary nitrate leaching (kg N-NO_3^-)	**cereals and oilseed rape**	7	8	9	11	12
	maize and sugarbeet	12	14	17	19	22

The "crop risk" weighting system and assignment of leaching quantities to each "environment risk" x "crop risk" combination were validated by measures on 5 sites for three to fourteen years on contrasting situations. Some simulations have also been made with the DEAC model (Cariolle 2002) in order to obtain references for a very low « soil risk ». The validity of the model at plot scale was also confirmed by a work being published. This work aims to compare three different models applied on two different study cases.

3.4. Implementation of the model for the AGRIBALYSE program

As no statistical data cover both agricultural practices and soil-climate data, different databases have been used (Table 4). It was not possible to localize precisely the agricultural plots from the public survey on agricultural practices but the sampling of this survey was built to provide representativeness at the scale of administrative regions. Hence, nitrate leaching was assessed at the scale of administrative regions, although these regions do not correspond to homogeneous agronomical units.

The crop risk was estimated for the 1,000 plots covered by the SSP for the 2006 farming practices. For each crop and each administrative region, the average risks were estimated for each "crop – following crop" combinations. The average risks for each crop and each administrative region were obtained from these risks for crop combinations weighted by the frequency of these combinations, also estimated with the farming practices survey.

The geographic French soil database managed by the INRA Soil Science Unit, Orleans, was used to estimate the environment risks. It describes a set of soil typology units, characterizing distinct types of soil. The soil typology units are described using attributes defining the nature and properties of the soils (eg: texture, water system, soil parent material, etc.).The environment risk was estimated for each soil typology unit based on soil water retention capacity and climatic data from the Arvalis database covering 84 weather stations over the last 30 years. The areas corresponding to each risk category in each administrative region were then characterized to estimate the average risk.

Average nitrate leaching amount for each crop was estimated at administrative region scale from the average crop risk in the administrative region and the average environment risk of the administrative region. However, for the plots of the farming practices survey, available data were insufficient to estimate a N recommendation and to compare it with the N inputs in order to take into account the effect of excessive inputs. Hence, we managed a sensitivity analysis, considering the frequency of excessive N fertilization from 5 to 20% and N inputs exceeding by 50 kg N/ha the crop requirement.

Table 4. Data sources for the implementation of the model for the AGRIBALYSE program

Input data	Source data
Volume of production of the crop per region	statistic of the French agricultural administration for 2005-2009
Following crop	2006 SSP farming practices survey
Intercrop following the crop studied	
Application of organic fertilizer in the fall	
Residue management	
Excess amount of N inputs	Expert opinion
Soil-climate data: water properties of the soil (characteristic humidity, root depth of crops), meteorological data (rain, potential evapotranspiration), organic matter content	geographic French soil database managed by the INRA Soil Science Unit, Orleans meteorogical: Arvalis database

3.5. Results

We can identify 4 groups of crops.
1) The lowest emissions are observed for sugar beet because of the low soil nitrate nitrogen after its harvest.
2) Sunflower and potato harvested in autumn are mainly followed by soft winter wheat. As the intercrop duration is short, emissions are low.
3) Nitrate leaching amounts are in the same range for pea, oilseed rape, cereals and grain maize. Emissions for barley are lower than those of soft winter wheat as 40% of barley plots are followed by oilseed rape, instead of 14% for soft winter wheat. As oilseed rape has a high capacity of N absorption, this explains this difference.
4) Finally, forage maize emissions are higher because of low residues restitution. As the C/N ratio of maize residues is high, those induce a net organization of soil nitrogen during the following intercrop and then reduce the risk of nitrate leaching.

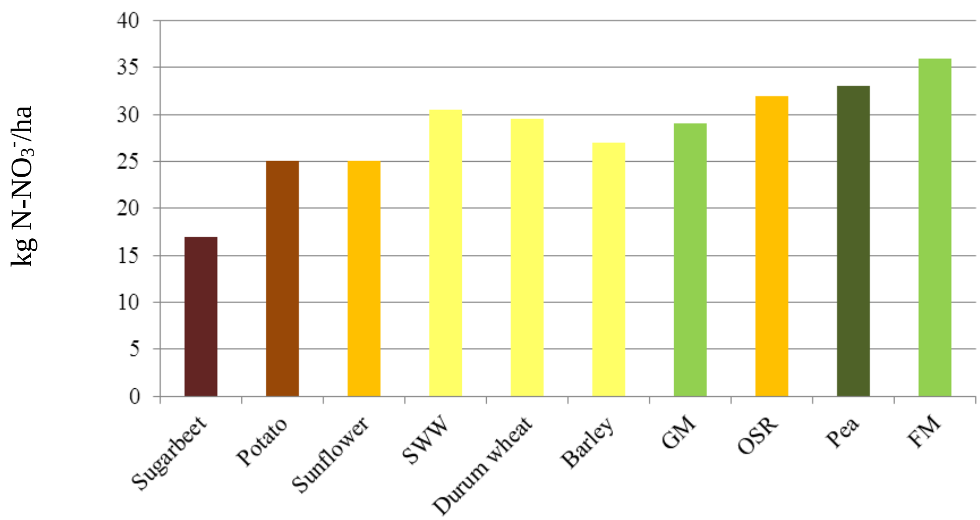

Figure 1. Average nitrate leaching amount for each crop at national scale. SWW: soft winter wheat; GM: grain maize, OSR: oilseed rape, FM: forage maize

As this model only concerns annual crops, its results can be compared to results from the literature at the regional scale for regions with a low proportion of area occupied by meadows and perennial crops. Using these results and the crop frequencies in each region, average nitrate leaching amounts per region were estimated and compared to literature results at the watershed scale (Table 5). The estimation of among 30 kg $N\text{-}NO_3^-$ leaching under root-zone is confirmed by these published results.

Table 5. Comparison of results at regional scale using the AGRIBALYSE methodology scale with bibliographic references

Watershed	Source	Years	Flow kg N/ha/an	Description	AGRIBALYSE results for the concerned regions, kg N/ha/an
Seine	Ducharne et al. 2007	1990-2000	30	NO_3^- leaching amount under root-zone estimated by STICS	26-30
Marne	Ledoux et al. 2007	1995-2000	20-33	NO_3^- leaching amount under root-zone estimated by STICS-MODCOU	34

The validation by experimental results shows that the model is relevant to estimate nitrate leaching at plot scale from easily available data. The application at administrative region hides a wide diversity of situations but provides consistent results for average nitrate leaching amount at regional scale.

4. Allocation of nutrient burden between crops

4.1. Principles and allocations for cropping sequences in the AGRIBALYSE database

It is difficult to allocate the impacts of a production system to each crop in a cropping sequence because certain practices may involve several crops in the rotation system and certain emissions depend on the practices and characteristics associated with a crop as well as on the practices and characteristics associated with previous or following crops.

The ILCD Handbook (JRC and IES 2010) recommends taking account of the nutrients remaining in the system after a crop has been harvested as a co-product of this crop and continues by extending the system or by allocation. Different allocation rules have been identified in bibliography (Audsley et al. 2003; Blonk 2010; Gac et al. 2006; Van Zeijts et al. 1999). However, these references rarely lead to common accepted rules in term of methodology or their suggestions are not always easy to apply because of data availability (Gueudet et al., 2012).

It is the case for allocation of Phosphorus (P) and potassium (K) inputs. For instance, in some studies, they are allocated in function of the nutrients exports (Gac et al. 2006; Van Zeijts et al. 1999) or of the recommended quantities (Audsley et al. 2003; Blonk 2010). We chose to allocate them in function of crop exports as the allocation based on recommended quantities require data that are not easily available at the national scale (PK soil content, PK input during the past few years).

Concerning the allocation of nitrate, Powers (2007) develops a method to allocate the flux between the different crops in function of the fluxes measured on fields cultivated on single crop. However, this is not applicable for every situation as some crops cannot be cultivated as single crop. Audsley et al. (2003) prefer to allocate these fluxes half to preceding crop and half to the following crop. William et al. (2006) allocate the total leaching fluxes at the rotation scale to the different crops in function of the post-harvest N surplus. These two options require data on precise practices data on the whole rotation that were not available at the national scale. Hence, in this study, we chose to allocate the estimated leaching flux to the crop 1.

Table 6. Allocation rules used for cropping sequences

Element	Comments	Allocation rule
Phosphorus (P) and potassium (K) inputs	These are immobile in the soil. Some farmers use residual nutrients by applying P and K fertilizers to one crop only in quantities sufficient to supply the needs of following crops. P and K inputs remaining as crop residues were considered as available for the following crops.	The impacts associated with the production of these inputs and emissions (P, PO4, ETM) related to their application are allocated to each crop proportionally to their nutrients exports, assessed from the harvested yield and PK contents of harvest. Sources: COMIFER farming practices survey and tables of crop exports
Phosphorus (P) loss	Main of phosphorus loss is induced by soil erosion. Soil erosion by crop was assessed by RUSLE, which takes into account occupation time and agricultural practices on each crop.	No allocation was managed on soil erosion and P loss.
Organic nitrogen	Only a fraction is directly available to the crop to which the organic nitrogen is applied. The rest contributes to a stock of organic matter, which could benefit all crops in the rotation.	The nitrogen available for the crop to which the fertilizer is applied (PAN) is allocated to that crop. The rest is allocated to all the crops in the rotation. Sources: Farming practices and the mineralization dynamics of organic fertilizers from the CASDAR project "Sustainable soil management"
Mineral nitrogen	The amounts of nitrogen applied in mineral form are directly available for the crop to which the fertilizer is applied.	The impact of production and the emissions of the nitrogen applied to a crop in mineral form are allocated in full to this crop.
Intercrop-nitrate	Residual nitrates remain in a soil after a crop has been harvested. These may be used by the following crop but a fraction may also be leached.	The impact of nitrate production and emissions between crops are allocated to the previous crop.
Nitrogen from crop residues	Crop residues may constitute a source of nitrogen for the following crop(s). They may also produce N_2O emissions evaluated using the methodology of IPCC Tier 1.	The impact of nitrogen contained in crop residues and the N_2O emissions from these residues are allocated to the crop which produced these residues.

4.2. Allocation of organic N, P and K inputs on the basis of the 2006 SSP farming practices survey

Organic N, P and K inputs were allocated to all crops in a cropping sequence according to the rules outlined in table 7. This type of allocation required a detailed knowledge of the fertilizers applied and the yield for each crop in the rotation system. There was little statistical data for cropping sequences and the information that was available did not cover the production of all the crops studied in AGRIBALYSE. The 2006 SSP farming practices survey covered crops and not cropping sequences. However, it had the advantage of covering most of the main production regions for about ten major crops. It also gave information on the history for each plot and in particular details about previous crops. The year 2006 was considered representative of fertilizer applications during the reference period 2005-2009.

The succession of crops grown in the 14,000 plots studied was known for the period 2001 to 2005. An analysis of this data showed nearly 4,000 different cropping sequences. This diversity and the size of the samples did not make it possible to reconstitute fertilization practices for each type of cropping sequence. To take account of this diversity, these rotation systems were grouped together as "cropping sequence groups" using appropriate statistical optimal matching methods (Gabadinho et al., 2011). The 4,000 rotation systems were grouped into 34 major cropping sequence groups, depending on the dominant crops and production region (Jouy and Wissocq, 2011; see
Table 7 for example). This made it possible to take account of the differences in the application of fertilizers for a given crop depending on the rotation system and region, based on SSP 2006 data. After allocation according to the rules in Table 6 for each crop within the cropping sequence groups, a French average input of organic N, P and K was calculated for each crop.

Table 7. Example of cropping sequences identified in the Northern region

Region	Cropping sequences	Area in 2006 (ha)
Northern	Sugarbeet (18%), winter wheat (50%), potato (8%)	719 000
	Silage maize (24%), temporary grassland (10%), winter wheat (39%), barley (13%)	561 000
	Oilseed rape (23%), winter wheat (44%), barley (23%)	551 000
	Winter wheat (43%), barley (13%), leguminous	254 000
	…	

4.3. Results

The allocation rules modify significantly the nutrient amount attributed to each crop (Table 8). For instance, organic manure is spread by preference on silage maize as this crop uses efficiently organic nitrogen. In the meantime, only a fraction is available for silage maize. Hence, organic N amount allocated to silage maize is much less than the spread amount. High amount of K_2O is applied on potato in particular as this crop requires amount superior to this exportation. A fraction of this amount is allocated to the other crop as this K_2O “excess” remains available for the following crops.

Table 8. Nutrient attributed by crop before (B) and after (A) allocation, example on a few crops

	kg organic N / ha		kg mineral P_2O_5 / ha		kg organic P_2O_5 / ha		kg mineral K_2O / ha	
	B	A	B	A	B	A	B	A
Silage maize	166	114	24	33	73	46	14	4
Soft winter wheat	11	18	25	39	7	19	42	10
Spring pea	-	9	29	22	-	7	46	19
Starch potato	55	41	47	25	21	12	202	161

Their effect was particularly significant on three indicators (Figure 2):

- the global warming (IPCC 2007) in particular on maize (variation of 10%) as N_2O emission is function of the applied organic N amount and NH_3 and NO emissions,
- the freshwater eutrophication potential (ReCiPe 1.05H). Field emissions do not significantly vary with allocations as SALCA-P was only sensitive to P_2O_5 spread as liquid manure and as mineral or solid manure. In the meantime, mineral P_2O_5 production contributes from 30 to 50% of the freshwater eutrophication potential, this explains the significant effect of allocations on this indicator (variation from 10 to 20%),
- the cumulative fossil and nuclear energy demand (CED1.8) of potato (variation of 7%).

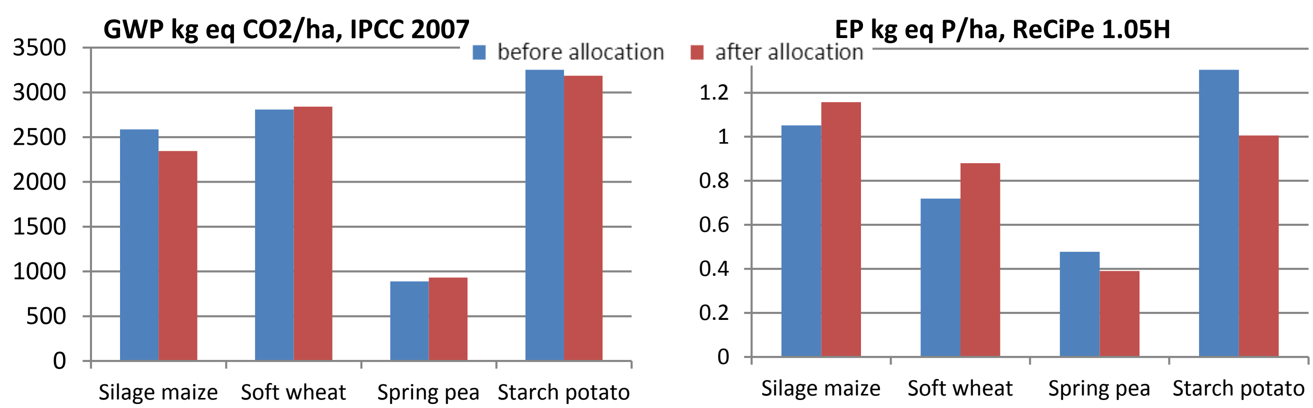

Figure 2: allocations effects on LCA indicators, example of global warming potential (GWP) and eutrophication potential (EP)

5. Conclusions

Substantial work and developments have been carried out within AGRIBALYSE program in order to produce consistent references relative to real agricultural practices and field observations in France. The implemented methods should evolve with improved knowledge.

In France, statistical databases on agricultural practices or on the soil are valuable sources of information for the LCAs of crops. Thanks to their exploitation and crossed with the expertise in the field, AGRIBALYSE was able to establish average references. Further work on typology of production systems would enhance the understanding of the variability of impacts due to the agricultural practices and the natural conditions. However, for some sectors (eg organic production), the statistics are lacking and should therefore be completed. The actual LCIs for these products have a lower representativeness than for other products.

Moreover, the estimation of some flows (eg N_2O emissions, carbon storage in the soil) may be improved soon. Further to AGRIBALYSE program, the project ECOALIM, funded by ADEME and CASDAR, aims to optimize feeding to reduce environmental impacts of livestock. Important work is carried out within this framework to estimate fluxes of nitrogen in water and air and allocate impacts in the crop rotation. But we must not stop there. Other flows (eg phosphorus, pesticides and trace elements) are estimated with a high uncertainty because the available models are not robust enough or due to insufficient data for adapting the models to the French context regarding phosphorus. They must be also subject of works.

Finally, some impacts, such as water and biodiversity, were not covered within AGRIBALYSE, due to a lack of adequate methods or of available data. Both are major issues and will be the subject of research efforts in the future.

ABSTRACT

We provide the first global environmental assessment of livestock production that includes both greenhouse gas (GHG) emissions and biodiversity criteria. We compared performances on these two environmental criteria across scales, commodities (dairy and beef cattle) and production systems (grassland and mixed). To do this, we combined a global model computing the greenhouse gas emissions of livestock with the Mean Species Abundance biodiversity indicator to quantify the biodiversity impact of livestock through land use. Results showed weaker synergies and more trade-offs between environmental criteria in grassland than in mixed production systems. Efficiency in the utilization of feed and their associated land use is likely to drive the synergies in mixed production systems. Grassland systems based on extensive feed land use with high biodiversity values may have contrasted GHG emissions performances. Our global mapping of the relationships between environmental criteria could be used for spatially targeting decisions and actions.

Keywords: Environmental sustainability, Life Cycle Assessment, multi-criteria, intensity

1. Introduction

Livestock production faces a challenge in satisfying an increasing food demand while improving its environmental sustainability. In the next decades, global population growth, urbanization and higher incomes will lead to a 70% growth in the demand for animal products (FAO 2011). On a global scale, livestock are major contributors to food security but also to environmental impacts such as greenhouse gas (GHG) emissions (Gerber et al. 2013), water pollution (Carpenter et al. 1998) or biodiversity loss (Steinfeld et al. 2006). Large scale assessments of the environmental impacts of livestock reveal both hotspots of impact and sustainable systems; they are thus key to effective action and improvement.

Most of the recent global assessments of the livestock environmental performances focused on GHG emissions. They provided consistent results for the emission associated with different types of livestock products and for the hotspots along the supply chain (e.g., review in De Vries and De Boer 2010). Relying on these assessments, technical (Smith et al. 2008; Garnett 2009) and policy (Gerber et al. 2010; Steinfeld and Gerber 2010) options have been proposed to mitigate the contribution of livestock to climate change. Yet, environmental impacts of livestock production are not restricted to GHG emissions and carbon footprint cannot be used as an indicator of the overall environmental impact (e.g., for meat production, Röös et al. 2013).

In particular, livestock have a very strong impact on biodiversity. The main global driver of biodiversity loss is habitat change (MEA 2005; Foley et al. 2005). As major users of land resources, livestock have a strong contribution to this driver. About 30% of the global area is currently dedicated to livestock production through pastures and feed crops (Ramankutty et al. 2008). The Amazonian forest may host up to a quarter of the world's terrestrial species (Dirzo and Raven 2003). Its conversion to pastures (representing 85% of the new agricultural lands, Steinfeld et al. 2006) and soybean crops is an important threat to biodiversity. In Europe, grassland intensification and conversion to cropland have caused an important decline of farmland species (Vickery et al. 2001; Firbank et al. 2008). Overgrazing is an important factor causing habitat degradation through desertification and woody encroachment in arid rangeland system, which leads to decrease in the species richness of plant communities (Milton and Dean 1995; Asner et al. 2004).

Although there is large evidence of the global impact of livestock on biodiversity, very few quantifications exist and including biodiversity impacts in LCAs is still an emerging area of work. A framework (Mila i Canals et al. 2007; Koellner et al. 2013) and several characterization factors (review in Curran et al. 2011) have been proposed to compute biodiversity impacts through land use in LCAs. Most of the characterization factors are available at country to region scale (Koellner and Scholz 2008; Schmidt 2008; Goedkoop et al. 2012). At global scale, Koellner et al. (2013) proposed a standardized land use classification for computing biodiversity characterization factors (as part of the UNEP-SETAC Life Cycle Initiative). De Baan et al. (2013) relied on this classification to quantify the land use impact on biodiversity with a Biodiversity Damage Potential characterization factor. This study did not describe several levels of intensity within the pasture/meadow and annual crop land use classes, which is a limitation for quantifying the impact of livestock production with precision. Alkemade et al. (2009) developed a Mean Species Abundance (MSA) indicator and computed its value at global scale for various land use and intensity classes. Authors did not used the MSA within an LCA perspective but to predict the effect of global socio-economic scenarios on biodiversity, certain scenarios specifically addressing livestock production (Westhoek et al. 2011; Alkemade et al. 2012).

Most large scale environmental assessments have focused on one environmental criteria, and chiefly on GHG emissions. Both synergies and trade-offs are however likely to exist between the performances on GHG emissions and on other environmental impact categories, such as biodiversity. For instance, grassland systems often involve lower feed digestibility and thus higher enteric CH4 emissions (Eckard et al. 2010). However, in some regions grassland systems are crucial for maintaining rich biodiversity habitats, and both intensification and abandonment lead to the loss of a unique pool of species (Bignal and McCracken 2000). Quantifying both GHG emissions and biodiversity impacts is important to reveal how policy options targeting one criteria will involve benefits or conflicts with the other criteria.

The objective of this paper was to compare the GHG emissions and biodiversity impact of livestock production on a global scale. We combined the GLEAM model (Global Livestock Environmental Assessment Model, Gerber et al. 2013; Opio et al. 2013) which computes the global GHG emissions of livestock, with the MSA methodology in order to quantify the global biodiversity impact of livestock through land use. We investigated the relationship between performances on these two environmental criteria among commodities, production systems, and across scales.

2. Methods

2.1. Overview

The methodology was based on GLEAM which models global livestock supply chains in details and computes the GHG emission (Gerber et al. 2013, Section 2.2.). Computing the land use for feed is an intermediary output of the model (Figure 1). We used this intermediary output to develop a new component of GLEAM, which estimated the impact of livestock on biodiversity through land use. For this biodiversity component, we relied on the MSA methodology which provides a biodiversity value (expressed as Mean Species Abundance) for several classes of land use and intensity (Alkemade et al. 2009; 2012, Section 2.3.).

All computations addressed the global scale and were based on GIS raster layers with a resolution of 3 arc minutes (5*5km at the equator). The year of reference was 2005. We focused on a single species (cattle) but we described two commodities (milk and meat) and two production systems (grassland and mixed). For the dairy herd producing meat as a co product, no allocation was performed; environmental impacts (GHG emissions and MSA impact) were expressed by kg of proteins, summing proteins from milk and from meat.

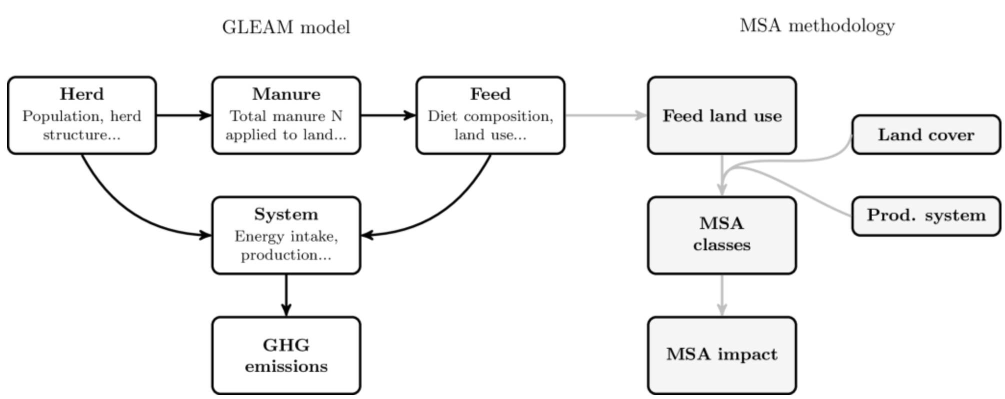

Figure 1. Overview of the modeling procedure used to compute GHG emissions, through the Global Livestock Environmental Assessment Model (GLEAM, Gerber et al. 2013) and the biodiversity impact, through the Mean Species Abundance methodology (MSA, Alkemade et al. 2009; 2012). Prod. = production. Adapted from Gerber et al. 2013.

2.2. GHG emissions: the GLEAM model

GLEAM is a novel modeling framework that enables a comprehensive analysis of the emissions of global livestock production (Gerber et al. 2013). It provides disaggregated estimates of the GHG emissions for the main commodities, production systems and world regions. The main GHGs in the agriculture context – CH_4, N_2O and CO_2 – are accounted for. GLEAM is built on modules reproducing the main elements of livestock supply chain: the herd module, the manure module, the feed module and the system module (Figure 1).

The GHG emissions results included emissions from feed production (main sources of emissions: N_2O from fertilization; CO_2, N_2O and CH_4 from energy use, fertilizer manufacture and land use change related to soybean cultivation) and livestock production (main sources of emissions: CH_4 from enteric fermentation and manure management; N_2O from manure management; CO_2 from on-farm energy use for livestock). For comparison with biodiversity impact through land use, we excluded emissions from manufacture of on-farm building and equipment, and post farmgate emissions. For a detailed description of the GLEAM model, refer to Gerber et al. (2013) and Opio et al. (2013).

2.3. Biodiversity impact: the MSA methodology

In order to compute the MSA values of different land use and intensity classes, Alkemade et al. (2009; 2012) conducted a meta-analysis and selected articles that presented data on species composition in disturbed (occupied) vs undisturbed (reference) land uses. No selection of specific species groups was performed; studies included in the meta-analysis addressed both plants and animals (mainly birds, mammals and insects). For each species k within each occupied land use i, the ration $R_{i,k}$ was calculated as:

$$R_{i,k} = \begin{cases} \dfrac{n_{i,k}}{n_{ref,k}} & if\ n_{i,k} < n_{ref,k} \\ 1, & otherwise \end{cases} \qquad \text{Eq. 1}$$

where $n_{i,k}$ is the abundance of the species k in an occupied land use i and $n_{ref,k}$ its abundance in the reference land use. The MSA of any occupied land use MSA_i is then calculated by summing and weighting the ratios $R_{i,k}$ of each species:

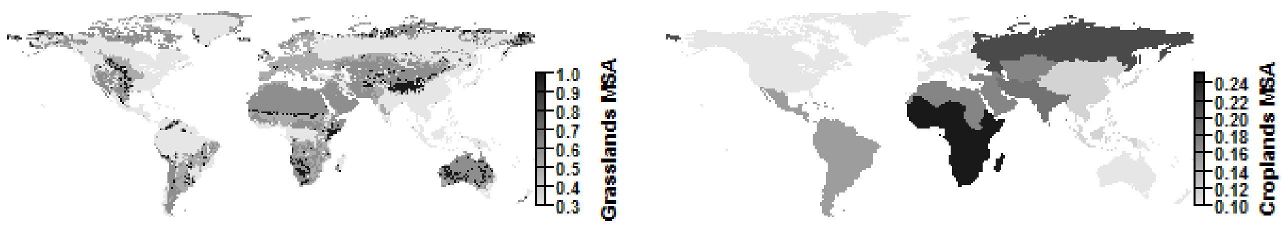
$$MSA_i = \frac{\sum_k \left(R_{i,k}/V_{i,k}\right)}{\sum_k 1/V_{i,k}} \qquad \text{Eq. 2}$$

where $V_{i,k}$ is the variance of the ratios of species abundances for each study and copes for differences between studies. MSA values vary between 0 and 1. MSA = 1 in undisturbed ecosystems where 100% of the original species abundances remains, conversely, MSA = 0 in a destroyed ecosystem with no original species left.

Table 1. Mean Species Abundance (MSA) value of the different land use and intensity classes of rangelands/grasslands, and croplands (Alkemade et al. 2009; 2012).

Land use and intensity classes	MSA value
Rangelands/grasslands	
Natural rangelands	1
Moderately used rangelands	0.6
Intensively used rangelands	0.5
Man-made grasslands	0.3
Croplands	
Low input agriculture	0.3
Intensive agriculture	0.1

Table 1 shows the MSA values of the different land use and intensity classes. Feed land uses as computed by the GLEAM model were translated into MSA land use classes (Figure 1). For each grid cell, we allocated a rangeland/grassland class (Figure 2a), and a cropland class (Figure 2b), corresponding to MSA values. For distinguishing between the different rangeland/grassland classes, we used information from three different layers mapping potential vegetation (ecoregions, Olson et al. 2001); global land cover (GLC 2000) and the distribution of grassland vs. mixed production systems (Gerber et al. 2013). We used the following hierarchic rules. The man-made grasslands class (MSA = 0.3) was allocated to grid cells with forest as potential vegetation, except for Europe where although forest is the potential vegetation, grasslands are sufficiently old to host specifically adapted species and very high biodiversity levels (Bignal and McCracken 1996; Benton et al. 2002). The natural rangelands class (MSA = 1) was allocated to grid cells with herbaceous land cover and grassland production systems. For grid cells with non herbaceous land cover (e.g., crops, crops/grass mosaic), the moderately used rangelands class (MSA = 0.6) was allocated to grassland production systems while the intensively used rangelands class (MSA = 0.5) was allocated to mixed production systems.



(a) (b)

Figure 1. Mean Species Abundance (MSA) value attributed to (a) the grasslands and (b) the croplands of each grid cell.

We further computed a characterization factor illustrating the impact of livestock production on MSA in each grid cell of the global raster:

$$MSA\,impact = \sum_i (1 - MSA_i) \times Area_i \qquad \text{Eq. 3}$$

where *(1-MSA$_i$)* stands for the loss of MSA in land use *i* compared to the reference land use. For instance, an MSA value of 0.6 in extensive grasslands means that the MSA loss *(1-MSA$_i$)* is 0.4, i.e. that 40% of the mean species abundance is lost compared to the reference land use. *Area$_i$* is the area of land use class *i* necessary to produce the feed consumed by cattle in the grid cell. Therefore, the MSA impact of land use for feed is not allocated where feed is produced but where it is consumed. For instance, the MSA impact of soybean cultivated in brazil and consumed by cattle in a given European grid cell will be allocated in this European grid cell. As a consequence, livestock production in a given grid cell could have a land use impact on a larger area than the grid cell area. The MSA impact is expressed as an *MSA loss * km^2* and then divided by the kg of protein produced.

2.4. Spatial analyses

We computed average GHG emissions and MSA impacts across grid cells, at the level of agro-ecological zones (intersection of climate zones and global regions, Fischer2008) and climate zones (arid, humid, temperate).

We investigated the relationship between GHG emissions and MSA impact environmental criteria at local (grid cell) scale. For the two environmental criteria, the environmental impact of a grid cell was compared with the average impact at sub-regional level (moving window average). If the impact on the two environmental criteria were both lower or both higher than the sub-regional average, we considered that there was a synergy between criteria for the grid cell. Conversely, if the impact was higher than the regional average for one environmental criteria and lower for the other, we considered that there was a trade-off between environmental criteria for the grid cell.

All analyses were performed using the R software, version 3.0.3 (R Core Team 2014). We used the raster package (Hijmans 2014) to perform GIS analyses.

3. Results

3.1. Relationship between environmental criteria across agro-ecological zones

As a general trend across agro-ecological zones, there was a synergy between the climate change and biodiversity performances: agro-ecological zones with lower GHG emissions also tended to have lower MSA impacts (Figure 3). This general trend was observed similarly for dairy (Figure 3a) and beef (Figure 3b) cattle, and for grassland and mixed production systems. For both commodities, the correlation between GHG emissions and MSA impact was much lower in grassland production systems (R^2 = 0.2936 and 0.2295 for dairy and beef cattle, respectively) than in mixed production systems (R^2 = 0.8577 and 0.7658 for dairy and beef cattle, respectively).

Figure 3 also shows that environmental impact on the two criteria was higher for beef cattle than for dairy cattle. For the two commodities, grassland production systems had a slightly higher MSA impact than mixed production system. In terms of GHG emissions, the difference between production systems was very small.

Environmental impacts on the two criteria across climate zones were similar for the two commodities (results not show). Environmental impacts were the highest in arid regions and the lowest in temperate regions. Humid regions had GHG emissions levels close to those of arid regions while they had an MSA impact intermediate between those of arid and temperate regions.

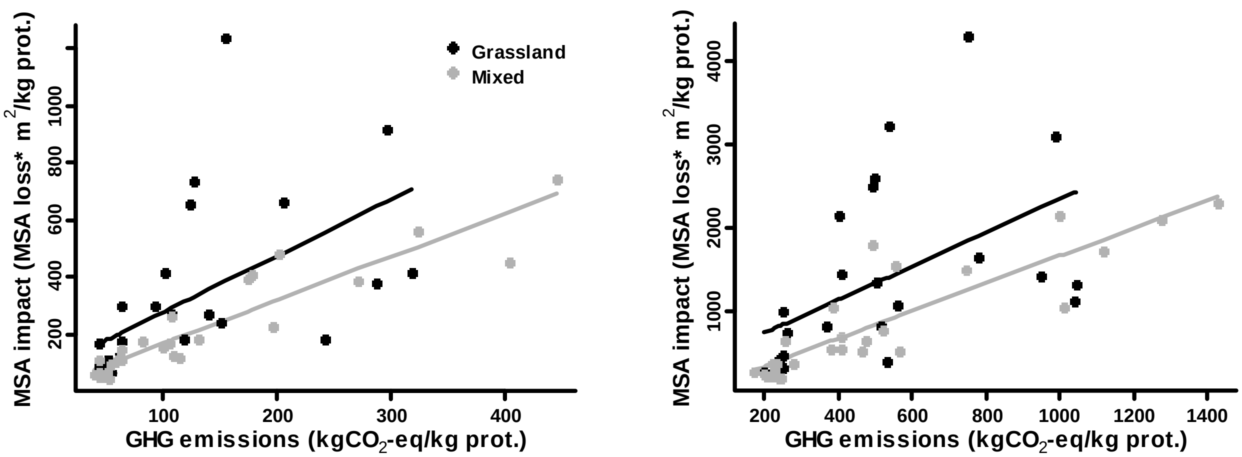


Figure 3. Relationship between GHG emissions and MSA impact per unit of production across agro-ecological zones. (a) Dairy cattle; (b) Beef cattle. Each point stands for the mean GHG emissions and MSA impact of one production system (see legend), within one agro-ecological zone. Regression lines are plotted. Prot. = protein.

3.2. Relationship between environmental criteria at local scale

Figure 4 shows the global distribution of synergies and trade-offs between GHG emissions and MSA impact. For both commodities, regions with a higher concentration of trade-offs included brazil and the western part of North America, as well as India for dairy production and western Europe for beef production. The rest of Europe Asia, and Africa showed more uniform proportions between synergies and trade-offs. Trade-offs tended to be more frequent in arid climate, grassland production systems and areas with high MSA values while synergies tended to be more frequent in temperate systems and area with higher yields.

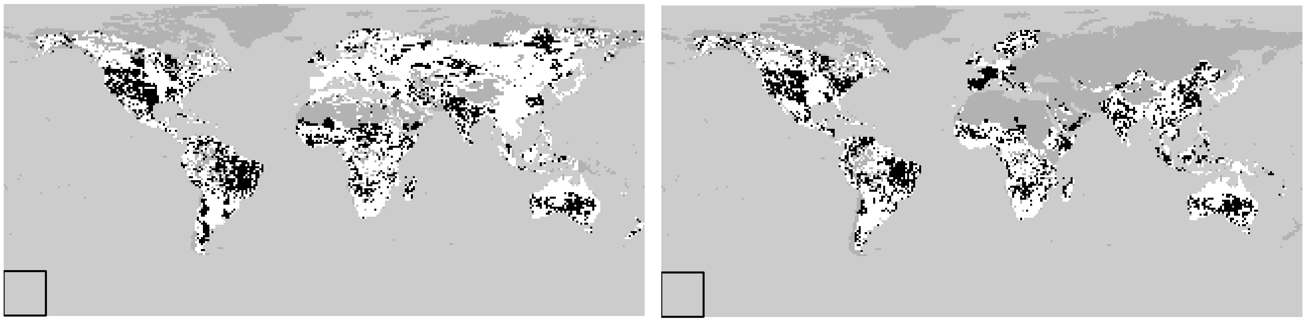

Figure 4. Relationship between GHG emissions and MSA impact per unit of production at local (grid cell) scale. (a) Dairy cattle; (b) Beef cattle. White = impact on the two environmental criteria are both lower or both higher than the sub-regional average (synergy). Black = impact is higher than the regional average for one environmental criteria and lower for the other (trade-off). Grey = no production. Black square = size of the moving window for the sub-regional averages.

4. Discussion

4.1. The MSA indicator

The MSA indicator is one of the very few biodiversity characterization factors for land use available at global scale. One limitation of the MSA indicator is that it does not make it possible to account for potential differences in conservation value, at the species and at the ecosystem levels. At the species levels, all species groups were included in the MSA. The MSA indicator is thus expected to be a good proxy for the overall biodiversity, although it is based on published literature where certain taxa are underrepresented (e.g., arthropods). However, common species and patrimonial or red listed species have the same contribution to the MSA. The IUCN red list is a widely recognized system for classifying species according to their risk of extinction and biodiversity indicators based on the red list are a useful tool for targeting conservation actions (Butchart et al. 2004). Characterization factors can be computed separately for common and red-listed species (e.g., in Koellner and Scholz 2008 for central Europe) but this distinction is not made in the MSA. Besides, while most biodiversity characterization factors are based on species richness (e.g., Koellner and Scholz 2008; Michelsen 2008; Schmidt 2008; Goedkoop et al. 2012), the MSA is based on species abundance which does not capture information about species extinction.

At the ecosystem level, the MSA value of each land use and intensity class is global and does not account for regional differences. It means that the biodiversity value of undisturbed forest – or the biodiversity loss following its conversion to pasture – is the same in Siberia and Amazonia for example. Yet, it is recognized that forests in certain specific areas are biodiversity hotspots (e.g., Amazonia, Dirzo and Raven 2003). The framework developed by the UNEP-SETAC Life Cycle Initiative (Koellner et al. 2013) includes a structure for including such regional differences, i.e. for the regionalization of land use elementary flows. Characterization factors computed by De Baan et al. (2013) follow this regionalization structure. The MSA indicator includes more precise land use and intensity classes, specifically adapted to livestock production. However, the absence of regionalization is a limitation. In the context of livestock production, the biodiversity value of grazing lands of varying intensity is very likely to differ between global regions. We accounted for one of these difference by making the assumption of extra MSA value to European grassland (compared to Alkemade et al. 2009; 2012) because they are very old ecosystems, although located in a forest ecoregion. Other differences were not considered; for instance, the management intensity threshold leading to rangeland degradation is lower in humid and arid regions than in temperate regions (Asner et al. 2004). Using information on rangeland productivity and livestock density would be an interesting development to regionalize the MSA values of grasslands and rangelands.

The UNEP-SETAC Life Cycle initiative recognizes that the effects of land use on biodiversity can be divided in three main stages that occur successively over time: land transformation, land occupation and land restoration (Lindeijer 2000; Mila i Canals et al. 2007). In this study, we only focused on occupation impacts. Calculating transformation impacts (e.g., impacts from land use change) and permanent impacts (i.e. impacts that cannot be recovered even after restoration) requires region and ecosystem specific data on the time and success of restoration (De Baan et al. 2013). Such data was not available; moreover the GLEAM model that we used to compute land occupation is a static model and its input datasets are not available as time series.

4.2. Impact categories coverage

The MEA (2005) recognizes five main driver of biodiversity loss at global scale: habitat change, climate change, pollution, invasive species and overexploitation. On a global scale, livestock production contributes directly or indirectly to each of these five drivers (Steinfeld et al. 2006). We focused on the habitat change driver and described it through land use only, which does not cover other of its components such as spatial heterogeneity and habitat fragmentation. This focus on land use leads our results to underestimate the overall biodiversity impacts. It also overemphasizes the role of productivity: productivity gains at feed production and animal level both strongly drive the calculated MSA impact. This results in a bias in favor of high productivity systems. Land use is expected to be the main driver of impact on biodiversity for extensive grassland systems which use large area to generate one unit of product because the conversion of grass to animal protein is rather inefficient (Wirsenius et al. 2011). Mixed systems and intensive grassland systems show higher yields, they need less area which limits their impact on biodiversity through land use, despite lower MSA values. However, they often involve important pollution that causes significant biodiversity impacts which are not captured in our results. This pollution includes two main categories. The first one is nutrient pollution which is associated with animal concentration (Peyraud et al. 2012) and can lead to biodiversity loss through acidification and eutrophication in soils and water (Carpenter et al. 1998). The second one is associated with higher input intensity; it is the release of ecotoxic components in the environment, mainly pesticides (at the feed production stage) and veterinary products (including hormones, at the animal husbandry stage). Hormonally active pesticides cause adverse effects on a wide range of organisms (Colborn *et al.*, 1993) and have recently been pointed as one of the responsible of bee population decline (vanEngelsdorp and Meixner 2010). Several veterinary products used on livestock have also been shown to impact biodiversity, such as anti-inflammatory drugs (Baillie 2004), hormones (Soto et al. 2004) or anthelmintics (Lumaret and Errouissi 2002).

Our results did not show significant differences in GHG emissions between grassland and mixed production systems. Adding the impact of climate change on biodiversity should not lead to important changes in the relative impact of grassland vs. mixed production systems on biodiversity. However, it could reveal new synergies between the two environmental criteria.

Many LCA studies on livestock focused on climate change as a single environmental criteria (see review in De Vries and De Boer IJM 2010). Adding land use impacts on biodiversity to the climate change impact is still far from a complete coverage of all the categories relevant to the environmental performance of livestock production at global scale. Interestingly, most of these additional categories are midpoint impacts which also have an effect on biodiversity. Including their assessment and their effect on biodiversity would be an important further development of our approach. Characterization factors to model their effect on biodiversity in LCA at global scale are still rare. In the MSA methodology, biodiversity characterization factors are also available for the impact of fragmentation and climate change (Alkemade et al. 2009). Other global characterization factors exist for climate change (Schryver et al. 2009), water use (Pfister et al. 2009) and ecotoxicity (Rosenbaum et al. 2008) while country to region characterization factors exist for eutrophication and acidification (Van Zelm et al. 2007; Struijs et al. 2011).

4.3. Implications

Across agro-ecological zones and at local scale, there was a weaker correlation and more trade-offs between GHG emissions and MSA impact in grassland production systems than in mixed production systems. In mixed production systems, feed mainly come from intensive land uses with low MSA values. Efficiency in the utilization of feed is a way to improve both environmental criteria. It makes it possible to use less area of intensive feed land uses with low MSA values, which also decreases GHG emissions associated with feed cultivation. At the same time, production is increased which leads to lower environmental impact per unit of product. In grassland production systems however, another option than efficiency to mitigate biodiversity impacts is to use more extensive feed land uses with high MSA values. This option can have contrasted effects on GHG emissions performances because more extensive systems have lower production levels and can be associated with higher emissions from manure deposition and enteric fermentation (Gerber et al. 2011).

By mapping synergies and trade-off between two environmental criteria on a global scale and at fine resolution, our method could provide a useful tool for spatially targeting interventions, or further investigations of the farming system properties. We reveal different relationships between the GHG emissions and biodiversity performances. The systems where performances on both criteria are higher in the surrounding region could be studied in order to apply beneficial management options to other systems, e.g., to those were performances on both criteria are lower than those of the neighboring systems. Systems were only one environmental criteria performs better than the surrounding region could reveal trade-offs between criteria that needs to be considered when designing interventions. Limitations of the implications of our results at the grid cell level include that certain parameters of the model only have a country resolution (e.g., animal's ration in OECD countries), and that management decisions could have different constraints across grid cells, even within a sub-region.

5. Conclusion

This study provides a tentative global quantitative assessment of the environmental performances of livestock production on two criteria: GHG emissions and biodiversity. It is a first attempt to develop multi-criteria assessments over such large scale, which are key to inform decision and action towards improving the overall sustainability of the livestock sector. Our preliminary results show that both synergies and trade-offs exist between the performances on the GHG emissions and biodiversity criteria. With our approach, more frequent and stronger synergies were found in mixed production systems where efficiency (i.e. decreasing the feed land use area while increasing production) could be a way to improve performances on both GHG emissions and biodiversity criteria. Weaker synergies and more trade offs were found in grassland production systems. Further developments, and testing of our approach are however required before results can be used for decision making. Improvements would include the inclusion of additional and regionalized biodiversity impacts.

Optimizing the LCA data processing for food products in the context of Life Cycle Sustainability Assessment: challenges and opportunities

Rémy Teuscher*, Jens Lansche, Thomas Nemecek, Gérard Gaillard

Life Cycle Assessment group, Institute for Sustainability Sciences, Agroscope, Zurich, Switzerland

ABSTRACT

Life Cycle Inventory (LCI) is the most time consuming and cost intensive part of a Life Cycle Assessment (LCA) study. This is especially the case for Life Cycle Assessment (LCA) of food products, where the numerous underlying agricultural systems represent generally a major part of the environmental impacts and a considerable amount of data to be collected. In particular the modelling of direct field and farm emissions requires a large amount of parameters (e.g. field management, soil properties, climatic conditions etc.) and involves iterative calculation loops at several levels (crop, field, farm and product). Through the generic tools SALCA*crop* and SALCA*farm*, an efficient and modular solution in the frame of Swiss Agricultural Life Cycle Assessment (SALCA) is already existing. Most of the LCA projects for field, farm or food LCA can be described in a workflow including SALCA*farm* and SALCA*crop*, but some adaptations are necessary according to the goal and scope of the project under study. In addition, if the data provider is not a LCA practitioner or a specialist in agriculture, a data collection tool must be developed. This was the case in the CANTOGETHER (Crops and ANimals TOGETHER) European project aiming at the environmental assessment of case-study farms and regions. Conventional LCA software tools such as Simapro 8, but also specific modeling tools such as *SALCAfarm*, *SALCA-BD*, *SPACSYS*, *RUSLE2*, and the *SIKtool-EFM* were integrated. To minimize the time-consumption of such adaptations and developments, a broader IT solution that can manage a high variety of LCA projects must be established in the future. Based on the experience of *SALCAcrop*, *SALCAfarm*, CANTOGETHER, and other LCA studies of food products, such a solution is under development: *SALCAfuture*. The main components will be a user-friendly data collection website, a centralized calculation and administration tool, and an analysis and assessment tool. SALCA*future* will be able to integrate a wide portfolio of LCA and eventually Life Cycle Sustainability Assessment (LCSA) projects from the agrifood sector. The various components will also be accessible to external users.

Keywords: farm and food LCA, direct emissions LCI, data collection, LCA tools

1. Introduction

The Life Cycle Inventory (LCI) phase is generally the most time consuming phase of a Life Cycle Assessment (LCA) study. In food LCA, the numerous and diverse underlying agricultural production systems contribute generally significantly to the environmental impacts (Weidema and Meeusen 2000). To estimate these impacts, the indirect emissions from the technosphere, but also the field and farm direct emissions must be modelled. This requires a broad and large amount of data: field management and related product use, soil properties, climatic conditions, animal and manure management, location, infrastructure, machinery, etc. This data is present at different levels from the crop, the field to the farm level. For food LCAs the impacts must be allocated to the product level, which requires additional data, for example the ratio of internal use and the amount of products that are bought or sold[1].

Concerning the calculations, the complexity is also present since several stages of iteration are necessary according to the crop, field, and farm and product level. In addition to this, the use of linear and non-linear models, and the high amount of data leads to the requirement of an efficient calculation procedure. This is achieved by SALCA*crop* and SALCA*farm,* generic tools for field or farm and product LCA.

Since their release, these tools were used in a considerable number of projects, and some experience could be gained regarding their future development. In addition, the recent discussion and development of conventional LCA in the direction of Life Cycle Sustainability Assessment (LCSA) establish the need for tools that can incorporate new sustainability metrics (Guinée et al. 2011). The goal of this paper is to describe the concept of a next-generation of tools for field or farm and product LCAs. Firstly, the current workflow of SALCA*farm* and SALCA*crop* will be briefly described with the perspective of a typical LCA project. Secondly, the workflow developed specifically for the project Crops and ANimals TOGETHER (CANTOGETHER 2014), including an adaptation of SALCA*farm* and the development of a flexible data collection tool will be presented. Finally the workflow of the next-generation of tools, in the frame of the project SALCA*future*, will be introduced.

[1] In this paper a product can be anything that the farm produces: a food product, but for example also energy from a bioenergy facility. C*rop level*, do not refers only to the crop product itself, but also to the calculation that requires data at the detail level related to the crop.

2. The workflow of SALCA*farm* and SALCA*crop*

The current tools used for field or farm and product LCAs are SALCA*crop* and SALCA*farm*. These generic tools were already described in detail in the reference Nemecek et al. 2010, in particular regarding the emission methods, the calculation procedure, and the impact assessment methods. In this paper we focus on the overall workflow with the perspective of a typical LCA project.

SALCAcrop and SALCAfarm are currently used for each project in the workflow of Figure 1, following the conventional phases of a LCA project. Firstly a data collection tool, generally based on Excel is used, or the data is entered directly in the input files PIfarm or PIcrop by LCA practitioners or agriculture specialists. This results in the agricultural Production Inventory (PI). In case a data collection tool exists, it was developed according to the specific goal & scope of the project. The development of such a tool can be intensive in terms of resources, in particular if the users aimed are for example farmers, and the required flexibility is high.

The next step is the calculation of the intermediate inventory, containing direct emissions, and inputs and outputs from technosphere. This is done with either SALCAfarm or SALCAcrop and results in an ecospold1 file that is imported in the conventional LCA software SimaPro7. It involves linear and non-linear calculations at the crop, field, and farm and product level with several direct emission calculation modules. The treatment of numerous farms is possible (batch processing). For most of the projects some adaptations are necessary, also according to the goal and scope of the study, for example the adaptation of national emission factors or the implementation of country-specific product commercial names.

Finally the results are imported and analyzed in SimaPro7 and extracted generally in MS Office tools for further assessment, analysis, and reporting. This includes several manual steps, which are reduced by generating one ecospold1 file with several farms in the case of a batch calculation procedure.

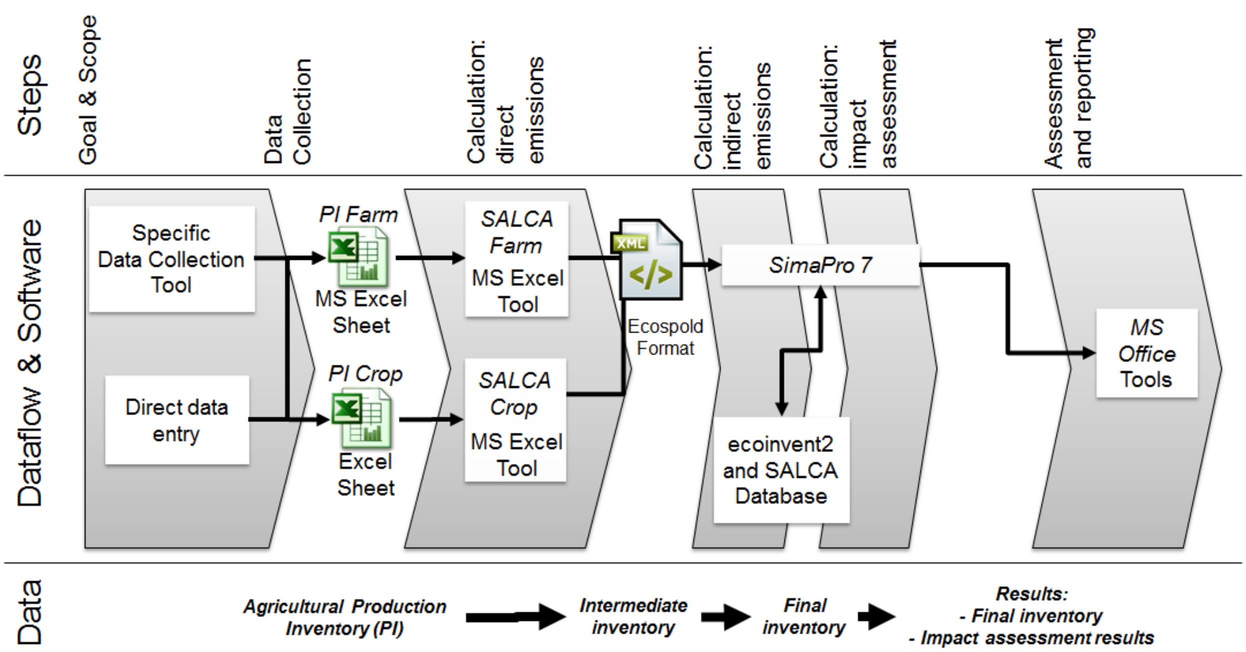

Figure 1: Current workflow, dataflow, and tools, according to the steps of a typical agricultural or food LCA project with SALCA*farm* and SALCA*crop*.

In this general workflow, the main strengths of SALCA*crop* and SALCA*farm* tools are:

- high scientific quality
- reliability, automation, and efficiency of the calculation of direct emissions at crop, field, and farm and product level
- modular construction of emission models (models parameters and calculation can be rapidly adapted to the goal and scope)
- possibility to perform batch calculation of several farms
- based on a conventional software (Excel) that is understood by a important share of the LCA practitioners or agriculture specialists, and that allows quick adaptations.

In practice, an important amount of projects requires the development of a specific data collection tool. In addition, although the modular construction of SALCA*crop* and SALCA*farm* allows some rapid adaptations of the models, this is not the case anymore if the adaptations change the input structure of the modules (e.g. adding new inputs, or increasing the detail level of the inputs). In summary theses developments and adaptations are time-intensive and may increase the resources needed to perform field or farm and product LCAs, depending on the goal and scope of the LCA project considered. In the next section we will illustrate theses adaptations by taking the example of the CANTOGETHER project.

3. The workflow of CANTOGETHER

In the CANTOGETHER project, a goal and scope was set with the assessment of 10 case-studies for 17 products and 7 scenarios. The case studies were made of either conventional farms, experimental farms, or pool of farms at regional level. Some case studies were containing an important number of fields, with a maximal number of about 45 fields. The data providers were agriculture specialists but could also be farmers in some cases. In this context, a data collection tool with demanding requirements for flexibility and user-friendliness had to be developed.

In addition, the methodological choices that were made for CANTOGETHER implied the use of various tools, including conventional LCA software tools such as Simapro 8, but also specific modeling tools such as *SALCAfarm*, *SALCA-BD*, *SPACSYS*, *RUSLE2*, and *SIKtool-EFM* (Cederberg et al. 2013). This resulted in the workflow described in Figure 2, with the following elements:

- **CANCollect:** Excel-based data collection tool. A high flexibility is available, with for example the possibility to add pesticides, mineral and organic fertilizers with the corresponding properties (e.g. N, P2O5, K2O content) and the possibility to describe field management events with a high level of detail (e.g. including the date of the event). The inputs of each modelling tools were analyzed in-depth and synergies were exploited in order to reduce the amount of data to be collected.
- **CANCalc:** Excel-based tool that contains two modules:

  1) The data transmission module, which extracts the data from CANCollect and implements it in each calculation tool (adapted SALCA*farm*, SIKtool-EFM, RUSLE2, SPACSYS, SALCA-BD). This includes some sorting, mapping, and database queries. In other words the data is translated from a user-friendly perspective to a software-friendly perspective.

  2) An adapted version of SALCA*farm* that controls the calculations and extracts the outputs of the SIKtool-EFM, SPACSYS and RUSLE2, and integrates new inputs and methods (e.g. for the water stress index). The inputs needed are at crop, field and farm level.

- **SIKtool-EFM:** Excel-based tool that calculates the livestock enteric fermentation and manure management emissions. The inputs needed are mainly at farm level (Berglund and Cederberg 2014).

- **SPACSYS:** C++ based stand-alone tool with inputs and outputs of all components organized as a database in either Microsoft SQL Server 2000, Access 2000 or MySQL5.0. This tool simulate root systems, nitrogen cycling, phosphorous cycling, water flows, plant growth and direct emissions (Wu 2013). The inputs needed are mainly at crop and field level, including daily data for weather and field management.
- **RUSLE2:** C++/SQLite based stand-alone tool that is used to compute the erosion caused by rainfall and its associated overland flow (USDA 2008). The inputs needed are mainly at crop and field level, including daily data for weather and field management.
- **SALCA-BD:** Java and Excel based tool that assess the impact of agricultural land use on biodiversity (Jeanneret et al. 2008). The inputs needed are mainly at crop and field level, including monthly data for field management.
- **CANAnalyse:** Excel-based tool that extracts the results of the various tools involved and allows in-depth analyzes.

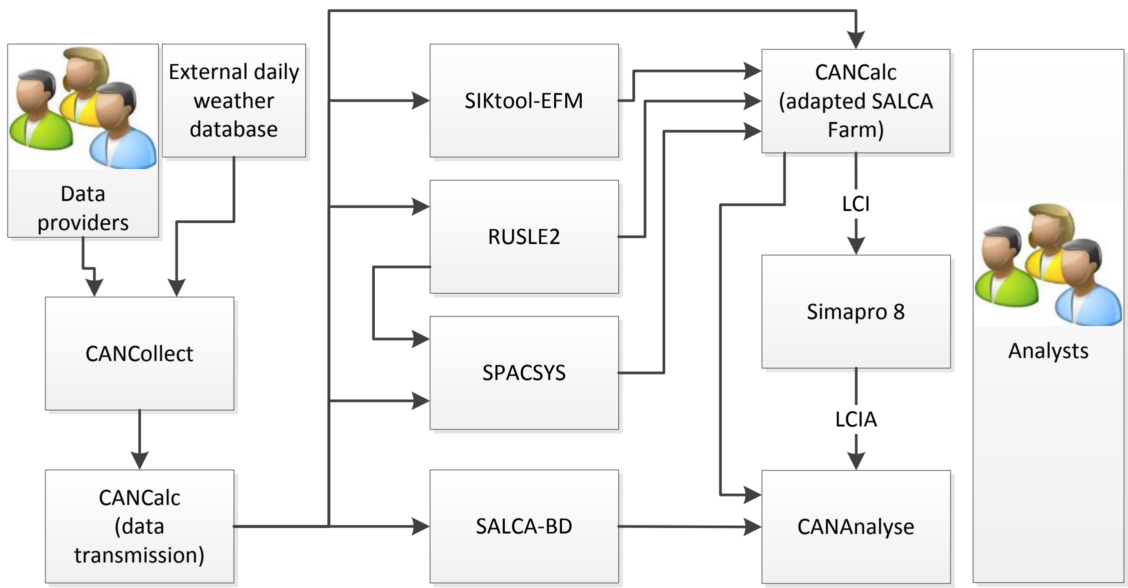

Figure 2: Workflow of the CANTOGETHER project, including the data collection tool CANCollect, the calculation tools (CANCalc, SIKtool-EFM, RUSLE2, SPACSYS, SALCA-BD and Simapro8) and the analysis and assessment tool CANAnalyse.

Most of the impact assessment results are calculated with the help of a traditional LCA software based on the inventory extracted from CANCalc. However, some tools deliver directly results at impact assessment level to CANAnalyse. For example, CANCalc provide the Water Stress Index (Pfister et al. 2009) for the water consumed at field level, and SALCA-BD provides a biodiversity assessment.

In summary, the development of the data collection tool CANCollect and the calculation tool CANCalc were resource intensive for the following reasons:

- Overall complex workflow for the data processing, with a high variety of links between the various tools
- Requirement of a user friendly data collection tool that can be transmitted to farmers and that allows to enter all the necessary data for the tools
- The presence of at least one crop or field level modelling tool with daily data requirements
- The presence of several stand-alone tools with their own lists of input data (i.e. their own terminology) and automation possibility
- The very large amount of data coupled with the presence of stand-alone tools: the overall solution must be automatized as far as possible.

Based on this experience of the CANTOGETHER project, the next generation of SALCA*farm* and SAL-CA*crop* should allow more extensive adaptations and avoid the development of a specific data collection tool for each LCA project.

4. The workflow of SALCA*future*

Projects in the field of agricultural or food LCA may have a high variety of goals and scopes which leads to different data collection needs, calculation models, and representation of results. As it was described in the previous sections, the tools SALCAcrop and SALCAfarm must be adapted and modified for most of the projects. In addition, the current excel input file is originally made for LCA practitioners and agriculture specialists and cannot be directly circulated to other stakeholders. This results in the development of specific data collection tools in most of the projects.

As described in the case of the CANTOGETHER project, some existing tools are already delivering some results at impact assessment level. This is due to the fact that some metrics are not integrated in traditional LCA software, because they are for example too specific to agricultural systems, or too recent. In the future, similar pathway would be necessary for new sustainability metrics that might not be supported in traditional LCA software (for example animal welfare, soil quality, social aspects etc.). Eventually this would allow integrating LCSA projects in the workflow presented before.

In this context, the project SALCAfuture was started with the aim of developing the next generation of SALCcrop and SALCA*farm*. The fundamental improvements are (Figure 3):

- A web-based application for the data collection, SALCA*collect*, with a high user-friendliness, and a data quality control. The data quality control will reduce the necessary number of data collection iterations.
- The merging of SALCA*crop* and SALCA*farm* in a centralized tool, SALCA*tools,* for the modelling of direct emissions. For the transparency and reproducibility of results, a version and user management will be implemented. In addition, it will be possible to import data based on .XML format
- The Implementation of Simapro 8 with the ecoinventV3 database
- A flexible analyzing and assessment tool (SALCA*analyse*)
- A high automation of the workflow
- A framework that allows the development of new sustainability metrics and eventually the integration of LCSA projects
- An improved accessibility for external user for SALCA*collect* but also for SALCA*tools* and SAL-CA*analyse.* This will improve the collaboration with partner in some projects, and also allow more transparency, allowing for example external reviews

In summary, SALCA*future* will be able to integrate a wide portfolio of LCA and eventually LCSA projects from the agrifood sector at an international scale. The web-application SALCA*collect* will, by definition, be easily circulated to any users, and will not require any installation of software. Typical users would be farmers, consultants in the agricultural sector, partners from others research institutes, or other specialists, and should be able to fill the data without any LCA knowledge. The modelling and calculation tool SALCA*tools*, and the analyzing and assessment tool SALCA*analyse* will be accessible to partners with LCA expertise, and will require the use of a widely available client software. The overall resources needed for the adaptations of the tools to a specific project will be reduced, allowing the data providers to enter data more efficiently and LCA practitioners to perform more in-depth assessments.

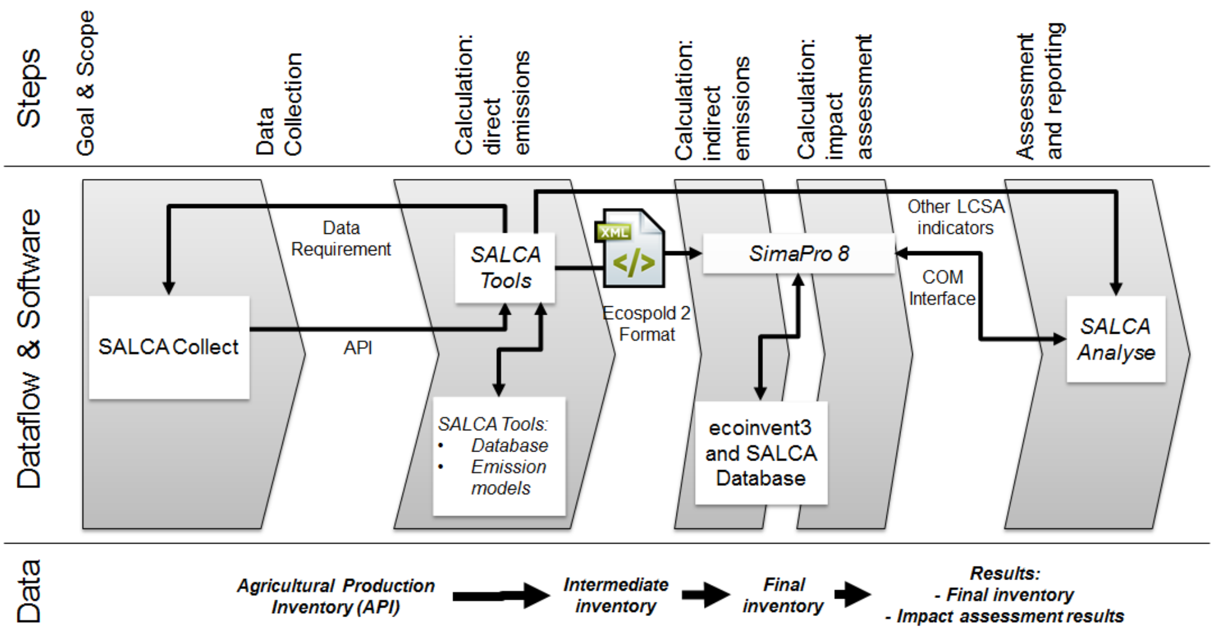

Figure 3: Workflow of SALCA*future* according to LCA Steps, dataflow, data, and the involved software.

6. Conclusion

In this paper, it was showed that current generic tools such as SALCA*crop* or SALCA*farm* can perform efficient calculation of Life Cycle Inventory (LCI) of agricultural systems. However, due to the very high variety of goal and scopes in LCA projects, a specific data collection tool must be developed, and some considerable adaptations of the existing tools must be achieved specifically for most of the projects.

This was typically the case for the project CANTOGETHER, with the development of a decentralized and flexible data collection tool, and with a vast adaptation of SALCAfarm including some integration of external stand-alone modelling tools.

Such developments and adaptations, specific for most of the projects, needs generally intensive resources and should be reduced with a higher flexibility of the tools. In addition, the specificity of agricultural systems and the emergence of Life Cycle Sustainability Assessment (LCSA) further increase the requirements in regards to the flexibility. To take these facts into account, the next generation of SALCA*crop* and SALCA*farm* was presented in the frame of the project SALCA*future*. In particular, SALCA*future* will handle these challenges and improve the availability of the tools for external users.

7. Acknowledgments

The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/ 2007-2013) under the grant agreement n°FP7-289328-CANTOGETHER.

ABSTRACT

Food service companies are important stakeholders in promoting sustainably produced and healthy foods. We worked in a transdisciplinary team to calculate the greenhouse gas emissions and virtual water demands of vegetarian and non-vegetarian meals in Germany using the LCA method. Partners from different scientific disciplines and the manager of a food service company as out industrial partner collaborated on the study's design and the definition of goal and scope. The result of the study was a management plan for the incremental implementation of short and long-term choices based on environmental sustainability indicators. The major reduction potential rests in shifting eating habits from quantity to quality, specifically to high quality organic meat and in using renewable energy during food preparation. Linking LCA to transdisiplinary approaches is important for the development of environmentally responsible choices considering the food service company's internal preferences and regional infrastructural constraints.

Keywords: food service, sustainable foods, carbon footprint, virtual water demand, LCA

1. Introduction

Individual eating behaviors and attitudes have lasting effects on the development of sustainable lifestyles. Establishing balanced global dietary patterns will be a major challenge in the coming decades as growing affluence is a major driver behind the increasing demand for food (Tilman et al. 2011). There is an increasing tendency towards eating outside the home. Such is the case for school meals, canteen meals and catering companies offering their services at events. In 2012, the turnover of the German food sector was about 68 billion-euro and the trend is rising. Therefore, food service companies are important stakeholders in promoting sustainably produced and healthy foods. In Germany, the contribution of organic products in the food sector is estimated at 300 million-euro per year which is 0.5 % of the total market for organic food products (MKULNV 2010).

Over the past several years, different communication labels such as primaKlima, EMAS or Stop Climate Change were established to certify a climate friendly and sustainable performance of companies and effort were made to develop sustainability standards for restaurants (e.g. Baldwin et al. 2011). At first glance, the definition of system boundaries and functional units are often not recognized. In order to have a tool to transfer knowledge to consumers, especially in the food service sector, it makes more sense to relate environmental impacts to kilocalories than to kilograms of food. Most of the studies aiming to support sustainable decision making focus on the ecological perspective and underestimate the complexity of economic and social aspects (Binder et al. 2012).

In this study, we worked in a transdisciplinary setting in order to extend the research beyond the specialized knowledge of ecological dimensions of food provision. We valued this transdisciplinary approach as a means to fundamentally understand the situation of food service companies and discover solutions using problem-driven research. Despite a long tradition of application to questions of sustainable development, neither trans- nor interdisciplinary research approaches are strictly defined. The two approaches are also often applied simultaneously. In our understanding, a transdisciplinary approach combines and synthesizes scientific systems and societal systems (Hirsch-Hadorn et al. 2006).

Therefore, depending on specific aims, food service companies have several options for environmentally responsible choices regarding their services. We conducted our study using an LCA framework with the goal of identifying leverage points and priorities for reducing climate impacts and the water use for small and medium enterprises.

2. Methods

In our study, we cooperated with a food service company that runs a canteen kitchen and a catering service. Our industry partner has observed a rising demand amongst costumers for quality food and an interest in environmental impact labeling of the company’s foods. We worked in a mixed team with partners from different scientific backgrounds, including ecology, economics and nutritional advisers. In order to address problem-driven research questions, the manager of the food service company played an important part in the team, providing practical viewpoints that brought new insights to the scientific partners. Using this transdisciplinary approach, we collaborated with our partners to define specific questions to be answered over the course of the project.

The project’s starting workshop provided the platform for intensive discussions with all partners resulting in the definition of the goal and scope of the LCA, as well as the definition of the functional unit. Moreover, the definition of the system boundaries and samples for sensitivity analysis were settled. We first focused on climate impacts as the key indicator of environmental performance of two standard dishes served in the food service canteen. We choose a vegetarian and a non-vegetarian plate. Table 1 gives details on the different ingredients. One of the food service company’s typical dishes is couscous with mixed vegetables accompanied with a full-fat sour cream used as a flavoring ingredient. In order to evaluate the differences in environmental impact of beef and pork, we choose typical German meatballs with gravy and potatoes. The meatballs are composed of 50 % pork and 50 % beef meat. We also conducted an analysis of the water demand of both dishes, which we termed virtual water demand. The virtual water demand was calculated in order to evaluate potential tradeoffs between the two indicators.

Table 1. Isocaloric meal ingredients and baseline for the identification of reduction measures

Lunch plate	Ingredients	Energy content [kcal]	Contribution [%]
Vegetarian	Couscous	68	14
	Vegetable mix (corn, pepper etc.)	34	7
	Olive oil	21	4
	Sour cream	378	76
	Total	500	100
Meat	Meatballs	374	75
	Gravy	5	1
	Potatoes	121	24
	Total	500	100

The functional unit was one portion of a typical German vegetarian and non-vegetarian dish offered by the company. Considering the importance of nutrition to the consumers, we used the energy content as functional unit for representing the results. We evaluated two isocaloric diets, one vegetarian and one non-vegetarian dish à 500 kcal from “farm-to-fork” (Baldwin et al. 2011). The meal ingredients are presented in Table 1. GHGE (greenhouse gas emissions) and water use were analyzed from agricultural production and its upstream supply processes (e.g. animal feed, fertilizers) along the supply chain to the serving counter in the canteen regarding food processing steps (such as slaughter), storage, and food preparation in the canteen kitchen (see Figure 1). Primary data from the canteen’s most important suppliers and processing companies were collected via questionnaires and in interviews. The catering company provided data and energy use on food preparation and food wastes, as well as cooking and chilling techniques, and the re-heating of the meals in the canteen.

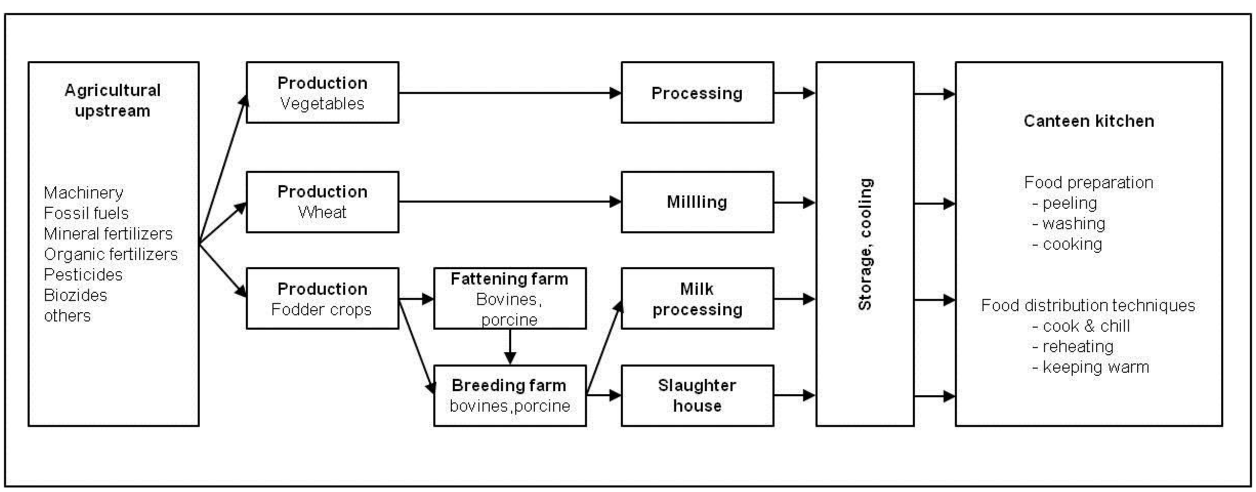

Figure 1. System boundaries for a typical lunch plate offered by the food service

2.1. Analysis of climate effects (GWP) and virtual water demand

This study used the life-cycle-assessment (LCA) method, following the ISO 14040 and 14044 standards (ISO 2006). The calculation of the carbon footprint was carried out using the SimaPro software, as well as the GEMIS 4.42 and ecoinvent v2.2 databases. The carbon footprint was calculated according to IPCC (2006). Primary data on agricultural production systems, specifically regarding yields, fertilizer input, cropping systems and supply chain, was available directly from the food service company's suppliers in Germany. Gaps in the data were filled with data from comparable agricultural production systems in similar climatic conditions in Austrian regions (Hörtenhuber et al. 2011, Lindenthal et al. 2010). Data on regional transport, including the different means of transport (truck size, refrigerated transport) and transport distance were obtained from questionnaires. Data on imported vegetables from South Spain, specifically on agricultural production, processing and means of transport, were obtained from Theurl et al. (2014). Food waste factors, obtained from primary data of the food service company for meat, fresh and frozen vegetables, were considered in the calculations of GHGEs and water use. The calculation of GHGEs is based on a specific, locally-adapted farm model in which methane emissions, as well as direct and indirect N_2O emissions are considered in the calculation of the GWP (Theurl et al. 2014; Lindenthal et al. 2010). Direct and indirect emissions due to land use changes from feedstuffs were also considered in our methods (Hörtenhuber et al. 2011). These farm models are also the basis for the evaluation of water demand. The calculation of the water demand is based on studies from Hoekstra et al. (2011) considering water use in different contexts. First, we considered "blue" water, which is consumed during production processes, including irrigation, cooling and water consumed in cleaning. Secondly, we included "green water" from precipitation and evapotranspiration of different crops and soil types (Asamer et al. 2011). Thirdly, we accounted for a theoretical water fraction called "grey" water that is necessary to dilute or assimilate a certain amount of pollutants in water bodies (see Mekonnen and Hoekstra 2011; Hoekstra et al. 2011, Chenoweth et al. 2013; Hörtenhuber et al. 2014). The virtual water demand is the sum of blue, green and grey water in liter per meal portion (500 kcal), whereas the climate effects defined by the GWP is depicted in kg CO_2eq per meal portion. The baseline for the identification of promising measures that entail a reduction of GHGE and water consumption is the conventional production system for beef and pork meat, as well as vegetables and potatoes. Natural gas for cooking and the average German electricity mix were considered as the baseline in both variants. An incremental plan was established that considered the use of organic livestock-based and vegetarian ingredients and the implementation of renewable energy sources, as well the use of frozen products.

3. Results

Following our transdisciplinary approach, we started with the identification and discussion of the most important questions to be addressed in the LCA. Intensive discussions resulted in the development of an incremental action plan that offers incentives to food service companies in order to implement feasible and ecologically responsible choices based on a baseline. We focused on three key questions:

1. What are the potential net savings from the implementation of green electricity in the canteen?
2. How much is the environmental impact of organic products especially organically produced meat?
3. What is the GHG mitigation potential of regionally produced vegetables versus imported ones?

The results for the GWP and the water demands of the vegetarian conventional (VC), vegetarian organic (VO) and non-vegetarian with conventional ingredients (MC) and the non-vegetarian plate with organic ingredients (MO) are presented in Figure 2. The column on the very left of each variant represents the initial baseline from which the incremental reduction measures of each indicator started. The baseline maximum magnitude is reached by the meat meal resulting in a water demand of 2,000 l and in a GWP of about 1.60 kg CO_2eq per portion. The baseline maximum of the vegetarian plate portion is considerably lower with a demand of 600 l water and 0.7 kg CO_2eq per portion. Farming stages contribute significantly to both indicators, especially for the meat variant.

The results show that the total sum of blue, green and grey water demand of the baseline meat plate is more than 70 % higher than the water consumption of the baseline vegetarian plate resulting in a potential water reduction of approximately 1,200 l per plate portion The virtual water demands are dominated by the water consumption of the agricultural production stages, whereas processing energy and transport have no visible impact on the overall water use for the vegetarian and the non-vegetarian plates. Although couscous contributes to only 14 % to the total energy content of the meal, it is related to a water consumption that is 300 l per portion. A switch to organic meat leads to a reduction of the virtual water demand of 305 l (17 %). Less significant would be a switch to organically produced vegetables where a reduction of 8 % or 50 l per portion could be obtained. According to our method, the water demands of the specific ingredients show wide ranges, the highest being for beef. In general, the overall virtual water demand and the advantages related to organic production systems were found to be related to grey water. Further, the results for livestock products are mainly dependent on the composition and quantity of the animal's diets and the related grey water content of the feedstuffs.

Our methodological approach to climate impacts (in terms of GWP) offered a more detailed picture in relation to potential ecological reduction measures based on the plate portion. The carbon footprint of the baseline is represented on the very left of the right half of Figure 2, which is followed by three respective potential reduction measures. Apart from beef and pork dominating on total GHGE per portion, cooking energy has a significant effect on total emissions per portion. Here, cooking energy is the sum of all preparation processes in the canteen kitchen including chilling and regeneration techniques, which are used in our project partner's food service and catering company. The implementation of organic meat was found to have a GWP reduction potential of more than 20 % (0.353 kg CO_2eq) including slightly lower cooking losses of the organic meat. The results show, that potatoes contribute 1-2 % of the total GHGE in the meat variant, which indicates negligible opportunities for reduction. The implementation of green electricity for the cook&chill and re-heating techniques has a potential reduction of 7 % related to the baseline, however in combination with organic meat and potatoes the reduction is about 40 % compared to the baseline. A total switch in the regenerative energy source in the canteen combined with organically produced ingredients reduces total GHGE by slightly more than 1.0 kg CO_2eq which is still higher than the vegetarian baseline.

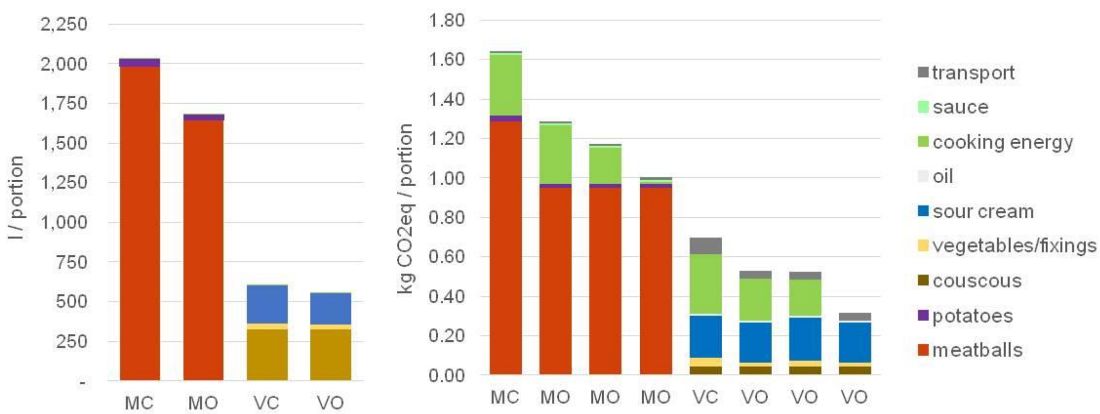

Figure 2. Virtual water demand (left part of the figure) and Global Warming Potential of vegetarian and non-vegetarian meals per portion after cooking, chilling and re-heating. Columns represent different plate variants and show incremental reduction measures. Conventional and organic ingredients were compared. MC: meat meal conventional; MO: meat meal organic; VC: vegetarian meal conventional; VO: vegetarian meal organic.

In the vegetarian meal variant, sour cream is of animal origin and contributes 0.3 kg CO_2eq to the total GWP. It can be seen from Figure 2, that a switch to sour cream from organic milk has a negligible reduction potential overall. The analysis shows that transport makes a higher contribution to the total GHGE per portion in vegetarian conventional and organic plates than in the non-vegetarian plates. Nevertheless, emission reductions due to the regional production of ingredients (presented in the first column) are negligible in comparison to the baseline and can easily be outweighed by calculation and data uncertainties. Although frozen vegetables from organic production show higher GHGE compared to the fresh organic variant, GHGE are found to be lower than a fresh conventional vegetables mix imported from Spain (regarding GHGE from agriculture and related upstream processes). However, in the case of a typical vegetarian meal with couscous and sour cream, no GWP reduction effect of using either fresh or frozen vegetables could be shown in our analysis. A considerable reduction potential is employing renewable energy to prepare vegetarian foodstuffs in the canteen kitchen. A switch from the average German power mix to green electricity for cooking, chilling and re-heating techniques in vegetarian plates could reduce the GWP of the vegetarian plate by 60 %.

4. Discussion and conclusion

Our current food systems are complex and ecologically, economically and socially unsustainable. Today, there are more people suffering from overnutrition and obesity than from undernutrition and related diseases (Searchinger et al. 2013). Due to the rising trend in out-of-home eating, food service companies are important stakeholders promoting sustainably produced and healthy foods.

Our results show that in addition to general suggestions of environmentally friendly measures, specifications on the energy mix used in the canteen kitchen should be considered. Substantial reductions of the climate effect, at least 22 %, can be achieved by switching from non-vegetarian to vegetarian plates (e.g. Stehfest et al. 2009, Carlsson-Kanyama and González 2009). Virtual water demands can be reduced by 17 % by shifting meat-eating habits from quantity to quality, specifically high quality organic meat., Beyond the impact of meal ingredients (directly related to consumer preferences), reduction potential also exists in the preparation of dishes and the selection of raw materials (an executive chief's decision). In German kitchens green electricity can reduce GWP considerably, because energy consumption from food preparation is a major contributor to total GWP, with a maximum of 65 % in vegetarian dishes and up to 30 % for non-vegetarian dishes. The virtual water demand is the lowest for the organic vegetarian dish with net gains of 1.126 – 1.431 l water per portion compared to the non-vegetarian variant. Plastically speaking, these amounts of water could be used to fill at least six bath tubes. The results show, that the virtual water demand of meat and vegetal ingredients is dominated by the amount of the grey water, which is calculated as the theoretical assimilation of nutrients in water bodies. Represented by grey water demand, the assimilation of nitrate and other harmful substances (such as pesticides) is 52 % and 33 % for conventional and organic meat ingredients respectively. For conventionally grown cereals and vegetables the share of grey water is 63 % and 41 % for organic products. It is evident that there is a close relation between our virtual water demand methods and the eutrophication potential commonly calculated in life cycle assessments (e.g. Saarinen et al. 2012).

One methodological limitation of our approach is that we assessed the environmental performance and reduction measures of lunch plates based on an isocaloric comparison instead of using a unit based on the nutritional quality of vegetarian and non-vegetarian plates. A detailed analysis of the environmental impacts based on the nutrient content of foods is desirable for further research. Nevertheless, carbon footprint and virtual water demands show similar performances regarding the incremental reduction plan based on the caloric value of meal portions. A relevant difference is that in order to reduce the virtual water demand per meal plate one would not consider the implementation of green. In a sensitivity analysis we considered the use of water power solely for the cooking, chilling and regeneration processes based on Mekonnen and Hoekstra (2012). The results showed that there is no meaningful impact on the total water demand for the non-vegetarian or vegetarian meal due to the use of hydropower.

One of the research questions addressed the differences between fresh and frozen vegetables, as this measure is easily implemented and reasonable in terms of cost from a food service company's perspective. We further wanted to evaluate the potential of frozen organic vegetables for consumption of organic vegetables produced regional but consumed outside the growing season. Here, we relied mainly on primary data and uncertainties were considered high. Although we found that frozen organic vegetables had a lower climate impact than conventional fresh vegetables and a slightly higher GWP than organic fresh vegetables, we did not consider the implementation of frozen vegetables as a major measure to reduce greenhouse gas emissions of food services companies based on a comparison of plate portions. We did not consider a detailed assessment of refrigerants that are related to a high amount of GHGE and which might lead to even higher GHGE from frozen products. The results show that the import of fresh organic non-seasonal vegetables including long distance transport would only have a small reduction potential compared to imported conventional vegetables. The latter would be overshadowed by uncertainties in the preparation process and waste along the supply chain and the use of animal-based side dishes such as sour cream.

This transdisciplinary approach enabled us to (re)act closely to the food service demands related to sustainability indicators. According to the manager of the food service company, data on the environmental impact is needed to directly inform the consumers in the canteen or to integrate labeling schemes directly in the menu. According to experiences of the food service company, consumers felt good about the fact that vegetables in the non-vegetarian meal are from organic production. An additional use of organic meat would require a much higher price per lunch portion and so far only few costumers are willing to pay more in our example. However, our results show that for the carbon footprint and virtual water demands, implementing organic potatoes has no potential reduction effect. Consumers tend to underestimate and misinterpret the complex interactions between raw material production, imported and regionally produced vegetables, and food processing. Integration of consumers in a transdisciplinary working group could help overcome this difficulty and could help researchers to better understand the preconditions under which consumers are willing to pay a higher price for sustainably produced food in canteens.

We conclude that taking environmentally responsible choices and measure for a reduction of the carbon footprint and virtual water demands in food service companies rely strongly on regional infrastructural constraints and company’s internal preferences and strategies. The outcomes of our calculations and the valuable discussions with the partners provided the basis for the establishment of a 5-minute-check online tool where small and medium sized food service companies are able to evaluate the performance of their supply chains in terms of GWP (http://klimae3.fiblprojekt.de/).

ABSTRACT
This study aims to present an incorporated model between multi-objective linear programming (MOLP) and life cycle assessment (LCA). The model is to determine an appropriate choice of variables involved in the packaging system for canned tuna products. By the demonstration through a single-serve two-piece can, the results showed that the MOLP technique yielded feasible solutions in term of quantities of raw materials required to use in two-piece can for tuna products with satisfaction of various constraints pertinent to the production. The optimal solutions relating to objective functions of the environmental impact's carbon footprint and total economic cost relating to the packaging production are 4,767 kg CO_2 eq and $US 8,994.57[1] respectively. To this end, such optimal practicable environmental model can be beneficial as a decision-support tool not only to the production of canned tuna packaging, but also to other businesses alike to achieve an optimal packaging solution that compromises both economic and environmental aspects.

Keywords: multi-objective linear programming (MOLP), carbon footprint, economic cost, two-piece can, optimal solution

1. Introduction

For many manufacturers over the global regions, the environmental impact throughout a packaged-product's life cycle has become as important issue due to the present packaging directives and regulation for the environmental impact of all products. The manufacturers are not only experiencing an increasing concern in order to alleviate the environment pressure, but they have to seek ways to survive in the market competitiveness by reducing the production cost and achieving the high profit. Upon reacting to such conflict of interest, it is necessary to the manufacturers to make a decision in such a way that the environmental and economic issues are compromised.

Carbon footprint is now being applied in many products and has become part of public consciousness. It is an acclaimed measure of the emitted greenhouse gases (GHGs) produced through burning of fossil fuels for electricity, heating and transformation, and so on. The extent of GHG is expressed as kilograms of carbon dioxide equivalent (kgCO_2 eq) (Muthu et al., 2011). The approach for calculating the product carbon footprint into four steps: process mapping, determination of the problem boundaries, data collection, and calculation for carbon footprint. Carbon footprint is therefore the environmental information delivered from the product manufacturers to their consumers.

Costing issue is one of main considerations for most product manufacturers. In general, a higher product production cost may be incurred if manufacturers determine to opt for a superior packaging system in functionality in order to maintain the product quality. Also, it usually occurs that such packaging selection based upon the innovation concern can result in a contradiction as the environmental implication is increased. For instance, excessive product protection than necessary (over-packaging) is chosen and the packaging waste management at the end-of-life can be difficult. It is therefore important for manufacturers to select the right packaging system that can increase consumer satisfaction while having minimized environmental impact and economic cost (Monte et al., 2005; Poovarodom et al., 2011).

A single-served canned tuna has been responded the modern life-style. Through the product's life span, the associated costs related to the production of the canned tuna packaging include costs of raw materials, labors, manufacturing and operation, and last but not least, transportation. In the environmental aspect, all said activities of the canned tuna production could induce GHG emissions that directly influence the environment condition. It therefore has driven pressures to the food industry in order to reduce the carbon footprint associate with the product (Poovarodom et al. 2011).

Many studies for the environmental impact in food industry have emphasized solely one aspect without taking others into account. Poovarodom et al. (2011) showed that the manufacturing process of retort pouches and cups produced 60% and 70% less greenhouse gas emissions than that of metal cans. However, the overall carbon footprint of canned tuna in retort cups was 10% and 22% less than that in metal cans and retort pouches, respec-

[1] $US 8,994.57 (Equivalent to 287,826.13 THB; $US 1 = 32 THB)

tively. As the result, the retort cup packaging system possessed a significant advantage over metal can and retort pouch in term of overall GHG emissions. Packaging and its associated processing constituted significant fractions of the product's carbon footprint, ranging from 20% to 40%.

Zabaniotou and Kassidi (2003) compared the environmental impact of two egg packages made of polystyrene and recycled paper. The study indicated that recycled paper eggcups had less environmental impact than polystyrene ones. This is because, throughout its life cycle, the polystyrene eggcup had more contributions to acidification potential, and winter and summer smog, while recycled paper eggcup had contributions to heavy metal and carcinogenic substances.

Monte et al. (2005) adopted the life cycle assessment to determine a choice of coffee packaging. By comparing coffee packaging in five categories: 125-g cans, 250-g cans, 3-kg cans, cans with 36 single-use coffee servings, and poly-laminate bags with 40 single-use coffee servings (280g). The study indicated that the bigger packaging size of the metal cans, the more reduction of environmental impact. With a bigger size is only available for niche market and a smaller package is a marketing prerequisite, a laminated plastic bag is therefore recommended as an alternative, due to slight increase for the environmental impact.

Linear programming (LP) model can be incorporated with the life cycle assessment (LCA). This is because LCA is based on linear relationships between activities and environment burdens. LP can be used to allocate environmental impacts in the impact assessment of LCA. The LP solution not only gives the environmental optimum of system as a part of the improvement stage, but also incorporates economic and social aspects of the system (Azapagic and Clift 1988; Azapagic and Clift 1995). However, goals toward the economic and the environmental aspects usually contradict to each other. Multi-objective linear programming (MOLP) can be employed to resolve such conflicts and to determine the best compromised solution. MOLP is a multiple criteria decision making. It is concerned with mathematical optimization problems involving minimizing or maximizing multiple objective functions simultaneously. Optimal decisions need to be taken in the presence of trade-offs between two or more conflicting objectives. This approach provides a decision making tool which can help the businesses to identify a path to sustainable development by establishing good trade-off between economic cost and environmental performance in term of carbon footprint.

In this study, MOLP is developed as an optimal practicable environmental model in order to determine the appropriate choice of packaging system by using two-pieces can for the canned tuna products as a case study. The trade-off between two objectives between minimized total cost and minimized carbon footprint is considered. The aim of the study is to enhance the application of MOLP at the early stage of a new product development and a product improvement.

2. Methods

2.1. Functional unit and system boundary

The demonstration through a single-serve two-piece can packaging is used. The packaging features consist of chrome-coated steel for can and a pull-ring aluminum tab closure. The two-piece can considered in this study is the plain can (no printing on it). The 85-gram packaging size is considered. Such size is regularly available for retail and becomes standardized for one single serving (Figure 1).

The functional unit is defined as 90,000 cans, equivalent to one pallet of end shell and three pallets of can body. The model is developed under assumptions in which the production of tuna, filling, storage, and disposal are excluded. The system boundary is considered as cradle-to-gate (Figure 2). It spans the acquisition of raw materials, manufacturing, and transportation. Other additional packaging types used in each individual process such as tier sheets, low-density polyethylene (LDPE) film, paper pallet tags, and polypropylene (PP) strapping are also included in the study.

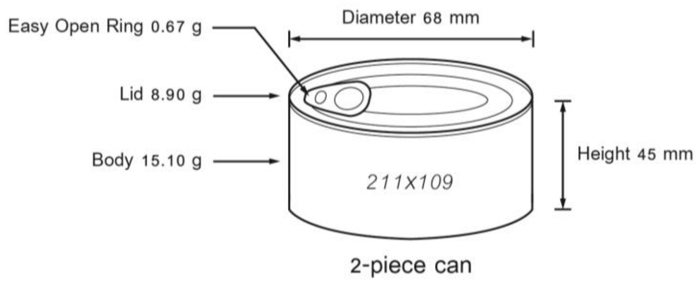

Figure 1. Two-piece can that use in the study.

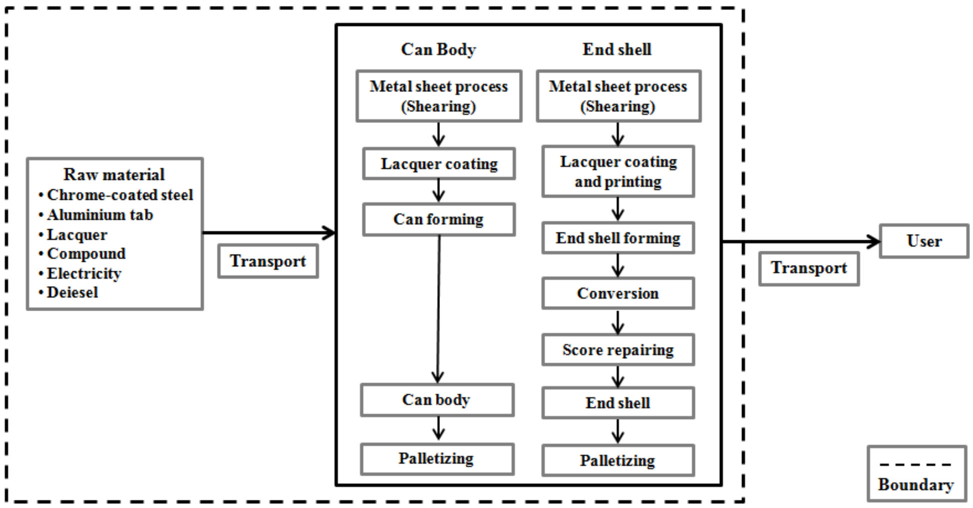

Figure 2. System boundary of two-piece can for tuna products.

2.2. Inventory analysis

Life cycle inventory (LCI) is collected from primary data (Table 1.). It is derived from questionnaires and by mean of interviewing personnel from can suppliers. Secondary data from literature and database are also used. Emission factors are obtained from Thai National Database (Thailand Greenhouse Gas Management Organization 2013) and some are provided from can suppliers.

Economic costs considered in this study include costs of materials, energy consumption, operation, and transportation. The unit costs are collected from can manufacturers.

Table 1. Information on raw materials and two-piece cans

Raw material	Source	Type of shipment	Distance (km)
TFS steel sheet	Thailand	Truck (10 wheels)	204
Lacquer A for can body	Thailand	Truck (6 wheels)	20
Lacquer B for can body	Thailand	Truck (6 wheels)	69
Lacquer C for end shell	Thailand	Truck (6 wheels)	36
Lacquer D for end shell	Thailand	Truck (6 wheels)	90
Lacquer E for end shell	Thailand	Truck (6 wheels)	36
Aluminum Tab	America	Ocean freighter	16,469
Solvent	Thailand	Truck (6 wheels)	30
Wax	Thailand	Truck (4 wheels)	50
Tab lube	America	Ocean freighter	16,718
Compound	Thailand	Truck (6 wheels)	36
Ink	Thailand	Truck (6 wheels)	80
Layer paper sheets	Thailand	Truck (10 wheels)	140
Linear low-density polyethylene	Thailand	Truck (6 wheels)	18
Polyethylene	Thailand	Truck (6 wheels)	33
Plastic strapping	Thailand	Truck (4 wheels)	30
Paper bag	Thailand	Truck (6 wheels)	20
Wood pallet	Thailand	Truck (6 wheels)	7

2.3. MOLP model

As previously mentioned, two objective functions considered in the study are total carbon footprint and total economic cost. The MOLP model is able to formulate and yield the optimal solution by using spreadsheet solver in Microsoft Excel. Steps for developing the model are described in the following.

Decision variables: The decision variables are quantity of raw materials and packages. The decision variables are expressed as X_j (quantity of raw materials in production of can body type *j* in kg) and Y_j (quantity of raw materials in production of end shell type j in kg). The decision variables are showed in Table 2.

Table 2. Decision variables for two-piece can system.

Production	**Decision variable**	**Description**	**Unit**
Production of can body (X_j)	X_1	Quantity of TSF steel sheets	kg
	X_2	Quantity of Lacquer A	kg
	X_3	Quantity of Lacquer B	kg
	X_4	Quantity of solvent	kg
	X_5	Quantity of wooden pallets	kg
	X_6	Quantity of layer paper sheets	kg
	X_7	Quantity of top wooden frames	kg
	X_8	Quantity of stretch film	kg
	X_9	Quantity of plastic strapping	kg
	X_{10}	Quantity of paper pallet tags	kg
Production of end shell (Y_j)	Y_1	Quantity of TSF steel sheets	kg
	Y_2	Quantity of lacquer C	kg
	Y_3	Quantity of lacquer D	kg
	Y_4	Quantity of lacquer E	kg
	Y_5	Quantity of solvent	kg
	Y_6	Quantity of ink	kg
	Y_7	Quantity of compound	kg
	Y_8	Quantity of Al Tab stocks	kg
	Y_9	Quantity of tab lube	kg
	Y_{10}	Quantity of repairing lacquer	kg
	Y_{11}	Quantity of wooden pallets	kg
	Y_{12}	Quantity of wrapping paper	kg
	Y_{13}	Quantity of shrink bag	kg
	Y_{14}	Quantity of stretch film	kg
	Y_{15}	Quantity of plastic strapping	kg
	Y_{16}	Quantity of paper pallet tags	kg

Objective functions: In order to determine the optimal solution for two-piece can system, two objective functions are minimized total carbon footprint (Z_1) and minimum total economic cost (Z_2).

$$Min\ z_1 = \sum_{j=1}^{n} e_{ij} x_j \qquad \text{Eq. 1}$$

$$Min\ z_2 = \sum_{j=1}^{n} c_{ij} x_j \qquad \text{Eq. 2}$$

where e_{ij} is emission factors related to raw materials, electricity, and transportation of raw material type *j* with objective *i* (i.e., *i* = 1, 2); C_{ij} is unit costs of raw materials, transportation, and operation for two-piece can system.

Constraints: Constraints concern mass balance and assured quantity of raw materials for two-piece can.

$$\sum_{j=1}^{n} x_j = m_b \qquad \text{Eq. 3}$$

$$S_{j(\min)} \leq x_j \leq S_{j(\max)} \qquad \text{Eq. 4}$$

where m_b is process outputs; $S_{j(min)}$ and $S_{j(max)}$ are minimum and maximum quantity of raw material type *j* in each process.

Target values: Each objective has its target value (t_i). However, percentage deviation from each target value will be calculated. Later, the weighted percentage deviation of each objective function is also determined (Ragsdale CT 2007). In this study, the weights factors depend upon the importance of each objective and can be derived from the interview according to preference of can manufacturers. The weight of importance for total carbon footprint is 2.7 while the total economic cost has been given to 3.3.

$$\textit{Percentage Deviation} = \frac{\textit{Actual value} - \textit{Target value}}{\textit{Target value}} \qquad \text{Eq. 5}$$

$$\textit{Weighted percentage deviation} = \textit{Weight factor} \times \textit{Percentage deviation} \qquad \text{Eq. 6}$$

MINIMAX objective: It minimizes the worst-case values of a set of multivariate functions, possibly subject to linear constraints. The MINIMAX objective is going to minimize the maximum of weighted percentage deviation (Q) (Ragsdale CT 2007).

Objective function: *MIN: Q* Eq. 7

Constraint: *Weighted percentage deviation* $\leq Q$ Eq. 8

Decision variable: Q

The optimal solution: Considered by decision makers.

3. Results

In this section, the results of the study are divided into three parts. The first part showed target values of each objective. The second part indicated weighting scores. The third part showed the optimal solution that is compromised both objectives on the environmental and economic cost aspects for two-piece can.

With LP technique by considering a single objective function and solving to find the solution of each objective, The results can be found as shown in Table 3. It indicates that if only total carbon footprint as a single objective function is determined, the model yielded the value of 4,745 kg CO_2 eq while the total economic cost was $US 8,994.40 (Equivalent to 287,820.65 THB; $US 1 = 32 THB). However, if the total economic cost as a single objective function is determined, the model yielded the value of $US 8,993.31 while the total carbon footprint was increased to 4,781 kg CO_2 eq. According to the results, it seems apparent that both objectives contradict to each other. As the result, the LP model could not yield the optimal solution for both objective functions simultaneously. If there is one objective function producing a better result, the solution of the other objectives becomes worse. With this reason, MOLP is taken in in order to solve for the optimal solution. However, the weighting factor of importance is needed to apply as earlier mentioned in Section 2.3.

The weighting scoring is a valuable decision-making tool. It is used to evaluate alternatives based on specific evaluation criteria weighted by importance or priority (Zimmer DA 2011). By evaluating alternatives based on performance with respect to individual criteria, a value for the alternative can be identified. The weighting value enables an organization to narrow the list of options using criteria such as cost, quality and efficiency. In this study, the weighting scores of both objective functions are provided by can manufacturers. The weights of the total economic cost and total carbon footprint are 3.3 and 2.7, respectively. After applying the trade-off between two objective functions for two-piece can system, the optimal solution of MOLP model functions is shifted as shown in Table 4.

Table 3. Target values of two objective functions.

Objective function	Total carbon footprint (kg CO_2 eq)	Total economic cost ($US)	Target values	Unit
Minimized total carbon footprint	4,745	8,994.40	t_1 = 4,745	kg CO_2 eq
Minimized total economic cost	4,781	8,993.31	t_2 = 8,993.31	$US

Table 4. Objective values (Z) and the maximum weighted percentage deviation (Q)

Objective function	Weighting	Optimal objective value (Z)	Unit	Maximum weighted percentage deviation from the target values (Q)
Minimized total carbon footprint	2.7	4,767	kg CO_2 eq	0.000494547
Minimized total economic cost	3.3	8,994.57	$US	

The MOLP model represented the optimal solutions for two-piece can system. By considering the two objectives, with the functional unit of 90,000 cans, the subsequent results were 4,767 kg CO_2 eq for total carbon footprint (Z_1) and $US 8,994.57 for total economic cost (Z_2). The maximum weighted percentage deviation from the target values (Q) was 0.000494547 or alternatively speaking that the solutions were within approximately 0.000494547% of achieving the target solutions for the both objective functions. These solutions of this study were depending on weighting score determined by can manufacturers. Thus, it enables a decision maker to explore several solutions by adjusting the weighting scores. According to the optimal values of decision variables in the case study can be determined as showed in Table 5. The results indicate that all quantities of decision variables were within the assured range for the production. It is noted that for the production of can body (X_i), the quantity of TSF steel sheets was decreased. On the other hand, the quantities of lacquer A, lacquer B and solvent in this process were increased. For the production of end shell (Y_i), the quantity of TSF steel sheets was decreased. In addition, the quantities of Lacquer C, Lacquer D, Lacquer E, ink and compound in this process were also increased.

Table 5. Optimal quantities of decision variables for two-piece can system (functional unit = 90,000).

Production	Decision variable	Description	Optimal value	Unit
Can body (X_j)	X_1	TSF steel sheets	1038.85	kg
	X_2	Lacquer A	20.34	kg
	X_3	Lacquer B	13.65	kg
	X_4	Solvent	0.92	kg
	X_5	Wooden pallets	180.09	kg
	X_6	Layer paper sheets	66.56	kg
	X_7	Top wooden frames	36.02	kg
	X_8	Stretch film	2.16	kg
	X_9	Plastic strapping	0.36	kg
	X_{10}	Paper pallet tags	0.04	kg
End shell (Y_j)	Y_1	TSF steel sheets	677.58	kg
	Y_2	Lacquer C	8.25	kg
	Y_3	Lacquer D	7.13	kg
	Y_4	Lacquer E	11.35	kg
	Y_5	Solvent	0.79	kg
	Y_6	Ink	0.50	kg
	Y_7	Compound	2.40	kg
	Y_8	Al Tab stocks	56.59	kg
	Y_9	Tab lube	0.75	kg
	Y_{10}	Repairing lacquer	1.86	kg
	Y_{11}	Wooden pallets	22.31	kg
	Y_{12}	Wrapping paper	0.62	kg
	Y_{13}	Shrink bag	3.69	kg
	Y_{14}	Stretch film	6.69	kg
	Y_{15}	Plastic strapping	1.12	kg
	Y_{16}	Paper pallet tags	0.13	kg

4. Discussion

The optimal solution of the developed MOLP model with two objective functions of total carbon footprint and total economic cost for 2-piece can system is evaluated. The results show that the optimal value on objective functions has improved. However, further improvement can be established if the constraints are not too much restricted. The region of feasible solution will be subsequently expanded. In addition, a change in the weighting factors of importance may also be implemented in order to obtain a better solution.

5. Conclusion

The MOLP can be used as the optimal practicable environmental model for compromising relationship between the two main objectives involving the total economic cost and the environmental performance in term of total carbon footprint. The developed model in the study represented the optimal solutions for two-piece can system for the canned tuna products. By considering two objectives function in term of functional unit of 90,000 units, the results showed that the optimal solutions were 4,767 kg CO_2 eq for the total carbon footprint and $US 8,994.57 for the total economic cost. With the maximum weighted percentage deviation from the target values of 0.000494547%, the MOLP model yielded the optimal solution in term of quantities of raw materials required to use in the production of the two-piece can with satisfaction of various constraints pertinent to the production.

ABSTRACT

Specialty food ingredients (SFIs or just 'specialty ingredients') such as emulsifiers, food enzymes, hydrocolloids and cultures are typically applied in small amounts (<1% w/w of the final food product). Generally, little attention has been given to specialty ingredients in the LCA community (Foster et al 2006, BCFN 2011). DuPont Nutrition & Health (N&H) is a leading producer of specialty food ingredients worldwide. During the last five years, DuPont N&H has completed cradle-to-gate LCAs of a wide range of specialty ingredients, based on both attributional and consequential modeling. The average carbon footprint of DuPont N&H products is 3-4 kg CO_2e per kg (cradle-to-gate) but they only represent a small share of the final consumer products carbon footprint. More importantly, most solutions enable significant reductions of our customer's footprint by enabling replacement of animal derived raw materials (with e.g. soy protein), increasing processing efficiency or enabling reduced food waste in retail and households. DuPont N&H has identified more than 70 'sustainable solutions' and LCA screenings of 40 cases show that they can help customers reducing between 10 and 100 kg CO_2e per kg specialty ingredient applied.

Keywords: Specialty Food Ingredients, Life Cycle Assessment, Carbon Footprint, Food Waste, Sustainable Food

1. Introduction

A significant number of food companies apply life cycle assessment (LCA) to quantify the environmental burdens associated with their products. LCA studies have been published on a wide range of food, including dairy products, meat products, vegetables, fruits, bread, alcoholic and non-alcoholic beverages, confectionary etc. (Foster et al 2006, BCFN 2011). Few studies, however, are available on specialty ingredients such as:

- Emulsifiers (e.g. used to strengthen and soften the dough in bread)
- Food enzymes (e.g. bakery enzymes used to extend periods for which breads stay fresh)[1]
- Hydrocolloids (e.g. pectin used as gelling agent in jam and marmalade)
- Bacteria cultures (e.g. acidifying cultures applied in the production of yoghurt and fresh fermented milks)
- Antimicrobials and antioxidants (e.g. rosemary extract used to prevent pathogens and oxidation in meat)
- Reduced calorie sweeteners (e.g. xylitol used as sweetener in chewing gum).
- Soy protein (e.g. soy protein isolate used to replace animal protein in different food applications)

Apart from a few examples such as soy proteins and some sweeteners, specialty ingredients are typically used in small amounts (<1% w/w) to obtain certain functions such as extended shelf-life/freshness or improved taste, texture and mouth feel. In most existing LCAs of food products, impacts associated with SFIs are only modeled coarsely. But it is also important for food producers to understand the environmental impacts associated with SFIs, and more importantly to be aware of the opportunities they bring in terms of replacement of high impact raw materials, improvements in processing efficiency and not least reduction of food waste.

As a leading producer of SFIs, DuPont N&H decided three years ago to carry out cradle-to-gate LCAs on all main product categories. This paper shows examples of results from these studies as well as results from LCA screenings of the use stage. In the discussion part of the paper, attention will be given to methodological challenges.

[1] Several scientific LCA studies on enzymes including food enzymes are available in the literature (Jegannathan and Nielsen 2013).

2. Methods

In terms of cradle-to-gate LCA studies there has been completed six studies which have been third party reviewed in accordance with the ISO 14044 standard (two additional studies are in review). Our goal is that all our main product categories should be analyzed through 3rd party reviewed ISO 14044 compliant LCA studies by 2015. In addition, 40 LCA screenings of use stage impacts have been completed for a range of products and applications that we call sustainable solutions. The following sections address key methodological choices related to our cradle-to-gate LCAs as well as the LCA screenings of the use stage.

2.1. Goal and Scope

Our cradle to gate (or cradle-to-customer) LCAs include all life cycle stages from raw material acquisition to final dispatch of products to our customers and includes in many cases even outbound transport to the average customer. The functional unit can vary from study to study but reflects a reference flow of 1 kg specialty ingredient in all studies. Specialty ingredients are sold because of their function which is the reason why we often describe them as ‘solutions’ rather than ‘products’. The functionality is therefore always described in detail, and relevant adjustments in the reference flow are made when comparisons are made between different SFIs.

2.2. Life Cycle Inventory (LCI)

In DuPont N&H consequential and attributional life cycle inventory modeling are seen as complementary rather than competing which will be explained later. Both approaches are therefore included in our detailed third party reviewed LCA studies as well as LCA screenings of the use stage.

In consequential modeling co-product allocation is consistently avoided by system expansion (substitution) and constrained processes are excluded from the analyzed product system. As an example, this means that hydropower would not be included in the grid mix for electricity in a country where all hydropower is fully utilized (e.g. Norway). Modeling of indirect land use change (ILUC) is only included in sensitivity scenarios.

Attributional modeling represents an approach where co-product allocation is typically handled with allocation, and where no distinctions are made between constrained and unconstrained processes (Sonnemann and Vigon 2011 p74). In DuPont N&H economical allocation is generally used for handling of co-product allocation in our attributional models, which is consistent with the ecoinvent V3 default allocation model (Weidema et al 2013).

Background processes have generally been modeled based on data from the ecoinvent V2.2 database (in all studies completed before 2014), but other data have been used when these have been deemed to represent a higher level of data quality. This includes, for example, data on country-specific marginal and average electricity which has been modeled separately in collaboration with 2.-0 LCA consultants (Schmidt et al. 2011). Ongoing studies are based on Ecoinvent 3 which allows for more consistent modeling, where either economical allocation or system expansion is used in all background processes.

2.3. Life Cycle Impact Assessment (LCIA)

The Recipe midpoint model has been used as the default method for impact assessment (in all studies completed before 2014) but other LCIA methods, including end-point methods, have been applied for sensitivity studies. Ongoing LCAs applies the ILCD LCIA method available in SimaPro 8 which is applied as it is recommended by the European Product Environmental Footprint (PEF) Guide and is a result of a consensus project aimed at establishing current best practice for LCIA (European Commission 2012).

2.4. Use stage modeling

In most cases, one type of specialty ingredient can typically be used in many different food products where it can have various functions. Furthermore, specialty ingredients are often used in various combinations and in different parts of the world. Needless to say, it is complex to model the use stage without focusing on concrete cases. The use stage has therefore been modeled separately and at screening level, focusing on specific applications in different parts of the world. Three scenarios are calculated for each solutions which represent attributional modeling, consequential modeling (incl ILUC) and consequential modeling (excl ILUC) which is chosen as our default model. The advantage of the different models is that it allows us to adapt to specific customer preferences. In terms of LCIA the screenings only address the carbon footprint based on characterization factors in the ILCD LCIA method in Simapro 8.

Conceptually, it is possible to distinguish three types of SFIs based on their functions: Specialty ingredients that mainly are applied to enable a substitution of raw materials (or modify recipes), ingredients that mainly aim at increasing processing efficiency and finally ingredients that serves to prolong the freshness or shelf-life of food products, see Figure 1.

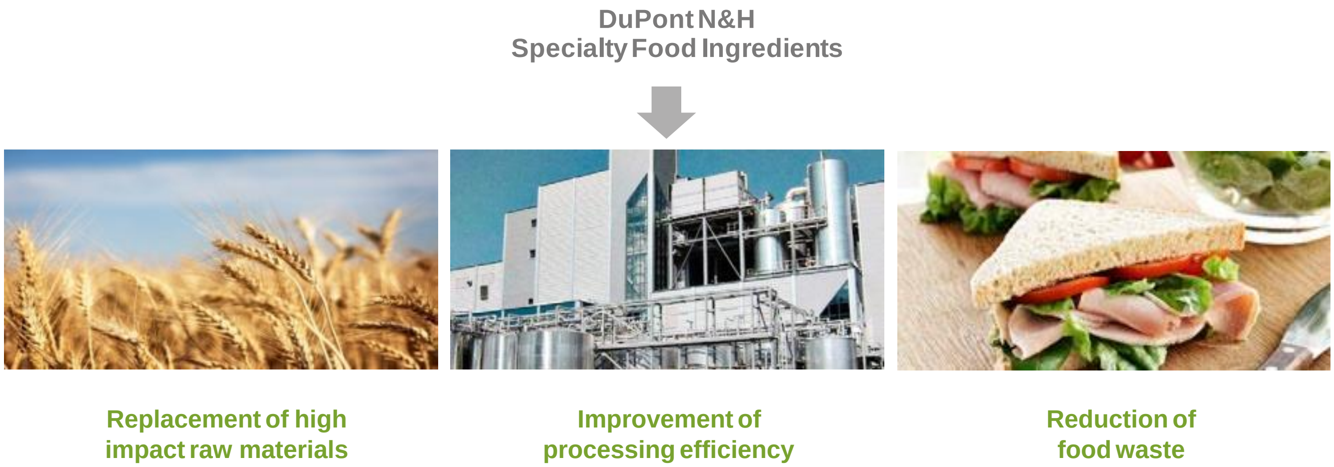

Figure 1. Conceptual model of interaction between SFIs (top center) and the food value chain with raw material providers (left), food producers (center) and finally end-consumers (right).

As illustrated the distinguishing feature between the three groups of SFIs depend on which part of the food value chain they mainly address:

- Upstream SFIs: Some SFIs address upstream impacts by enabling modifications in raw material composition e.g. by replacing animal protein and fat with vegetable protein and fat (Figure 1 left). This application can be divided in two sub-categories: direct upstream where the SFI itself constitutes the replacement (e.g. soy protein that replaces milk protein) and indirect upstream where the SFI has an indirect role allowing the replacement to take place (e.g. hydrocolloids that facilitate a reduction of animal fat or a replacement with vegetable fat in dairy, while maintaining similar taste and texture).
- Processing SFIs: Another group of SFIs addresses the food processing directly – e.g. by allowing for larger throughput and/or increased efficiency (Figure 1 center).
- Downstream SFIs: These are SFIs that address the food products’ freshness and their taste and texture as perceived by the end customers in a typical use scenario (Figure 1 right). This application has the potential to reduce food waste significantly, especially for categories of food products where the dominating reason for food waste is that it has passed a date label, has gone moldy or rotten, looked, smelt or tasted bad.

All three functions have a significant potential to promote sustainability in the food value chain – especially upstream and downstream SFIs that address the most important hot-spots of average food products (raw materials and food waste). A large generic group of SFIs such as food enzymes or hydrocolloids can have several of the above mentioned functionalities, while more specific products typically have a more narrow functionality related to one of the functions.

3. Results

3.1. Example of comparative LCA on Xylitol/Xivia®

One of the first LCAs completed by DuPont N&H was a comparative LCA on the sweetener xylitol, which was reviewed by a third party panel in 2011. Two production methods were compared – one based on a side stream from the pulp and paper industry (the wood based concept used by DuPont), and one based on corn cobs (used by most of our competitors). The study was completed by Earthshift consultants and applies attributional modeling but with the use of system expansion (substitution) for energy and waste related foreground processes. In this particular study, Impact 2002+ has been used for life cycle impact assessment (LCIA). A significant difference was anticipated, but it was a surprise to most that the wood based technology actually generated 85-99% lower impacts across all investigated impact categories (see Figure 2).

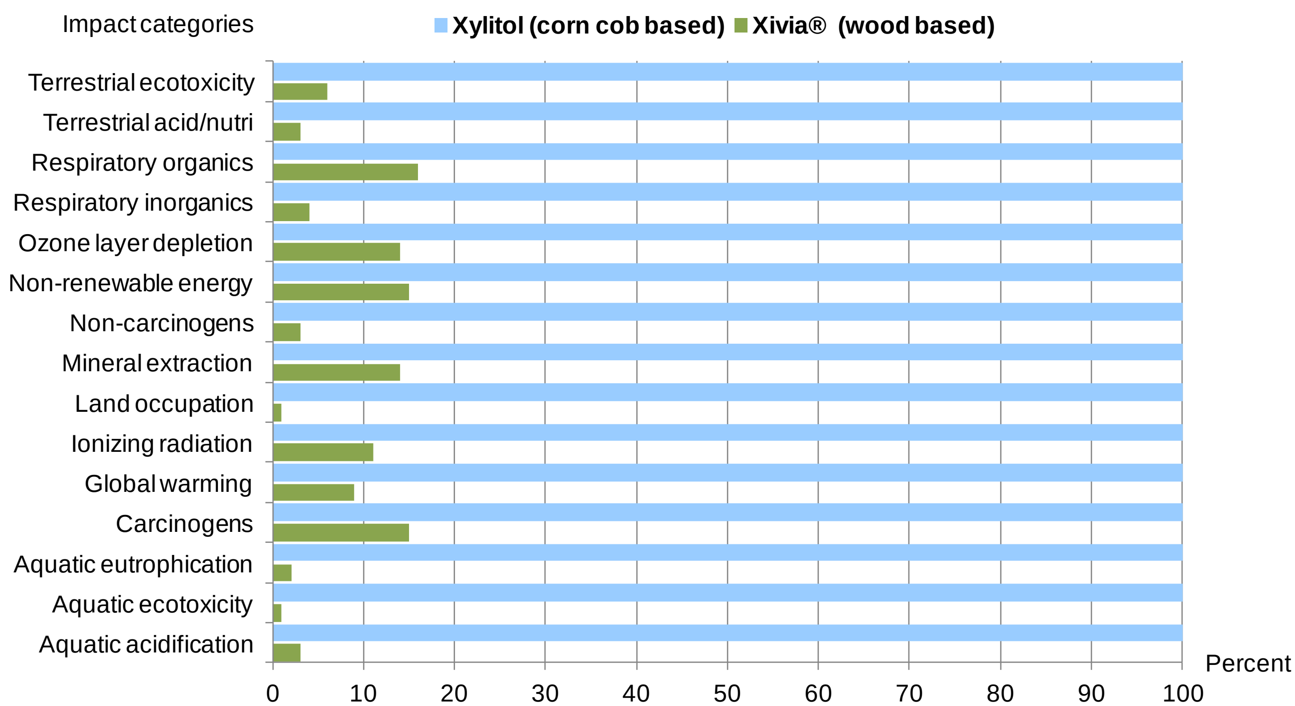

Figure 2. Characterized results from comparative LCA (based on Impact 2002+) of corn cob based xylitol and DuPont's wood based xylitol (Xivia®) based on Dahliwal, Hamilton and Laurin (2010).

In terms of global warming potential the wood based technology contributed 3.6 kg CO_2e per kg Xivia® (cradle-to-gate) while the corn cob based technology contributed 38.6 kg CO_2e per kg xylitol from cradle-to-gate (Dahliwal, Hamilton and Laurin 2010). Results also published in Danisco (2011) and Dahliwal and Thrane (2011).

3.2. Carbon footprint and hot-spots for different groups of SFIs

Based on findings from LCA studies of SFIs as well as DuPont's Corporate Footprint based on WRI & WBCSD (2004 and 2010), it can be concluded that average carbon footprint of DuPont N&H's specialty ingredients is in the range of 3 to 4 kg CO_2e per kg from cradle-to-gate, excluding ILUC. The main contribution comes from raw materials (53%), while processing represents 35% of the cradle-to-customer footprint. Inbound and outbound transport both represents 6% respectively (Thrane 2011, Dalgaard et al. 2013).

With a typical application level of less than 1% w/w of the customer's final product, this suggests that specialty ingredients in most cases have a modest contribution to a food product's total footprint. There are cases, however, where SFIs are used in larger amounts such as for soy proteins, and in the case of Xivia® in chewing gum applications.

Emulsifiers: For average emulsifiers, the raw materials (mainly vegetable oils) constitute about 80% of the cradle-to-gate footprint, and the average emulsifier has a carbon footprint of 3-5 kg CO2e per kg product from cradle-to-gate (Muñoz 2014). Both attributional and consequential modeling has been applied, but the results are within the range mentioned above in both LCI models.

Food enzymes: LCA of enzymes have been conducted for several years in DuPont Industrial Biosciences. In terms of carbon footprint, the most important life cycle stage for food enzymes are processing (fermentation, formulation and recovery) followed by raw materials use in the fermentation process. The carbon footprint ranges between 1 and 10 kg CO_2e per kg enzyme from cradle-to-gate mainly depending on the type and quantity of raw materials, the fermentation time and the concentration (Dettore 2014). Again both consequential and attributional modeling has been used and both approaches are represented within the indicated carbon footprint range.

Hydrocolloids: In terms of carbon footprint, the processing stage is important for most hydrocolloids. Processing aids also have a noteworthy contribution to the footprint, but it should be stressed that hydrocolloids are a very diverse group of ingredients with large variations in hot-spots and impacts. The typical carbon footprint ranges from 1-12 kg CO_2e per kg hydrocolloid from cradle-to-gate. This range covers many different hydrocolloids of which most have been analyzed through screening level LCAs apart from a third party reviewed LCA of pectin published in 2011 (Thrane 2011). Consequential modeling has been applied in combination with attribution modeling in the third party reviewed LCA which showed only a minor difference in impacts.

Cultures: Similar to most hydrocolloids, the processing stage represents an important contribution to the carbon footprint for cultures – mainly due to the energy use. Two types of direct inoculation cultures exist: Frozen cultures and freeze dried cultures, which are concentrated and therefore more efficient. Adjusted for functionality, the cradle-to-gate footprint for both types of cultures are in the range between 8 and 12 kg CO2e per kg. Cultures are added at rather small dosages in yoghurt and cheese; between 0.5 and 2 kg frozen cultures per 10,000 liters of milk. As for most SFIs their contribution to the final products footprint is therefore small. In a cradle-to-customer perspective, the carbon footprint for outbound transport can be important, especially for frozen cultures. The reason is that frozen cultures have to be stored at minus 50°C to 60°C and frequently require air transport – especially for transcontinental shipments. In cases where outbound transport involves airfreight, freeze dried cultures are likely to offer a low carbon footprint alternative to frozen cultures. Both consequential and attributional modeling has been applied and again no significant differences in impacts have been identified apart from what is covered by the suggested interval (Thrane 2012, Thrane 2013a, Thrane 2013b).

Reduced calorie sweeteners: For this category, only Xivia® has been analyzed and the study shows that the raw material- and processing stage represent the largest carbon footprint (due to energy use). The carbon footprint of Xivia® is within the same range as our average product, 3-4 kg CO2e per kg (Dahliwal, Hamilton and Laurin 2010). But as Xivia® is the only sweetener type that has been analyzed, it is not possible to conclude that this product is representative for the other products in this category.

Protein solutions: For soy protein concentrate (min 65% protein per dry matter) and soy protein isolate (min 90% protein per dry matter) the main contribution comes from the processing stage due to energy use. A detailed LCA is being completed but final results are not yet available. Preliminary results indicate that the carbon footprint is around 2-4 kg CO_2e per kg protein product. Consequential modeling suggests a lower impact compared to attributional modeling.

Apart from the product groups mentioned above, DuPont N&H also produces antimicrobials and antioxidants (covering products such as Natamax®, Nisaplin® and GUARDIAN® Rosemary Extract) as well as a range of other products that could be termed 'other' which include fibers, rare sugars, soy lecithin etc. Considering the large number of ingredients and applications, the scope has been limited to cover the above mentioned groups in the present article.

3.3. LCA screenings of avoided burdens (use stage impacts)

As mentioned, the use stage has also been modeled by LCA screenings focusing on the carbon footprint. So far, more than 70 solutions have been identified and 40 of these have been quantified by LCA screenings. In a typical case, 1 kg specialty ingredient contributes to avoiding 10-100 kg CO_2e (net) compared to a situation where the ingredient is not used. All LCA screenings have been made according to both attributional and consequential modeling, but the results presented in the following are only based on consequential modeling, which in most cases represent a more conservative estimate of potential savings.

Direct upstream SFIs: One example of direct raw material replacement is the use of Xivia® instead of corn cob based xylitol in chewing gum. The net avoided impact per kg applied Xivia® is the difference in impact between one kg corn cob based xylitol and one kg Xivia®, which amounts to 35 kg CO_2e. LCA screenings shows that the carbon footprint is reduced by 42-85% per kg chewing gum when switching from corn cob based xylitol to Xivia®. The large interval represents differences in xylitol content in the final recipe with all ingredients including gum base. The modeled xylitol content ranges from 5% to 55% (Dalgaard et al. 2013a). Another example could be the use of soy protein to replace milk or meat protein in different applications such as dairy products, sausages and burgers. Updated third party reviewed LCA results of soy protein isolate are not yet available, but our LCA screenings suggest that 1 kg isolated soy protein contributes to reducing 10 kg CO_2e (net) in application where it replace milk protein[2] and even more when replacing meat protein. An example of a beef burger, where the beef content is partly replaced with textured soy concentrate, shows that the carbon footprint of the beef can be reduced with as much as 35% (Dalgaard et al. 2013 a and b).

Indirect upstream SFIs: An example where the specialty ingredient has an indirect effect on raw materials could be a pectin based ingredient solution, such as GRINDSTED® SB555, that makes it possible to replace milk protein with vegetable protein in yoghurt, without compromising organoleptic properties. An LCA screening shows that 1 kg GRINDSTED® SB555 contributes to reducing 12 kg CO_2e per kg (net) in a specific application where it allows for using vegetable protein instead of milk protein in yoghurt. The solution allows the footprint of the final yoghurt to be reduced with 18%. Other solutions exist which enable replacement of meat protein in sausages, burgers etc. (Dalgaard et al. 2013b). Another example of indirect upstream substitution could be the enzyme Alphalase® AP4 applied in beer production. This solution makes it possible to brew a good quality beer where 60% of the malt is replaced with barley. LCA screenings show that 1 kg Alphalase® AP4 contributes to reducing 100 kg CO_2e (net) in this application and the footprint of the final beer is reduced by 12% (Dalgaard et al. 2013a).

Processing SFIs: An example of processing SFIs is FoodPro® Cleanline - an enzyme solution which can significantly reduce the impacts of ultra high temperature processing of milk in dairies (UHT). This solution prevents fouling in the UHT processing systems, leading to higher capacity while reducing the need for cleaning cycles that otherwise would require significant amounts of water, energy and cleaning chemicals. An LCA screening shows that 1 kg FoodPro® Cleanline contributes to reducing 35 kg CO_2e per kg (net) when applied in UHT processing. In a large scale dairy with 6 UHT lines, this translates in to annual net savings of 322 tons CO_2e (Dalgaard et al. 2013b).

Downstream SFIs: Finally an example of a solution that addresses downstream food waste is the use of emulsifier and enzyme blends in bakery products. Food waste is a major issue, and bakery products are one of the worst culprits for avoidable food waste. Approximately 30% of bakery goods like bread, cakes and cookies are wasted in the households and according to WRAP about 90% of this waste occurs because the products are not perceived as fresh (Gustavsson et al. 2011, Quested and Johnson 2009). DuPont has developed enzyme solutions that apart from providing the usual bread softness and crumb elasticity, also keep the bread moist longer. The enzymes are sold under the Powerfresh® brand name and are often used in combination with emulsifiers. An LCA screening has been completed for a use of 50% higher dosage of Powerfresh® (increase from 20 gram to 30 gram enzyme dosage per 100 kg flour) in toast bread in North America, enabling the bread to stay fresh for 21 days compared to 14 days with the lower dosage. Based on a model of the relationship between freshness and bread waste, calibrated with data from Quested (2013), it is estimated that the bread waste in retail and households is reduced by 30%. The LCA screening shows that the carbon footprint is reduced with 12% per kg bread consumed in this case – and several thousand kg CO_2e is avoided per kg extra enzyme that is applied. This example involves our newest and most sophisticated enzymes, but even standard enzymes (and emulsifiers) can make a huge difference in markets where enzymes are more rarely used, such as parts of Eastern Europe and Russia.

A new exiting product range with a significant potential for food waste reduction is protective cultures such as HOLDBAC® cultures used for spoilage and pathogen prevention in dairy and meat applications. LCA screen-

[2] In this example the milk protein is modeled based on the LCAfood database where the process "Milk powder, no quotas' has been modified and updated based on LCI data on milk from Schmidt and Dalgaard (2012) & Dalgaard and Schmidt (2012) using the consequential mode. If attributional modeling had been used instead the avoided burden would have been 15 kg CO2e per kg soy protein that replaces milk protein (Dalgaard et al. 2013 b).

ings of protective cultures applied to fresh cheese shows that the carbon footprint can be reduced with nearly 5% per kg consumed cheese – and 220 kg CO_2e is avoided per kg HOLDBAC® cultures applied (Dalgaard et al. 2013b).

4. Discussion

4.1. Difference between attributional and consequential modeling

In LCAs of specialty ingredients, the difference between attributional and consequential modeling is often modest. But there are situations where the differences actually matter. These can be situations where a part of the product system that is constrained, is left out in the consequential model. An illustrative example is SFIs that enable a partial replacement of milk fat with palm oil in cream cheese. This results in a significant improvement when attributional modeling is applied, but has no effect when consequential modeling is used. The latter presumes, according to the consequential model we have used, that milk fat is a dependent co-product constrained by the main product milk. Hence, instead of influencing the production of milk, a change in demand for milk fat would affect the marginal oil on the world market (namely palm oil). In terms of modeling, this implies that we replace palm oil with palm oil – hence no effect.

4.2. Consequential modeling (pros and cons)

The advantage of consequential modeling is arguably that it better reflects the functioning of the market and attempts to model consequences of concrete decisions or choices in a concrete market context. From a consumer perspective, it could be the environmental impacts of buying product A versus not buying it – or buying product A instead of product B. Both situations imply changes – which is exactly what consequential LCA attempts to model. A hot-spot assessment is not necessarily about changes – but as soon as it is used to guide decisions or to make strategic choices it does concern changes. Consequential modeling is tailor-made to decision support and is better able to address the bigger picture including the direct and indirect market effects.

Consequential modeling avoids co-product allocation – often by system expansion. This leaves less room for arbitrary choices of allocation methods, but on the other hand consequential modeling opens up for different choices and assumption related to identification of marginal products and other market aspects. It could be argued that consequential modeling, by including markets aspects, requires too much from the LCA practitioner and makes LCA a too broad research discipline. Some would probably argue that ‘the best is the enemy of the good’ in this context. Ultimately one of the fundamental challenges of consequential LCA is that it can be hard to comprehend, not least for non-experts. As an example it can be difficult to communicate that an LCA of soy oil based emulsifier does not include soy oil in the inventory, because it is constrained by the demand for soy meal. The consumer, customer or other stakeholder might get confused – and skeptical when they are told that palm oil is included instead because this is the marginal oil on the world market. But this is rather a communication issue than it is a real disadvantage of consequential LCA. Another challenge is that it, by putting attention to the marginal, could lead to a missed opportunity to collaborate with the suppliers of soy oil to reduce upstream impacts. This does not have to be the case, but could be the outcome when results are interpreted by non experts.

4.3. Attributional modeling (pros and cons)

Attributional modeling is often described as a more normative approach with fewer considerations about the functioning of the market. Instead it follows traditional supply chain logic and it better reflects how current supply chains are physical connected. The fewer number of variables related to the market, also reduce to option for modeling related differences when comparing results from LCA studies. Attributional modeling is arguably easier understand, and from a supply chain logic, it makes intuitively more sense that soy beans are included in an LCA of soy oil, instead of the marginal vegetable oil (palm oil) as suggested in consequential modeling. It can be argued that, attributional modeling better reflects the way many consumers and NGOs attribute a responsibility on the suppliers in the actual supply chain. An example is when stakeholders avoid agricultural products than are produced in regions where deforestation is taking place – by sourcing from other regions may just reflect a shift of burdens via indirect land use changes, and eventually the effect on deforestation may be the same.

The main disadvantage of the attributional approach is that it includes constrained suppliers, i.e. the results of an LCA include emissions from suppliers that will not change their production as a consequence of a change in the demand for the studied product. Further, the attributional approach often involves different allocation methods for multiple product output activities. Apart from making studies more difficult to compare, this approach ignores the real effects of by-products and the allocated processes fail in some cases to maintain basic balances such as mass balance, carbon balance, energy balance etc.

It is out of scope in the present article to make a more elaborate description of pros and cons, but it should be clear that depending on the purpose of the LCA, both approaches have advantages and disadvantages and that it can be fruitful to provide both perspectives in LCA studies.

4.4. Other aspects of Sustainability

The present article has focused on environmental impacts, mainly the carbon footprint. But there are obviously many other elements of sustainability such as food security, health and nutrition aspects.

Several initiatives are taking place to broaden aspects of sustainability within our own supply chain. Emulsifiers and hydrocolloids can enable reductions of salt and fat (including trans-fat) in food products. Reduced calorie sweeteners can obviously reduce sugar levels, and products such as Litesse® can increase fiber contents of foods. Other examples are probiotic cultures, which can promote a healthy bacteria flora in the digestive system. Social sustainability aspects related to food are however complex to describe and include in a short article about SFIs, and it is highly context and culture dependent. In Mexico for example, milk competes on price with soda. This means that solutions to make milk more affordable is likely to have a positive effect on both food security and health – despite reducing the amount of milk solids on a per liter basis. The theme about what defines a sustainable and healthy diet has recently been described in a discussion paper by Garnett (2014).

5. Conclusion

DuPont N&H continuously seeks to reduce the environmental impacts from all life cycle stages including raw materials, transport, processing and use. It should be recognized, however, that environmental burdens associated with SFIs typically are small or insignificant in the final consumer products. This is due to the small amounts used (typically < 1% w/w) and the relative modest carbon footprint of 3-4 kg CO_2e per kg average SFI. The latter is close to the footprint of the products in which they are typically used.

More importantly, SFIs can make a significant difference in terms of reducing the footprint of the food products in which they are used. SFIs have the largest potential to leverage sustainability in the use stage where they can affect all stages of the customer’s value chain. Three groups of SFIs can be distinguished depending on how they influence the customers’ value chains:

- SFIs that influence the first stage of the customers value chain (raw materials) – e.g. by allowing replacement of animal based with vegetable based protein or fat.
- SFIs that contributes to improve customers manufacturing efficiency.
- SFIs that mainly address the last stages of the customer’s value chain, by enabling food products to stay fresh longer and thereby reducing food waste.

Food enzymes are an example of specialty ingredients that can address raw material substitution, processing efficiency and downstream food waste. Other groups of SFIs are typically less comprehensive in their functionality, but they can have the same potential to reduce impacts such as isolated soy protein replacing animal protein.

DuPont N&H has identified 70 solutions that allow for carbon footprint reductions in the customers value chain. LCA screenings of 40 solutions reveal that these solutions allow for reductions between 10 and 100 kg CO_2e per kg SFI applied. But there are also examples where 1 kg specialty ingredient can lead to reductions of more than 1000 kg CO_2e by reducing food waste.

Detailed third party reviewed LCAs have been applied for cradle-to-gate LCAs, while the use stage has been modeled through screening level LCA. Both attributional and consequential modeling is applied in all studies and generally results vary little. There are cases, however, where significant differences emerge, especially for dairy products. While these differences may appear inconvenient they show that methodological uncertainty can be significant in certain cases.

Boosting grain yield by including leguminous bioenergy crops in the rotation – a life cycle approach

ABSTRACT

Introduction of rotational grass/clover for anaerobic digestion in a grain production system was evaluated using life cycle assessment. Energy requirement, global warming potential and land use were compared in two scenarios; one cropping system including only cereals and another also including two-year grass/clover. Use of fossil fuels and greenhouse gas emissions were reduced substantially, mainly due to replacement of diesel with biogas, but also when digested grass/clover biomass replaced N mineral fertilizer. High N use efficiency throughout the production chain was required for a high replacement rate of mineral fertilizer. The residual effect from rotational grass/clover increases the yield potential and provides N for subsequent crops. Both these aspects should be included in LCA of break crops through evaluation of crop sequences rather than specific crops. We recommend that introduction of different rotational crops relying on N-fixation be evaluated as a future strategy for improving productivity and environmental performance.

Keywords: Crop rotation, multifunctional bioenergy crops, N-fixation, land competition

1. Introduction

Bioenergy production in the EU is currently based largely on annual oilseed, starch, and sugar crops (Pedroli et al. 2013). Using common crops for bioenergy production may perpetuate monoculture cropping and there is thus a need for more innovative production systems with multifunctional benefits. At present, only a small proportion of bioenergy feedstock comes from perennial ligno-cellulosic species such as miscanthus, willow, reed canary grass, and switchgrass (AEBIOM 2013). Introducing perennial crops which stay in place for a longer period of time decreases the flexibility and increases the investment costs, and might therefore be less attractive from the farmer's perspective (Gabrielle et al. 2014).

There has been a substantial increase in global crop production in recent decades, but there are now indications that the yield increase has started to slow down (Foley et al. 2011). Sustainable intensification of existing farmland is required to meet the predicted future increase in demand for food. Sustainable intensification is often discussed in terms of higher efficiency, as more product delivered per unit input of different resources (Smith 2013). Soil fertility is critically important for obtaining high yields, and strategies for maintaining and increasing soil fertility are thus essential components of sustainable intensification. Replacing monoculture with more varied cropping systems can improve soil structure, decrease the vulnerability to pests and diseases, and improve long-term productivity (Zegada-Lizarazu and Monti 2011). Introducing bioenergy crops with benefits for subsequent food crops in a crop sequence can thus improve current cropping systems, thereby mitigating negative land use impacts to a varying extent. Perennial or annual crops relying on symbiotic fixation of nitrogen (N) are of special interest as feedstock for bioenergy production from an environmental point of view. One reason is their potential to reduce the N mineral fertilizer requirement of the actual crop and of subsequent crops in the rotation. Another reason is their potential to increase yield in subsequent crops in both the short and long term (*e.g.*, Gan et al. 2003). According to a literature review examining cropping systems in different countries, mean yield benefits of up to 20% or more can be obtained when break crops are included in crop sequences (Kirkegaard et al. 2008). These multifunctional aspects are important to consider in assessments of crops relying on symbiotic N-fixation and in future policy development.

In this paper, we briefly describe how the introduction of perennial grass/clover in rotation with cereal crops affects subsequent food crops, using results from an LCA study conducted with Swedish data. The aims were to evaluate energy use, greenhouse gas emissions, and land use for grain production when rotational grass/clover is included for anaerobic digestion in a cereal cropping system, and to discuss how rotational aspects affecting yield potential can be included in life cycle assessments.

2. Methods

In the scenario study, life cycle assessment was used to evaluate two crop rotations: (i) a reference scenario including winter wheat-winter wheat-spring barley in a three-year crop rotation and (ii) a grass/clover scenario including two-year grass/clover followed by winter wheat-winter wheat-spring barley. The functional unit was 1 tonne of harvested grain, since the main focus was on how grain production was affected when introducing grass/clover for biogas production into the rotation.

The scenario study included only the operating phase. The assumed location was the county of Uppland in eastern Sweden. It was assumed that the grass/clover was digested and further upgraded to vehicle fuel quality, replacing diesel. The generation of biogas in the grass/clover scenario was accounted for through subtraction of the avoided burdens from the other activities in this scenario. The digested mixture of grass and clover replaced mineral N fertilizer otherwise used in cereal production. Band-spreading with trailing hoses was assumed for the digested grass/clover. In total, 73% of the N requirement of the cereals in the grass/clover scenario was met by digestate, while 27% was met by N mineral fertilizer. More details and references are provided in Tidåker et al. (2014), while yields and fertilizer rates are summarized in Table 1.

Special consideration was given to the effects of the grass/clover on subsequent cereal crops in the rotation. The cereal yield assumed in the grass/clover scenario was modified based on a compilation of numerous Swedish field experiments examining the residual effects of two-year grass/clover (Lindén 2008). Accounting for higher expected yield after grass/clover ley is also recommended in practical farming by the Swedish Board of Agriculture. Therefore, additional yield in the first and second year of winter wheat following grass/clover of 1000 and 400 kg ha^{-1}, respectively, was assumed. According to recommendations by the Swedish Board of Agriculture, the N delivered from the N-fixing clover to the subsequent crop could be expected to be 40 kg ha^{-1}. Changes in soil organic carbon in the two different crop rotations were modelled using ICBM (Andrén and Kätterer 1997).

Table 1. Assumptions in the two scenarios based on regional standard yield data, long-term field experiments, and guidelines for fertilization from the Swedish Board of Agriculture

	Yield (kg ha^{-1})	Fertilizer (kg N ha^{-1})[b]	Type of fertilizer
REFERENCE			
Spring barley	4300	80	Mineral fertilizer
Winter wheat	5600	135	Mineral fertilizer
GRASS/CLOVER SCENARIO			
Spring barley	4300	80	Digestate
Grass/clover[a]	7000		
Winter wheat I	6600	110	Mainly mineral fertilizer
Winter wheat II	6000	140	Digestate

[a] Grass/clover yield expressed in kg DM.
[b] Only N considered to be available for the crop was accounted for.

3. Results

The primary energy use was 1480 MJ in the reference scenario and -2900 MJ in the grass/clover scenario, *i.e.*, more energy was produced in the latter scenario than was required for grain production (Table 2). Replacing diesel with biogas was the most important factor explaining the difference, followed by the avoided use of mineral fertilizer in the grass/clover scenario.

The contribution to global warming potential (GWP) was 351 kg CO_2-equivalents for the reference scenario and -102 kg CO_2-equivalents for the grass/clover scenario. These figures included carbon sequestration in the cropping systems under study, but not indirect land use change. The replacement of mineral fertilizer in the grass/clover scenario decreased the emissions of greenhouse gases, but this gain was offset by the increased emissions due to more field operations being required and higher N_2O emissions in the grass/clover scenario.

The production of 1 tonne of grain occupied 0.20 ha in the reference scenario and 0.31 ha in the grass/clover scenario. The higher land requirement in the grass/clover scenario was due to the fact that the cereals occupied only 60% of the total area. However, due to the yield-increasing effect of the grass/clover, grain production in this scenario was 66% of that in the reference scenario, *i.e.*, higher than the proportion of occupied land.

Table 2. Primary energy use and global warming potential (GWP) for the two scenarios

	Reference scenario		**Grass/clover scenario**	
	Energy use	**GWP**	**Energy use**	**GWP**
Farm operation + transport	327	24	781	66
Mineral fertilizer production	1156	156	425	46
Direct field emissions		177		273
Indirect emissions		12		24
Gas production			1972	156
Carbon sequestration		-18		-216
Substitution of diesel			-6080	-451
TOTAL	1482	351	-2902	-102

4. Discussion

Bioenergy production based on dedicated crops grown on arable land has been increasingly questioned due to its negative land use impact. Competition between food, feed, and fuel crops is an important aspect to consider, especially since the demand for food is projected to increase substantially. This competition can be reduced or even eliminated for bioenergy crops by using residues or perennials from marginal land, or by growing additional crops between the main seasons or between rows (Tilman et al. 2009). However, bioenergy substrates are unlikely to be produced commercially on marginal land due to low economic incentives (Bryngelsson and Lindgren 2013) and residues for bioenergy production are limited. Rotational grass/clover could be another alternative, because it provides several benefits in a cropping system perspective, *e.g.*, N-fixation, carbon sequestration, *etc*. In this study, the improved short-term soil productivity due to crop sequencing effects was addressed by assuming higher yield potential for winter wheat in the first and second year after the grass/clover crop. It is likely that a long-term increase in productivity will also occur if the break crop recurs in the crop rotation, so assuming only a two-year effect might be somewhat conservative.

Different indicators for land use impact have been suggested, with soil organic matter proposed as a general indicator of soil fertility (Milà i Canals et al. 2007). Changes in soil productivity through increased yield potential can not only be measured as a separate indicator for land use impact, but can also be directly reflected in the area required for producing a certain amount of crops.

Higher yield potential for subsequent cereal crops following the grass/clover could not offset more than a small proportion of the displaced grain yield. However, the increasing yield potential together with carbon sequestration and N delivered from crop residues can counterbalance some of the negative impact from *e.g.*, indirect land use change, and is thus important to consider as a future strategy for mitigating climate change and decreasing the competition between food, feed, and fuel crops. It is therefore a need for environmental assessments of rotational crops relying on N-fixation in different cropping systems, taking into account their multiple benefits. One such crop besides clover is alfalfa (Gabrielle et al. 2014).

The N delivered to the wheat, as a residual effect from the grass/clover, replaces N mineral fertilizer in the subsequent crops. Applying a cropping system perspective and including the crop sequence rather than one specific crop is thus crucial to capture the multiple benefits. Digested mixtures of grass and legumes have the potential to replace a considerable proportion of the N fertilizer otherwise used in cereal production. Careful handling of the N-rich residue is crucial for many environmental aspects, and a sound management strategy is thus important. Experimental field data indicate large variations in ammonia volatilization (Webb et al. 2013). Anaerobic digestion increases the pH in the residue, which increases the risk of N losses. More experimental studies evaluating different biogas management systems are required in order to maximize the environmental benefits and minimize the emissions.

5. Conclusions

Introducing rotational grass/clover for anaerobic digestion into crop sequences can sequester carbon and replace a considerable proportion of the N mineral fertilizer otherwise required in cereal production. Furthermore, subsequent crops benefit from the residual effect of the grass/clover, thus increasing the grain yield potential. All these multiple benefits can help counteract some of the negative effects of indirect land use change and need to be included in assessment of leguminous crops for bioenergy production.

ABSTRACT

Certain complexities in the agricultural production differentiate this sector from the conventional industrial processes. The main feature to take into account is that the resources consumption and production is subjected to high variability in soil, rainfall and latitude. We show here an environmental tool developed in close cooperation with farmers in order to achieve applicability and comprehensibility. The procedure relies on the data retrieved from parcel management monitoring of different crops, mostly allocated in Catalonia and Ebro river watershed region (NE Spain). A set of comprehensive but also simple reports are provided, including material and energy balances, agronomic efficiencies and water and carbon footprints. The calculations also cover impacts due to infrastructure, including the estimation of materials in the use of greenhouses. Besides, a simple algorithm for reporting uncertainty using an approximation method of error propagation was added using the input uncertainties as defined by their data pedigree.

Keywords: decision making, calculation tool, sustainability indicators, growers, uncertainty analysis

1. Introduction

Today's society is more aware than ever of the state of the planet and the necessity of enhance the environment protection to deal with new issues such as global warming, overpopulation, water scarcity, etc. To face these challenges environmental regulations become more restrictive, and the productive sectors are forced to adopt measures, providing reliable information and applying tools for understanding and mitigating environmental damage. Particularly, the global food system, from land use change, through fertilizer manufacture, to food storage and packaging, is responsible for about one-third of all anthropogenic greenhouse gases (GHG) emissions (Vermeulen et al 2012). In this sense, the Global Warming Potential (GWP) is the most widely studied impact category as a result of the evidences of the rising global temperatures that are accompanied by changes in weather and climate thus affecting ecosystem and society. The GWP measures the environmental impact from a life-cycle perspective as the sum of GHG emissions caused by an organization, event or product, expressed in CO_2 equivalents. International standards such as the ISO 14067:2013 (ISO, 2013) provide guidelines for calculating carbon footprints. Furthermore, specific standards such PAS 2050.1 (BSI, 2011) provide specific guides for measuring the Carbon Footprint (CF) of horticultural and agricultural products.

Together with climate change, water scarcity has become one of the biggest environmental problems worldwide. The lack of access to fresh drinking water and sanitation has major impacts on people's well-being, causing massive health impacts. Moreover, the lack of water for productive purpose results in malnutrition, poverty and illnesses for a large portion of the world population. Agriculture represents a serious burden as the largest consumer of water and the main source of nitrate, ammonia and phosphate pollution in ground and surface water. It is of capital importance the implementation of good water management practices in irrigated agriculture, in an attempt to fix this increasing problem while providing food for the fast growing population. The concept of Water Footprint (WF) introduced by Hoekstra et al (2011) provides a framework to analyze the link between human consumption and the appropriation of the freshwater resources that incorporates both direct and indirect water use of a consumer or producer.

Nevertheless, the application of standardized LCA methodology to the evaluation of the agriculture sector has more complexities when compared to conventional industrial processes. The main issue to take into account is that the resources consumption and production is subjected to high variability in soil and weather conditions. Besides, the lower energy consumption of agriculture activities compared to industrial processes increases the relative significance of other parameters like transport or infrastructure. Therefore, in addition to the complexity of LCA tools we need to account for the extreme variability of agriculture. All these complexities and variability in the LCA indicators associated to agriculture make unpopular their application for farmers.

With the aim of involving the farmers in the tasks of accounting sustainability in their decisions and to retrieve from them reliable information, the principle of parsimony "as simple as possible and as complex as necessary" (Pidd 1996) is applied to develop the structure of a combined tool for the sustainable performance evaluation of agriculture processes.

Within the calculation and software tools available in the agricultural field, two calculators stand out: the Fieldprint calculator (www. fieldtomarket.org/fieldprint-calculator/) that assesses the CF and WF associated to crop production, and the Cool Farm Tool calculator (Hillier et al 2011) that is an open source software that considers crop management, livestock and manure management, field energy use and primary processing energy use. Both the mentioned software tools as well as the tool presented hereby are designed for farm-scale usage and for a certain growing season because of the variability above mentioned. Moreover, they are intended to be a decision-support tool for the farmer based on inputs that are well-known by the user.

Within the context of LCA, uncertainty analysis is used to better explain and support LCA conclusions based on the cumulative effects of uncertainty and variability. Reporting the outcome of the model with a quantitative measurement of the data quality means an added value compared with building deterministic models that assign single values to model parameters to obtain results as point estimates. In this sense, ISO 14044:2006 lists under "data quality" several aspects such as reliability, uncertainty/precision, methodological consistency, data sources used and reproducibility. The procedure implemented in the tool for the uncertainty quantification provides additional information about the confidence of the LCA results.

2. Methods

The calculations of the model are based on the primary data provided by the farmer at Farm Management Unit (FMU) level, which is the portion of land for which the data are representative. Two types of indicators are computed for FMU and growing season, carbon footprint (CF) and water footprint (WF), besides other agronomic parameters such as crop yield, gross irrigation requirements, pumping energy use efficiency and water used efficiency that are directly connected with the production costs.

The applicability of the tool is shown with four case studies: corn, nectarine, grape crops and tomato production in low-tunnel greenhouse. The obtained indicators are referred to mass of product (kg or t), although the reference flow for the compilation of the input data in the inventory questionnaire is referred to hectare and campaign. The use of this unit simplifies the work of the farmer when providing the information, because the amount of materials and energy corresponds to the spent for a hectare of land for the whole campaign assessed (a year in annual crops).

To carry out the CF and WF calculation a cradle to gate system boundary was considered. The frame includes the pre-farm processes such as the extraction of raw materials, production and transport of inputs. Within the production system (gate to gate) activities, the tool assesses the transport of the product to the closest cooperative, tillage tasks, energy consumption, irrigation, heating (protected crop), waste management, packaging and auxiliary equipment. Results of CF and WF are presented distributed in the different stages so the user can extract some valuable conclusions about the relative GHG emissions, material, energy and water consumption in the different process steps, for future environmental improvements and savings.

The software is developed in a spreadsheet format for its adaptation as a web tool with the following structure:

- Inventory questionnaire: list of necessary activity data for the compilation of all model inputs that have to be provided by the user.
- Database and default data: secondary data are provided from datasets of Ecoinvent Database (http://www.ecoinvent.org/), likewise default data for intermediate calculations are included (such as life span or material composition).
- Greenhouse module: equations for the accounting of materials involved in the greenhouse infrastructure.
- Calculation module: translates the activity data that characterize every sub-process in the system boundaries to environmental impact indicators considered.
- Uncertainty analysis module: applies an approximation method of error propagation from the activity data and emission factors uncertainties.
- Results: numerical and graphical report of the resulting values.

2.1. Inventory and scope

The system boundary was defined from raw material extraction to farm gate. Pre-farm processes (often referred to as 'cradle') such as the extraction of raw materials, production, and transport of inputs used on the farm are also included in the assessment. The production system (farm-gate) is structured in different stages: fuel, transport, energy, fertilizer, treatments, packaging, infrastructure, etc. Fuel stage includes the fuel consumption from farm tasks, and energy stage involves the pumping consumption for irrigation. The transport stage includes the production transport from farm to wholesale, the transport of materials within the farm and the transport of waste materials to a treatment plant. The fertilizer stage implies both manufacturing and consumption. In addition, four types of greenhouse structures are available: glass, multi-tunnel, "parral" or "Almeria-type" and low-tunnel. The assumptions applied for the average dimensions and the materials involved in each type can be found in Antón et al (2013), as well as the equations that relates the size and other parameters (depending of the type and subtype of greenhouse) with the amount of materials used.

2.2. Carbon footprint

The carbon footprint is a measure of the impact that human activities have on the environment in terms of the amount of GHG emitted over the full life cycle of a process or product measured in units of carbon dioxide equivalents ($CO_{2\text{-eq}}$). The CF is calculated based on the IPCC guidelines (IPCC 2006) that suggest a time horizon of 100 years for the decay rates and can be expressed as follows (Eq.1):

$$CF = EV * AD \qquad \text{Eq. 1}$$

where, *EV* is the emission vector per unit of reference for the specific activity (*e.g.* kg $CO_{2\text{-eq}}$ per kg of pesticide for the activity of pesticide manufacturing); *AD* is the activity data that expresses the intensity of the activity in the units of reference per functional unit (*e.g.* kg of pesticide$\cdot$(ha$\cdot$y)$^{-1}$).

The calculations include the N_2O induced emissions from managed soils, both direct and indirect releases. It comprises the emissions due to nitrification and denitrification processes from soils to which the nitrogen is added, volatilization of NH_3 and NO_x and subsequent redeposition, and leaching and runoff of nitrogen. Default emission factors are used for the evaluation of these three pathways based on the equations proposed in the chapter 11, volume 4 of the IPCC guidelines (IPCC 2006).

2.3. Water footprint

The water footprint indicator distinguishes the quantity of water consumed using a color code (green, blue and grey) depending on the type of water sourced and polluted. WF in a crop can be calculated using equation 2 (Hoekstra et al 2011):

$$WF = WF_{green} + WF_{blue} + WF_{grey} \qquad \text{Eq. 2}$$

where, WF_{green}, is the volume of rainwater consumed (the total rainwater evapotranspiration plus the water incorporated into the harvested crop); WF_{blue}, is the volume consumed of fresh surface or groundwater; WF_{grey}, is the volume of freshwater required to assimilate the load of pollutants based on natural background concentrations and existing ambient water quality, although this concept was left out of the scope in this study.

The mentioned water volumes can be used as translated to midpoint and endpoint impacts in assessment methods when applied to freshwater consumptive use by using the Water Stress Index (WSI) (Pfister et al 2009). The WSI can range from 0.01 to 1 and indicates the portion of consumptive water use that deprives other users of freshwater for a certain watershed, where a value of 1 means a serious water stress in a basin (0.259 for the Ebro basin). Therefore, the water footprint impact assessment for WF_{blue} and WF_{green} can be calculated as follows (Eq. 3 and 4):

$$WFIA_{blue} = WF_{blue} * WSI \qquad \text{Eq. 3}$$

$$WFIA_{green} = dGW * WSI \qquad \text{Eq. 4}$$

where $WFIA_{blue}$ and $WFIA_{green}$, are the water footprint impact assessment for the WF_{blue} and WF_{green}, respectively; dGW is the delta green water consumption (Nuñez et al 2012) that can be calculated as the difference between the WF_{green} and the consumed by the reference system (crop evapotranspiration) represented as ET_c.

2.4. Uncertainty analysis module

The procedure included in this module assesses the uncertainty that arise from two types of parameters: activity data and characterization factors. The approach follows the detailed guidance of the ILCD Handbook about data quality concept and approach and the data quality guidelines for Ecoinvent database v.3 (Weidema et al 2012).

Parameter uncertainty is represented by a lognormal probability distribution using the Pedigree Matrix approach that relates quality indicators to uncertainty ranges. Both basic and additional uncertainty, through variances of the underlying normal distribution, can be assigned. On the one hand, the activity data uncertainty is defined by the user/farmer following quality rules depending on the type of data estimation. However, there are available default uncertainty values according to different types of exchanges. On the other hand, basic uncertainty of the characterization factors is quantified for each LCA vector included in the inventory, as well as additional uncertainty according to five independent characteristics: reliability, completeness, temporal correlation, geographical correlation and further technological correlation.

As long as the tool needs a prompt response about the environmental performance of the scenario (i.e., for a given growing season and facility), an analytical propagation method is proposed. Particularly, Taylor series expansion method (Ciroth et al 2004) was formulated in the model to retrieve the uncertainty of the studied scenario computing the geometric standard deviation (GSD) as a function of each parameter GSD and its sensitivity associated (i.e., the influence or contribution of the impact due to a certain parameter over the total inventory impact). Therefore, the impact indicators of the crop (e.g., kg $CO_{2\text{-eq}}$ per kg of product) for a given season and field are depicted with an error bar.

3. Results & discussion

Figure 1 shows the results that the tool provides in terms of the carbon footprint impact for the production during a campaign of corn, grape and nectarine, with yields of 50800, 15300 and 47100 kg·(ha·y)$^{-1}$, respectively. The outputs are detailed for different productive processes considered in the system. Besides, error bars are included to represent the uncertainty associated with each value. From the results of the carbon footprint is possible to conclude that the contribution of fertilizer production and application to the global warming potential is the highest in grape and corn crops, while for nectarine the fuel consumption has the highest impact.

In addition, the uncertainty analysis yields the worst value for the corn production while the lowest uncertainty is obtained for the vineyard farm. These outputs are explained by the influence that the most uncertain activities have in the overall result. It is the case of the impact for transport and the use of fertilizers. In the case of transport, the uncertainty is due to the default uncertainty associated to the activity data. In the case of fertilizers the emissions factors have high uncertainty according to their data pedigree, as well as the high default uncertainty associated with the emissions of N_2O for the nitrogen application. Both activities are determinant in the corn faming because of their high contribution in the total impact.

In Figure 2 the water footprint values obtained for the three mentioned crops are displayed. The results raise higher water footprint impact assessment for corn production due to a higher value of blue water footprint considering the Ebro basin, followed by the grape and finally the nectarine production as the less water consumptive. The same trend for the green water footprint is shown, that is also higher in the case of corn farm.

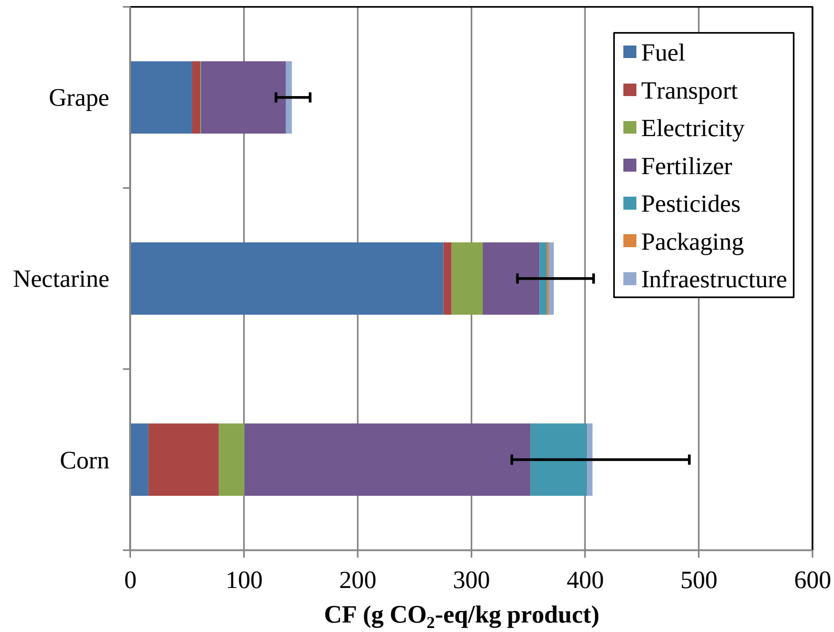

Figure 1. Carbon footprint results for each type of crop and distributed in different activities of productive process.

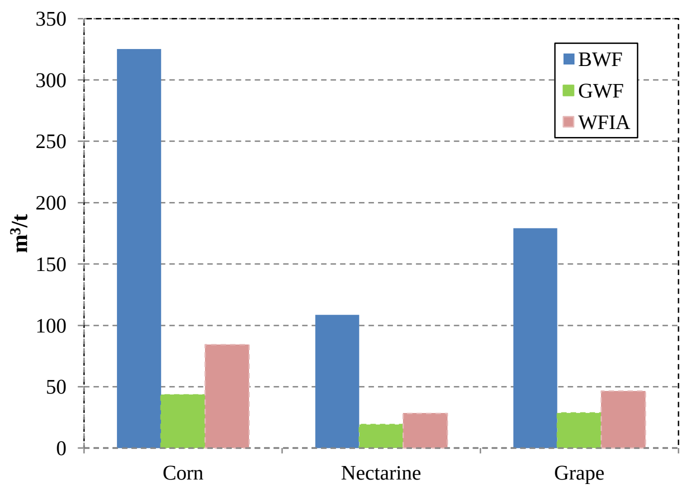

Figure 2. Blue and green water footprint (BWF and GWF) results and the total water footprint impact assessment (WFIA) for each type crop.

The production of 150000 kg·(ha·y)$^{-1}$ of tomatoes in a low-tunnel greenhouse without heating was evaluated obtaining a total carbon footprint of 293 g $CO_{2\text{-eq}}$/kg of tomatoes. The water footprint was not analysed for this time. Figure 3 shows the share of the different activities included in the inventory. The carbon footprint calculation for the tomato production in low tunnel greenhouse highlights the importance of including the infrastructure impact in the protected crops evaluation. Particularly, near a 30% of the global warming potential impact comes from the greenhouse structure followed by the fertilizers contribution. Nevertheless, the contribution of the structure would to the total impact would be reduced the 10% if the crop requires climate control systems since their impact usually become the most important.

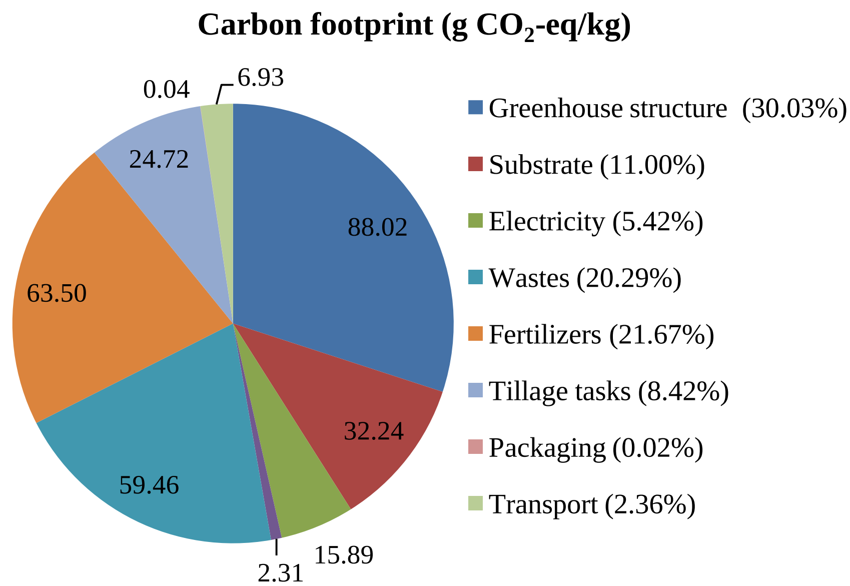

Figure 3. Carbon footprint impact for the tomato production in low tunnel.

Table 1 shows the values reported for the uncertainty analysis in the case of the corn production. The GSD of the whole inventory allows us defined 95% confidence interval for the calculated environmental indicator; particularly, the values correspond to the carbon footprint calculation. The Monte Carlo simulation was applied for the internal validation of the analytical propagation method proposed. More precisely, 5000 iterations were simulated using this method obtaining the corresponding confidence interval and the relative error indicated in the fourth column. A relative standard deviation of 24% was obtained from the uncertainty propagation procedure over the CF value obtained for corn production. The selected approximation method yields similar results to the Monte Carlo simulation with a difference lower than 5%, although the stochastic procedure tends to overestimate the impact. Nevertheless, the uncertainty outputs can be qualitatively characterized by comparing the resulting uncertainty with the intrinsic variability of the process, which is due to several factors varying with growing season and farm characteristics (e.g., crop production, weather conditions, soil conditions, etc.). Therefore, a quality rating can be derived depending on where the scenario's uncertainty is located with respect to the intrinsic variability of the system. This can be accomplished taking advantage of the potential spreading of the use of this tool, allowing us the access to primary data from different estates, crops and weather conditions.

Table 1. Results reported by the uncertainty analysis module for the carbon footprint of corn production.

	Taylor series expansion approximation	**Monte Carlo simulation**	**Error %**
Geometric mean	0.407	0.419	3.568
Geometric standard deviation	1.100	1.108	0.708
95% lower bound	0.334	0.342	2.187
95% upper bound	0.490	0.516	4.930

Some innovative aspects of the presented tool can be highlighted: the adaptation of the required data for the LCA to the reality of farms after conducting a sensitivity analysis for the identification of key inputs; the linking between the tool and quality standards for processes that are implemented at farm level, such as Nature 's Choice, GLOBALGAP or Integrated Production; and the best available technology for the data acquisition in surveillance systems to measure and calculate the actual values of the parameters needed for the evaluation and that can be also used to compute the effects of mitigation measures.

4. Conclusions

The developed tool provides a thorough inventory to assess the carbon and water footprint at farm level that is at the same time accessible and handy for the farmers to make available the reliable primary data needed. The tool is designed to support decision making, adapting the requirements of data to the reality of the farms.

The application of life cycle assessment indicators (carbon and water indices) enabled to take advantage of their benefits for suggesting environmental improvement in crop production. Through the carbon and water indices is possible to identify hotspots within the studied life cycle stages such as tillage task, energy consumption, treatment, fertilization, transport, etc. Moreover, the feedback from the users and stakeholders helps to incorporate new features and to continuously improve the tool.

The findings of this work reveal that the use of fertilizers has an important contribution in the global warming potential and hence it can be a priority in the reduction of the greenhouse gas emissions. Besides, the use of fertilizers is a source of uncertainty; therefore it is vital to have an accurate estimation of the fertilizer's contribution by means of the collection of high quality primary data about the chemical amount and composition, and the use of recognized emissions factors for the fertilizer manufacturing. The module for the calculation of the materials of the greenhouse structure is a value add-in given the widespread use of protected crops and the high impact in terms of carbon footprint of which greenhouses structures are responsible.

Additionally, the procedure for the uncertainty quantification module provides additional information about the confidence that the LCA inventory results can have. The method is intended to improve the agricultural activities management. The impact indicators accompanied by the confidence interval derived provide an important perspective when interpreting the results and when defining benchmarks for product comparison.

To achieve the indispensable participation of the farmers in the compilation of the inventory data, their cooperation is rewarded by raising awareness of the benefits that the results of the resulting reports can offer: adjusting the resources consumption (water, fertilizers, energy requirements, etc.); application of simple metrics for the diagnosis, comparison and impact evaluation of the management decisions; useful information in accordance with other quality requirements (e.g., Global GAP); and the availability of technical arguments for the product distinction in the market. Moreover, farmers use the tool based on data from their usual field notebook, in this way they can directly relate the resulting indicators, such as water or carbon footprint, to their common practice. Thus, a reduction in diesel consumption in irrigation and machinery can be evaluated simultaneously as economical and environmental savings.

Furthermore, the benefits are extended to the supply chain and stakeholders since the results allow them to evaluate different suppliers based on the mentioned metrics by product origin, thus helping in a better communication with the final consumer.

ABSTRACT

The aim of this study was to investigate how the present Danish diet could be changed in a climate friendly direction that follows the recommendations of a healthy diet. The carbon footprint (CF) of an average Danish diet was calculated and compared to CF of a recommended healthy diet by 1) modifying the average diet according to the Danish food based dietary guidelines, 2) and adjusting to ensure an iso-energy content and a nutrient content according to the Nordic Nutrient Recommendations. Afterwards the healthy diet was changed further to reduce CF.CF from the diet was reduced by 4%, if the healthy diet was eaten instead of the average current diet. However, if the diet was climate optimized by choosing foods with a low CF within the food groups; meat, vegetables and fruit, CF of this diet may be reduced by 23 % compared to CF of the average diet.

Keyword: Danish average diet, carbon footprint, Danish food based dietary guidelines

1. Introduction

In recent years focus has been on emission of greenhouse gases (GHG) from the food production. It has been estimated that the food sector in the developed countries contributes with up to 30 % of total GHG emission (Heller et al 2013; Tukker et al. 2009). Several Climate Summits organized by United Nation (latest COP19 was held in Warsaw, Poland from 11 to 23 November 2013) have been held in order to address the climate change at an international level, which unfortunately didn't result in specific targets or actions (UN 2009; UN 2010).

The special thing about food production is that in addition to contributing to emission of CO_2 from fossil energy consumption it also contributes with the so-called non-energy-related GHG emission – in form of the nitrogen oxide (N_2O) emissions related to use of fertilizers, deforestation (CO_2), and methane (CH_4) from ruminant digestion.

The diet and consequently the related food production contribute to the GHG emission. The different stages of each food items life cycle contribute to the GHG emission: the primary agricultural food production, food processing, as well as during transport and storage of food (Carlsson-Kanyama et al. 2003; Carlsson-Kanyama and Gonzales 2009; Garnett 2008; Garnett 2011; Nielsen et al. 2003). Finally, also the cooking at home contributes to the GHG.

The climate impact can be assessed from different perspectives; a production perspective i.e. the burden of the total food produced in Denmark inclusive emissions from food that is exported to other countries, or alternative from a consumer perspective – i.e. the burden of the food consumed in Denmark exclusive emissions from food that is exported and inclusive emissions from food that is produced outside Denmark. Seen from the production perspective, Denmark's agricultural production was estimated to represent 16 % of the total Danish emission of GHG (Olesen 2008). The climate impact of the Danish food consumption from the consumer perspective was calculated to be around 2.8 tons CO_2-eqv / person/year – equivalent to approximant 15.4 mill. tons CO_2 for the total Danish population and thus approximate 25 % of all GHG from The Danes' total consumption according to IDA's Climate Plan 2050 (Anonymous 2009).

Different types of foods contribute to different degrees to the climate impact. There are big differences between the level of GHG emission from different food groups e.g. between animal products such as meat and cheese and vegetable products such as vegetables, flour and grain. Also within the various food groups there are differences, e.g. between different types of fish or meat depending on the way the products are produced (Carlsson-Kanyama and Gonzales 2009; Olesen 2009).

The amount of GHG emitted by a produced food product is called the food's carbon footprint (CF). CF or global warming is one among several impact categories; acidification, nutrient enrichment, photochemical smog and land use etc. The CF is calculated by a life-cycle assessment (LCA), which includes GHG emission from the foods whole life cycle: agriculture, horticulture or fishing, including emissions related to the production of inputs such as fertilizers, processing, transportation and storage of food products until the food products are placed on the shelf in the supermarket. The CF of the preparation at households is typical not included (Mogensen et al. 2009a; Garnett 2008) and not needed in some comparison studies (Tukker et al. 2011). Some LCA calculations also include estimations of GHG contribution derived from food waste (Mogensen et al. 2011; Anonymous 2009). Differences in the used LCA calculation methods may complicate comparisons between CF from different sources. Furthermore, production methods and energy resources change over time, and therefore influence the results of calculations.

This study (Thorsen et al. 2012) was based on Danish food based dietary guidelines from 2005 (Astrup et al. 2005) including currently updates. They aim at increasing the intake of fruit and vegetables, bread and cereals (coarse or wholegrain) and fish, and a decrease in intake of fat from dairy and meat products and of sugar containing products. In 2013 the scientific evidence of the Danish food based dietary guidelines was updated. The main conclusions were that the increase of fruit and vegetables was maintained, fish intake was increased, an increased intake of wholegrain cereals was specified and the decrease in fat from dairy and meat products was emphasized. Furthermore the intake of red meat (cow, sheep, pig) and the sugar containing foods were restricted, especially sugar containing beverages.

1.1. Objectives

The aim of this study was to investigate how the present Danish diet could be changed in a climate friendly direction and at the same time following the recommendations of a healthy diet.

2. Methods

The carbon footprint (CF) of the average Danish diet estimated from the National Danish Survey on Diet and Physical Activity from 2003 to 2008, including 3354 adults, 18-75 years of age, hereof 47% men (Pedersen et al. 2010) was estimated. CF of an average diet was compared with CF of a diet that follows the Danish dietary recommendations. This diet was obtained by 1) modifying the average diet by scaling the food groups according to the Danish food based dietary guidelines (Astrup et al. 2005), and 2) adjusting to ensure an iso-energy content of the diets and a nutrient content that follows the Nordic Nutrient Recommendations (Nordic Council of Ministries 2004). The healthy diet was designed by using a modeling tool developed from the Danish nutrient calculating system GIES (Biltoft-Jensen et al 2008).

To assess the impact of food production on global warming the CF from each food item was calculated by use of life cycle assessment (LCA) (ISO 2006a; ISO 2006b). The LCA method implies that all emissions of GHG from cradle to grave are included. I.e. all GHG emissions from production and transportation at the farm, but also the GHG emissions related to processes after the food leave the farm are included. The CF from individual foods i.e. is expressed in CO_2 equivalent per unit of food produced, and the functional unit (FU) is one kg food. The CF values are from Mogensen et al. (2009 b) and are based on data from Nielsen et al. (2003). The average CF for the individual food group is weighted according to the distribution of different types of food items within the food group in both diets.

In the calculation of the CF of food intake the contribution from GHG emissions related to food waste was taken into account from the whole food chain, from production to retail and households. As there is no Danish estimations of food waste in households, waste was estimated from an English report about food waste on individual food groups; on average about 20% of purchased food ends up as edible waste, i.e. waste that could have been avoided (WRAP 2008).

The healthy diet was investigated further with the aim to reduce CF of the diet by using the “hot spot” approach. Hot spot food groups were in focus, i.e. food groups where it is easy and convenient to change between different food products in the group in order to minimize the CF. Hot spot analyzes are interesting because in that way you could help the consumer to choose more climate friendly food, while taking into account also the Nordic recommendations (Nordic Council of Ministries 2004) and the 8 Danish dietary guidelines (Astrup et al. 2005).

When the hot spot perspective is related to the dietary guidelines it is important to focus on food groups that have a high food consumption (large amount of food) and/or include foods having a large CF (high CO_2/kg food). The next step is to assess how foods of the hot spot food groups could be exchanged with similar foods within the group with lower CF.

Finally, the Danish food based dietary guidelines from 2013 (Danish dietary guidelines 2013; Tetens et al. 2013) were investigated and if relevant, complementary advises related to improving the climate impact were added.

3. Results

The estimated CF from the Danish' average diet (2003-2008) and a modeled recommended diet that meets the dietary guidelines and the nutritional recommendations are shown in Table 1.

Table 1 comprises 14 different food groups. Both diets are scaled to an energy intake of 10 MJ/day. These food intakes also give rise to food waste in retail, processing and household. Regarding fruit and vegetables also a 20 % peel waste (inevitable waste) is included. Table 1 shows an estimate of how much the changes from the average diet of the modeled recommended diet would benefit the climate. It is seen that the largest differences obtained by a reduction of the amount of meat with approximate 50 g. This is to some extent cancelled by the contribution from the foods replacing the meat such as the food groups of fruit, vegetables, milk and fish which according to the Danish food based dietary guidelines 2005.

The calculation shows that CF from the diet was reduced by 4%, if the healthy diet was eaten instead of the average current diet. The largest reduction is a result of reduced intake of meat and beverages (beer and wine). The GHG contribution of beverages (excluding milk and juice) has declined by almost 40 %. Overall the recommended diet has a CF that was approximate 4 % lower than the current average diet.

Table 1. The carbon footprint (CF) for an average Danish diet and for a modelled recommended diet (that fulfills both the dietary guidelines and the Nordic recommendations). Both diets are scaled to a daily energy intake of 10 MJ. The CF values are from Mogensen et al. (2009 b) and are based on data from Nielsen et al. 2003.

Food group	CF, kg CO_2/kg food	Intake g/person/day		Food waste, % [6)]	CF form the diet gram CO_2/person/day	
		Present average diet	"Modelled recommended diet"		Present average diet	"Modelled recommended diet"
Milk, dairy products	1.2	359	500	3;2;2	462	644
Cheese	11.3	38	25	3;2;2	455	303
Bread, rice, pasta	0.8-3.3	236	274	31;6;2	403	480
Vegetables	0.1 – 2.9	186	304	(19-45);6;2; (0-20)	381	567
Potatoes	0.2	113	192	19;2;2;20	31	52
Fruit (ex. Juice)	0.4	245	271	26;6;2;20	230	260
Juice	1.0	80	50	18;2;2;0	102	63
Meat	3.6 – 19.4 [2)]	121 [3)]	87 [4)]	13;2;2;0	1599 [7)]	1277 [7)]
Poultry	3.4	27	31	13;2;2;0	149	171
Egg	2,0	19	25	18;2;2;0	49	63
Fish	1.8 – 10,5	25	42	13;2;2;0[8)]	170	292
Fats	5.1	38	32	3;2;2;0	219	173
Sugar and candy	1.0	36	23	18;2;2;0	41	29
Beverages	0.02 – 2.1	2273	1955	3;2;2;0	698	417
Total diet [1)]					**4986 (100)**	**4790 (96)**
Recommended and climate friendly diet [1,5)]						**3864 (77)**

1) Beverages are included, figures in brackets: percentages related to average diet.
2) Climate footprint per kilo carcass – Amount of carcass behind an intake is calculated by using a factor 1,47 for beef, 1,33 for pork and 1,38 for poultry (chicken)
3) Type of meat in the present average diet: Men: 135 g meat/day: 25 % beef, 75 % pork. Women: 106 g meat/day: 28 % beef 72 % pork.
4) Meat in the recommended diet: Men: 92 g meat/day: 30 % beef, 70 % pork. Women: 81 g meat/day: 33 % beef, 67 % pork.
5) Climate friendly diet: The only difference from "recommended" diet is: within the food group: fruit, vegetables and meat a climate-friendly solution is chosen e.g. For the food group vegetables carrot is chosen, for the food group fruit apple is chosen and for the food group meat the reduction is done for beef and then for pork.
6) A larger food production is needed than the food intake figures show since food waste is found in all parts of the food chain. The figures cover edible food waste in household ; retail; processing; and peel/skin (not edible, inevitable waste for fruit, vegetables and potatoes).
7) Incl. calculation from carcass to meat.
8) All fish products are calculated without bone like fillet and peeled shrimp

In Table 2 we take a closer look at the CF for the hot spot food groups: meat, vegetables, fruit and fish. From Table 2 it can be seen that it is possible within the different food groups to reduce the contribution to CF by choosing foods with a lower CF. In order to choose climate friendly foods it is better to choose e.g. poultry or pork instead of beef, and fruit or vegetables in season instead of food produced in a greenhouse or imported. Regarding fish a climate friendly choice would be herring or mussels instead of flatfish or shrimps.

In addition the diet was optimized to reduce CF of the diet by choosing foods with a low CF within the food groups; meat, vegetables and fruit, CF of this diet may be reduced by 23 % compared to CF of the average diet.

Table 2: Effect on the contribution to carbon footprint (CF) from different food groups dependent on choice of food item within food group

Food group	Foods item	"Modeled" recommended daily intake in gram[2)]	Food waste % [5)]	CF from the food items kg CO_2/kg food	Contribution to CF from the production of the daily intake of food [1)], gram CO_2/day
Meat and meat products	Average diet – mix of food items within the food group	87	13;2;2;0	9.2 [4)]	1277[6)]
	Beef	87	13;2;2;0	19.4 [3)]	2966 [6)]
	Pork	87	13;2;2;0	3.6 [3)]	498 [6)]
	Chicken, fresh	87	13;2;2;0	3.1 [3)]	445 [6)]
	Chicken, frozen	87	13;2;2;0	3.7 [3)]	531 [6)]
Vegetables (ex. potatoes)	Average diet – mix of food items within the food group	304	(19-45);6;2;(0-20)	1.32 [4)]	567
	Carrot	304	19;6;2;20	0.122	62
	Onion	304	19;6;2;20	0.382	195
	Greenhouse vegetables	304	19;6;2;0	2.7	1099
Fruit	Average diet – mix of food items within the food group	271	26;6;2;(0-20)	0.52 [4)]	260
	Orange	271	26;6;2;20	0.7	347
	Banana	271	26;6;2;20	0.5	248
	Nuts, almonds	271	26;6;2;0	0.88	350
	Danish apple, pear	271	26;6;2;20	0.1	50
	Imported apple, pear	271	26;6;2;20	0.4	198
Fish and fish products [7)]	Average diet – mix of food items within the food group	42	13;2;2;0	5.7 [4)]	292
	Herring, fillet, peeled, frozen	42	13;2;2;0	1,8	90
	Shrimp, frozen, peeled	42	13;2;2;0	10,5	528
	Codfish, fillet, frozen	42	13;2;2;0	3,2	161
	Flatfish, fillet, frozen	42	13;2;2;0	7,8	392

[1)] Calculation of CF is based on produced amount of feed, taking into account food waste.
[2)] Food intake is an average for men and women.
[3)] CF of meat is given as CF per kg carcass, needed amount of carcass per kg meat intake: 1.47 for beef 1.33 for pork and 1.38 for poultry.
[4)] Average CF for all type of meat in the meet group, weighted according to distribution of different types of meat, accordingly average CF for the other food groups
[5)] Food waste in household; retail; processing; and peel/skin (not edible, inevitable waste for fruit, vegetables and potatoes)..
[6)] Incl. calculation from carcass to meat.
[7)] All fish products are calculated without bone like fillet and peeled shrimp

In the climate friendly diet, we have reduced the meat intake by 50 g/day, removed the beef and then reduced the pork. The intake of vegetables was increased with 300 g/day, and the vegetables with the lowest CF (such as carrots) was chosen, and regarding fruit the amount of fruit was increased by 50 g/day and fruit with the lowest CF (such as Danish apple) was chosen. The results are shown in Table 1 above and in footnote 5.

4. Discussion

The present study showed that the climate impacts from human food consumption can be reduced by conscious food choices. Beside that minimizing food waste and choosing a more sustainable food production in relation to agriculture could reduce CF from food production further.

In this study, the most recent dietary data were used for rough calculations of the climate contribution of a recommended diet compared to the current Danish diet. According to our calculation the climate contribution from the diet will be 4 % reduced, if the recommended diet is eaten instead of the average current diet. A saving in carbon footprint in the order of 4% CO_2-eq is so small compared to the uncertainty of the data included that is not necessarily a real saving.

In addition to eating a recommended diet people would optimize their diet in a more climate friendly way by choosing foods with a low carbon footprint, especially in the food groups; meat, vegetables and fruit. Our calculations show that the CF of such a climate friendly diet including beverages would be reduced by 23 % compared to CF contribution of the average diet. Thus, a climate optimized recommended diet would provide a significant reduction of the CF (23%) as compared to a recommended diet (4%). The number (23 %) is not essential, it can be less or more, but the savings are significant compared to the recommended diet. In real life the savings from the food groups meat, fruit and vegetables probably would be less than estimated here, but on the other hand optimized choices within the other food groups is expected to provide further savings. Thus there is a great potential for reducing CF of the diet by choosing climate friendly within a recommended diet. If households further reduce their food waste, it will have a major effect on climate impacts. The total food waste in households is estimated to be around 20%, accounting for 12.5% of the CF of food production. However, the calculations are based on English data from investigating food waste in households (WRAP 2008). More recent data from Danish households are needed to validate this part of the calculation.

Other studies (Mogensen et al. 2009b; Saxe et al. 2006; Tukker et al. 2011) find similar to the present study that a diet following the dietary guidelines will have a slightly lesser impact on the climate all other things being equal. However, it has also been found that high-nutritional diets had significantly higher GHG emissions than low nutritional quality diets (Vieux et al. 2013), Another study found that the GHG emission was 27 % lower when the diet (the New Nordic) was climate optimized by choosing either less beef or by substituting all meat with legumes, dairy products and eggs (Saxe et al. 2013).

In this study the energy and nutrient content are estimated for the average as well as the recommended diet. The diets are comparable since the energy content equals, and the recommended diet is also adjusted so that the nutrient contents are in accordance to the recommended levels. (Vitamin D is an exception, so other sources should be taken into account, such as supplementation and/or production within the body exposing the skin to sunlight). Therefore the functional unit kgCO_2/kg food of CF is used for the foods and g CO_2/day for the diets. However, the present study is an approximation with regard to the CF calculations and is conducted to get an overview of the CF from the overall diet. More accurate calculations of the climate-optimized diet require more in-depth investigations and further nutritional calculations that are beyond the aim of this study. For instance in the climate-friendly diet the milk intake is set to be 500 g/day, although this could be reduced to 250 ml/day in accordance with the Danish dietary guidelines from 2013 (Tetens et al. 2013), it might not be in accordance with removing all of the beef. Furthermore, a decrease in milk content of the diet needs to be accompanied by an increase in other food items that will provide energy and nutrients in approximately the same amount.

Fruits, vegetables, cereals and potatoes, which according to the dietary guidelines should be by far the largest part of the diet, are all low in climate impact, especially when choosing open field grown products and avoiding products transported by airplane. Meat and cheese are generally high in CF, but CF from meat as beef and lamb is higher in CF than pork and poultry. Also vegetable oil should replace butter and hard margarines, vegetable oils generally have a lower CF. Stimulants as sweet and alcoholic drinks, sweets and cakes, which should decrease in the Danish diet, probably have a rather high CF, but the data concerning CF of this food group is weak and should be improved considerably. An increased intake of fish that is advised by the dietary guidelines would by all means increase the climate impact and might be problematic if leading to overfishing (Clonan et al. 2013), but the negative impact may be limited by a conscious choice of fish products. Eating the recommended diet would change the diet in the direction of lower fat and higher fiber content, e.g. by reducing the intake of red meat and cheese and instead eat more coarse vegetables and fruit, bread and grains. By further choosing foods with a low carbon footprint whenever possible the climate impacts of the food consumption is reduced significantly. The climate friendly additions to the dietary guidelines should be short advises that are easy to understand and follow by the consumer. Therefore advises regarding the transportation of the foods are not included, since it is very complicated to explain the exceptions and since the consumer usually has no knowledge about how and how far the food items have be transported. These qualitative advices was in line with guideline development in Sweden and the Netherlands (Fogelberg 2008; Health Council of the Netherlands 2011).

5. Conclusion

It was concluded that there is potential synergy between a healthier diet and a more climate friendly diet. There seems evidence to complement the Danish dietary guidelines 2013 with the following advice *(in italic type)* to reduce the CF from the diet:

- Eat a varied diet, not too much, and be physical active
- Eat fruit and many vegetables – *preferably open field and in season*
- Eat more fish - *choose the climate friendly fish; herring and mussels*
- Choose whole grain
- Choose low-fat meat and meat products – *choose pork and poultry rather than beef and lamb*
- Choose low-fat milk and milk products - *restrict intake of cheese*
- Eat less saturated fat - *choose vegetable oils rather than animal fat*
- Eat foods with less salt
- Eat less sugar - from soft drinks, sweets and cakes
- Drink water - rather than sweet and alcoholic drinks
- Avoid overeating - *and waste - will also reduce CF from food production since less food need to be produced*

ABSTRACT

To facilitate the adoption of low-carbon farming practices in Europe, the European Commission developed a carbon calculator that assesses greenhouse gas (GHG) emissions and recommends mitigation actions suitable for each farm. The Carbon Calculator, which quantifies GHG emissions based on international standards for life cycle assessment and carbon footprinting, delivers carbon footprint results both at the farm and product level. To best fine-tune the calculator, a testing phase was conducted by calculating the carbon footprints of 54 farms located in seven European countries that were characterized by a variety of different practices and products. Wide variation was found in the carbon footprints quantified within each product group. This variation can be explained by different levels of input use, crop yields and other farming practices. It was concluded that the calculator can help EU farmers identify actions that could lead to substantial reductions in the carbon footprints of their farms and products.

Keywords: life cycle assessment, agriculture, greenhouse gas emissions, carbon footprint, environmental footprint

1. Introduction

In the European Union (EU-27 Member States), direct emissions of greenhouse gases (GHG) from agriculture accounted for around 10% of total emissions in 2011 (EEA 2013). According to the European Commission's Roadmap 2050, the target is to reduce agricultural GHG emissions by 42 – 49% relative to 1990 levels by 2050 (EC 2011).

To facilitate reducing farm-level GHG emissions, appropriate and context-specific policy instruments are needed. These measures are to be coupled with supporting tools in order to promote low-carbon farming practices. Many farm-level carbon footprint calculators have been developed to provide support to farmers in identifying the main GHG emission sources along with possible reduction strategies. Examples include the Cool Farm Tool (Hillier et al. 2011), CLA CAML Calculator (CLA 2014), Farm Carbon Calculator (FCC 2014) and Cplan Carbon Calculator (Cplan 2014). As a part of the European Commission project on Low-Carbon Farming, a new farm-level carbon calculator was developed. The Carbon Calculator is suitable for the main farming types in the whole EU, and it also generates farm specific mitigation action recommendations.

During the development process of the Carbon Calculator, the tool was tested on 54 farms around Europe. In this paper the preliminary results of the testing phase are presented and the reasons for differences in the results between different farms are investigated.

2. Methods

2.1. Carbon Calculator

The Carbon Calculator quantifies GHG emissions according to international standards and other technical specifications for life cycle assessment (LCA) and carbon footprinting (GHG Protocol 2011; ISO 14040 2006; ISO 14044 2006; ISO/TS 14067 2013) while also striving for alignment with the European Commission's Environmental Footprint methods (EC 2013) and the EnviFood Protocol (Food SCP RT 2013). The tool is designed to be suitable for the most common farm types in the EU-27.

The main elements of the method underpinning the Carbon Calculator are described below. For a broader description of the method, see Bochu *et al.* (2013). The Carbon Calculator has been developed in Microsoft Excel. Visual Basic for Applications (VBA) was used for creating user forms for data entry. Specific skills for using Microsoft Excel spread sheets are not required to operate the calculator. The tool has been designed to be used by farmers or farmers' advisors. The latest version of the Carbon Calculator, the user handbook and the methodology guide are available for free download at http://mars.jrc.ec.europa.eu/mars/Projects/LC-Farming.

2.2. System boundaries, functional units, allocation rules

The system boundaries for the Carbon Calculator extend from cradle to farm gate. Processing of foods at farm is not included in the system boundaries. The GHG emissions included are CO_2, CH_4, N_2O and hydrofluorocarbons (HFC). GHG emission sources considered are: CO_2 emissions from fuel use and burning of crop residues; CH_4 emissions from ruminant enteric fermentation and manure management; N_2O emissions from soils due to use of organic and synthetic N fertilizers; and HFC emissions from leakage of refrigeration gases. In addition, the upstream emissions generated outside of the farm include emissions from the production and transportation of farm inputs, production of buildings and farm machinery, pumping drinking or irrigation water by collective pumping systems, fuel use by contractors for field operations; and N_2O emissions from NH_3 volatilization and from N leaching and runoff are also incorporated. The user of the Carbon Calculator can choose whether direct land use change (LUC) emissions related to purchased feed are included or not.

Changes in carbon stocks in soils (management practices and land use changes) and in farmland features (natural infrastructure), as well as GHG emissions avoided through the production of renewable energy (whether used on the farm or sold) are quantified but reported separately from other GHG emission results. In addition, the carbon calculator delivers results in terms of direct primary energy use, water use and the nitrogen balance of the farm.

The Carbon Calculator quantifies emissions from the whole farm during a year (or production season). Results are presented on the basis of two different functional units, i.e. (i) the utilized agricultural area (UAA) of the farm (tCO_2-eq/ha UAA) and (ii) a ton of each of up to five main products. In the case of livestock meat production, the functional unit is a ton of carcass live weight. If the farm produces more than five products, the remaining products are allocated to a sixth category named "other products".

In the Carbon Calculator, the production data are entered separately for each crop and livestock type and, in most cases, the inputs can be directly attributed to specific products. In some cases the user has to allocate environmental loads between different products. Regarding the use of fuels in farm machinery (excluding machinery use for crop production), electricity, buildings and other materials used as production inputs (e.g. plastics), the user has to allocate the energy inputs between the products of the farm. Fuel used for field operations is directly attributed to the corresponding crops. The user has to indicate whether each crop is used for feed at the farm or sold out.

In the case of co-products (e.g. milk and meat or eggs and meat) physical allocation based on protein content is used. Meat output is determined based on the weight of the animals sold during the assessment period. The emissions of the whole cattle herd during the assessment period are fully allocated to the products (meat, milk or eggs) delivered by the farm during the assessment period. If the farm does not sell any animals during the assessment period, the carbon footprint of meat is not measured by the Carbon Calculator and all emissions are allocated to the milk sold. Indeed, this is a weakness of the current Calculator that will have to be remedied in its next version.

Two options for the end of life management of exported manure are included: manure is spread on another farmland or treated as residue. If manure is spread on another farm, the farm inventory is credited for the avoided emissions from nitrogen-based fertilizer production calculated as an equal amount of nitrogen from mineral fertilizers. If manure is managed as residue, the emissions from its management are included in the carbon footprint of the farm. In both cases, the emissions from transportation of manure are included.

2.3. Data for emission factors

The IPCC (2006) Tier 2 methodology is used for i) CH_4 emissions from enteric fermentation, manure storage, manure application and manure deposited on pasture land; ii) N_2O emissions from manure storage and application and N fertilizer use; and iii) changes in carbon stocks. The emissions for production and transportation of mineral fertilizers are based on Weiss and Leip (2012), Wood and Cowie (2004), ADEME (2012), GESTIM (2010) and Brentrup and Palliere (2008). For purchased feedstuff the user can choose between two datasets: data based on Weiss and Leip (2012) include LUC emissions whereas data based on ADEME (2012) do not include

LUC emissions. Data from ADEME (2012) is also used for seeds, buildings, machinery, plastics and collective irrigation. Data from the European Life Cycle Data System (ELCD) (2001) are used for electricity and fuels.

2.4. Mitigation and sequestration actions

The Carbon Calculator includes 16 GHG mitigation actions. The actions were selected based on the mitigation potential and practicality of implementation by the farmers. The tool calculates the mitigation costs/savings for six mitigation actions.

2.5. Farm data

Data for the Carbon Calculator were collected from 54 farms in seven European countries, including 20 farms in Spain, 19 in the United Kingdom, 6 in the Netherlands, 4 in Italy, 2 in Germany, 2 in Poland and 1 in Slovenia. The data included 43 conventional, 8 organic, 2 integrated and 1 conservation farm. The study regions were chosen on the basis of their suitability to represent a wide range of environmental zones. The data were collected as a part of a survey that studied the farmers' willingness to use the carbon calculator (except the data from Italy) (Elbersen et al. 2013). A tutorial for the Carbon Calculator was shown to farmers before they were requested to complete a survey regarding their willingness to use the tool. The farmers were subsequently queried as to their willingness to provide farm data for the Carbon Calculator. In total, 170 farmers were approached in eight EU countries (i.e. Denmark, Germany, Spain, Netherlands, Poland, Slovenia, Sweden and United Kingdom) as part of the survey. Of these, 50 farmers provided data for the Carbon Calculator. In addition, data from 4 Italian farms were collected at a later stage.

3. Results

The three main sources of GHG emissions from livestock farms were enteric fermentation, N_2O emissions from soils and manure management. The main emission sources on crop farms included fertilizer production, N_2O emissions from soils and machinery manufacturing (Table 1). The sources with lowest contribution in both farm types were fuels manufacturing and transportation and other inputs (e.g. seeds, pesticides and plastics), and purchased feedstuff for the livestock farms.

The results of the carbon footprint of products show that the median values are close to the reference values found in literature (Table 2), even though the range between minimum and maximum values is wide. The wide range of the results, especially in livestock sectors, is explained by the allocation technique used, which attributes all of the emission of the cattle produced during the assessment period to the livestock product output produced during the assessment period. The high emissions in some crop farms can be explained by high levels of nitrogen fertilizers used on those farms.

Due to insufficient number of samples from organic farms, it was not possible to statistically evaluate the differences between carbon footprints of organic and conventional farms. The results of milk and barley were selected for further analysis as they represent the most common livestock and crop products in the dataset (Table 3). Wilcoxon non-parametric test for sample pairs showed significant difference in the carbon footprint results of milk between the UK and Italy ($W = 6$, $p= 0.022$) and Italy and Spain ($W = 12$, $p = 0.034$) whereas no significant differences were found between the other countries.

In the case of barley production, the statistical difference was tested only between Spain and the UK due to the small sample size in Poland. Significant differences in the carbon footprint results of barley production were not found between Spain and the UK.

Spearman's rank test was used for testing the correlation between nitrogen balance of the farm and carbon footprint results of milk and barley. Significant correlation was not found between nitrogen balance (nitrogen inputs – nitrogen outputs) and carbon footprint of milk production. In the case of barley, statistically significant moderate positive correlation was found between nitrogen balance and carbon footprint ($r = 0.596$, $p = 0.032$).

Table 1. Results of the sources of greenhouse gas emissions from livestock and crop farms.

Emission source	Livestock farms (N=41) % of total emissions	Median ($kgCO_2/ha$)	Variation Coefficient	Crop farms (N=13) % of total emissions	Median ($kgCO_2/ha$)	Variation Coefficient
GHG emissions from direct activities	**87**	**5960**	**1.0**	**43**	**895**	**0.5**
Enteric fermentation	54	3697	1.0	-	-	-
N_2O emissions from soils	18	1256	1.2	32	663	2.1
Manure management	12	797	1.3	-	-	-

d Nijdam et al. (2012)

It was found that the results of emission sources for milk and barley production in the inventory correspond closely to the results found in literature for average emissions of milk production in EU and barley production in the UK (Table 4). These results exclude land use change emissions related to purchased feed production. In the case of milk production, the main difference between the median and the reference value was in fertilizer production. This could be explained by the relatively high number of conventional farms in our database that used only manure as fertilizer. The relatively low contribution of capital goods such as buildings and machinery to the overall carbon footprint of milk may be explained by the incomplete submission of data from some farms. Often, it was found out that farmers are seemingly likely to collect little information on capital goods. Comprehensive assessments are difficult without using default data. In the case of barley, the largest difference in the median and reference values was in N_2O emissions from soils. This could be explained by high variation in the nitrogen balances in our dataset.

Table 3. Descriptive statistics of the carbon footprint results of milk and barley production (tCO_2-eq/t).

Country	Number of farms	Min	Max	Average	Median	Standard Deviation	Variation Coefficient
Milk							
Italy	4	1.27	1.55	1.37	1.34	0.13	0.09
Netherlands	4	0.80	1.62	1.07	0.92	0.38	0.36

[b] Williams et al. (2006)

The most common mitigation actions recommended by the Carbon Calculator were agroforestry, biogas production, and reduction of methane from enteric fermentation (Table 5). The most effective mitigation actions in terms of the median mitigation potential (as % of total farm emissions reduced) included use of no-tillage, improvement of the nitrogen fertilizer balance and biogas production.

The current version of the Carbon Calculator estimates the costs/savings of some of the mitigation actions. In nearly all cases, the Carbon Calculator showed savings gained by implementing the mitigation actions (Table 6). However, these results do not include possible investment costs, but represent only the changes in the input costs.

Table 5. Preliminary results of the mitigation actions recommended to the farms in the dataset (in % of total farm-level emissions reduced).

Mitigation Action	Number of farms	Median	Variation Coefficient
No-tillage	16	9.5	0.87
Adjust N fertilizer balance	16	9.2	1.1
Biogas production	37	8.6	0.77
Agroforestry	45	6.9	1.2
Soils covered all the year	13	5.3	0.64
Reduce methane from enteric fermentation	32	4.8	0.42
Implementation of hedges and other landscape elements	15	4.2	0.60
Introduction of legumes in the rotation	27	3.0	0.82
Change in slurry management system: cover/crust	1	1.9	-
Wood boiler	2	1.8	0.31
Reduce engines fuel consumption (test and eco driving)	10	1.3	0.56
Solar panel on suitable buildings	0	-	-
Introduction of legumes in grasslands	0	-	-
Avoid burning residues	0	-	-
Reduction of electricity consumption of the milking system	0	-	-
Heat water with solar panel	0	-	-

Table 6. Preliminary results of the greenhouse gas mitigation costs/savings

Mitigation action		Mitigation savings (Euro/ha)		
	N	Median	Min	Max
Adjust N fertilizer use	19	93	3.1	1000
Soils covered all the year	14	62	-7.2	1200
Use of wood boiler	5	33	4.0	75
Heat water with solar energy	1	9.6	9.6	9.6
Reduce tractor fuel use	19	8.7	1.7	65

4. Discussion

The preliminary results show that the Carbon Calculator generates carbon footprint results that are close to the reference values found in literature. However, the variation in the results was wide. In the case of livestock meat, the variation can be explained by the allocation method used for allocating emissions to the end product. For instance, in the case of beef, all emissions related to raising the beef cattle are allocated to the meat sold in that year. Assuming a situation when only a relatively small quantity of animals is slaughtered compared to the total number of animals raised in a certain year, the meat produced receives a relatively high apparent carbon footprint. Therefore, the allocation of the impacts to the livestock products does not reflect reality, and thus, caution is needed when the results are compared with other farms or within the same farm between different years.

In the case of crop products, some large carbon footprint preliminary results were explained by high level of nitrogen fertilizer used on those farms. The detailed results of barley production showed that the emissions of fertilizer production varied between 87 and 719 kg CO_2-eq/t barley, and the N_2O emission from soils varied between 114 and 538 kg CO_2-eq/t barley.

The data presented in this paper did not include LUC emissions related to purchased feed production. It has been shown that inclusion of LUC emissions can triple or even quadruple the carbon footprint of livestock products produced in Europe, especially when imported soybean feed is used (Weiss and Leip 2012). We found the same effect in our data when we tested the impact of the choice of purchased feed emission data on the results (data not shown).

The results produced by the Carbon Calculator have to be interpreted with caution. Due to the attributional LCA approach used, the tool does not capture possible impacts associated with indirect effects, such as substitution effect, indirect land use change, income effect, secondary effects, market-clearing price and quantity adjustments. For instance, the emissions of a farm and its products may be reduced by extensification (reduced inputs and reduced yields). However, this may lead in increased production somewhere else, assuming that consumption quantities remain at the same level. Therefore, the impact of the mitigation actions can only be judged when changes in the production patterns and outputs quantities at the farm do not induce market-level changes in production and consumption.

The results presented in this paper showed that mitigation actions recommended by the Carbon Calculator can help farmers to reduce costs while also reducing GHG emissions. This is also supported by literature. For example, MacLeod et al. (2010) showed that, in particular, mitigation actions related to improved nitrogen use efficiency can reduce costs.

In addition to GHG emissions, the Carbon Calculator reports direct energy and water use, and nitrogen balance. To avoid burden shifting from climate change to other environmental impacts, future versions of the tool the scope should be extended to include a broader range of impact categories.

5. Conclusion

This paper showed that the Carbon Calculator generates results that are comparable with results from literature. The Carbon Calculator can also help farmers identify mitigation actions that reduce input costs while decreasing GHG emissions. Due to the methodological choices related to allocation for livestock emissions, comparisons of the results between different farms should be undertaken with caution. In the case of livestock farms, the current version of the tool is best suited for comparing carbon footprint results of one farm within different years if the farm has the same number of animals and animals sold in each year. Further improvements to the tool are required before it can be used for benchmarking purposes.

Other improvement possibilities for the Calculator include harmonization of its underpinning methodology with the European Commission Organizational Environmental Footprint guidelines (EC 2013), including addition of more environmental impact categories. Further harmonization can also be sought against the forthcoming guidelines on environmental assessment of feed and livestock developed in the context of the FAO-led Livestock Environmental Assessment and Performance (LEAP) Partnership. There is also room for adding more mitigation actions, providing uncertainty assessments and providing cost/saving estimates for each mitigation action.

ABSTRACT

Cultured meat is produced by culturing animal muscle tissue in a laboratory without growing the whole animals. Its development is currently in a research stage. An earlier study showed that cultured meat production could potentially have substantially lower greenhouse gas emissions, land use and water use compared to conventionally produced meat. The aim of this paper is to amend the previous study by considering alternative production scenarios. The impacts of replacing cyanobacteria based nutrient media with plant based media are assessed. This paper includes more specific modelling of a bioreactor suitable for cultured meat production. Further, this study estimates the water footprint of cultured meat based on a method that is compliant with life cycle assessment. The environmental impacts of cultured meat are compared with conventionally produced meat and with plant based protein sources. It is concluded that regardless of the high uncertainty ranges cultured meat has potential to substantially reduce greenhouse gas emissions and land use when compared to conventionally produced meat.

Keywords: in vitro meat, livestock, tissue engineering, carbon footprint, water footprint

1. Introduction

Livestock production contributes 15% of global greenhouse gas (GHG) emissions (Gerber et al. 2013), 33% of the global land use (FAO 2006), and 27% of the global water footprint (Mekonnen & Hoekstra 2011). The consumption of livestock products has been predicted to increase by 70% between 2010 and 2050 (Gerber et al. 2013). Conversion of forests to feed production is one of the main drivers of deforestation and degradation of wildlife habitats.

Tissue engineers have started developing in vitro technologies for producing edible meat. Their aim is to culture animal muscle tissue in a laboratory without growing the whole animals. Currently, cultured meat technology is in a research stage, and the first commercial products are predicted to be available within a decade. An earlier study showed that cultured meat production could potentially have substantially lower GHG emissions, land use and water use compared to conventionally produced meat (Tuomisto & Teixeira de Mattos 2011).

The aim of this paper is to amend the previous study by considering alternative production scenarios. The impacts of replacing cyanobacteria based nutrient media with plant based media are assessed. Cyanobacteria based growth media for tissue culturing is still under development, whereas plant based alternatives are currently available. The previous study had high uncertainty in the estimates of the energy requirements for the bioreactor used for culturing the cells. In this paper, the impacts of a different type of bioreactor, hollow fiber bioreactor, are assessed. Further, this study estimates the water footprint of cultured meat based on a method that is compliant with life cycle assessment (LCA) (Kounina et al. 2013). The environmental impacts of cultured meat are compared with conventionally produced meat and with plant based protein sources.

2. Methods

2.1. Goal of the study

The goal of this study is to estimate the energy use, GHG emissions, land use and water use for industrial scale production of cultured meat. LCA methodology based on ISO14040 and ISO14044 (2006) guidelines is used. The production is assumed to take place is Spain.

The water footprint method was based on recommendation by Kounina et al. (2013) to include only blue water footprint and use country specific water scarcity characterization factors. Both direct and indirect water use is included. Direct water use refers to the direct water inputs used in the process, whereas indirect use refers to the water needed for production of energy sources used in the process.

2.2. Scope definition

The functional unit (FU), towards which all the impacts are allocated, is 1000 kg of cultured meat with dry matter (DM) content of 30% and protein content of 19 % of mass. The cultured meat process described in this paper produces minced-beef type of product as the production technologies for steak type of products are under development. The muscle cells are grown in a bioreactor on a medium composed of a plant-based energy and nutrient source supplemented with the growth factors (proteins that stimulate cellular growth) and vitamins.

The system boundaries cover the major processes from input production up to the factory gate, including production of input materials and fuels, production of the feedstock, and cultivation of muscle cells. The production of growth factors and vitamins are not included in the study as the quantities needed are small (under 0.1% of the DM weight of the media), and therefore, the environmental impacts are assumed to be negligible.

Land use category includes the land requirement for cultivation of feedstock. The indirect land use associated with land use change and the production of energy inputs are not included in the study. The production of the animals that donate the initial cells for cultured meat is not included in the study due to the low number of cells needed.

The GHG emissions are assessed as global warming potential (GWP) by using the IPCC (2006) impact factors for 100-year timescale. The electricity and fuels used are converted to primary energy by using conversion factors that describe the amount of primary fuels required for extraction and supply of fuels. In this study it is assumed that electricity is used for sterilization and muscle cell cultivation. The emission of electricity production are based on an average European electricity generation portfolio.

2.3. Feedstock production

Three alternative feedstock sources of nutrients and energy for muscle cell production are compared: cyanobacteria, wheat and corn. Cyanobacteria are assumed to be cultivated in open artificial ponds. The details of cyanobacteria production are explained in Tuomisto and Teixiera de Mattos (2011). The data for wheat and corn production are based on Williams et al. (2006). After harvesting, the feedstock is sterilized and hydrolyzed in order to break down the cells. It was assumed that 2 kg of wheat or corn was needed for producing 1 kg of cultured meat. This is most likely an overestimate, but more accurate data was not available. The feedstock was assumed to be sterilized by using autoclaving before it was hydrolyzed. The data for blue water consumption or wheat and corn is taken from Mekonnen and Hoekstra (2011). The water scarcity characterization factors were based on data from Pfister et al. (2009), which give index of 0.715 for Spain.

2.4. Bioreactor

To achieve large scale production of cultured meat it is necessary to select the bioreactor configuration that provides a suitable physiological environment. The hollow fiber bioreactor replicates the capillary system found in most tissues. It has the added advantage of having the highest surface area to volume ratio of all bioreactors thereby reducing space and consumables costs.

Heating and pumping energy was balanced against heat energy generated by cell growth. The analysis included a best case and a worst case scenario. In the best case 95% cell viability with maximum theoretical cell yield of 2 x 10^8 cells/mL were assumed and 1 x 10^6 cells as the starting population. In the worst case 80% cell viability with half-maximum theoretical cell yield of 1 x 10^8 cells/mL and 2 x 10^4 cells as the starting population were assumed. The populations under all conditions were assumed to double every two days, and receive the required amount of nutrients and oxygen to achieve these cell densities.

Different sizes of reactors were assumed to be used during the 90 days production period, with increasing the size based on magnitude of volume required. The media was assumed to have the physical properties of water at 37 °C. The bioreactor material was 5mm thick stainless steel and lagging was 25mm thick glass wool. The hollow fibers membranes were made from polylactide. The fiber volume was negligible compared to the media volume and therefore ignored in the heat requirement calculations. The theoretical pumping requirements were calculated and a low efficiency of 0.5 was assumed; selection of the correct pump will improve this efficiency.

The nutrition media was initially heated from 4 °C to 37 °C for the bioreactor volume and for the media that is added during the culture period. The energy required to maintain a temperature of 37 °C is equal to the heat loss to the surroundings, and it was calculated based on the material properties, surface area and temperature differences. It was assumed that the surrounding temperature was 25 °C and that an electrical heating elements were used. The nutrition media was assumed to be changed every three days.

Taking the value of energy released per mole of electrons transferred to be 115kJ, the amount of energy released from the consumption of one mole of oxygen is 460 kJ. Therefore, the heat of reaction, assuming the cell culture is a fully aerobic system, is -460 kJ mol^{-1} of O_2 consumed (Doran 2013). The average oxygen uptake of cells in a culture can be taken as 5.455×10^{-12} mol $cell^{-1}$ day^{-1} (Goudar et al. 2011). This could then be multiplied by the heat of reaction to find the total amount of energy released in a day.

2.5. Comparison with other products

The results of cultured meat production were compared with livestock and vegetable products based on data from literature. The data about GHG emissions and land use of livestock products was from Nijdam et al. (2012), energy use from Williams et al. (2006) and water use from Mekonnen and Hoekstra (2010). When the results were reported in live weights or carcass weights, the conversion factors presented in Table 1 were used to attribute the impacts to edible meat. An economic allocation was used to allocate the impacts between the edible and non-edible parts of the animal. Non-edible part of the animal generally accounts for around 10% of the market value of the animal, and therefore, 90% of the impacts of producing the whole animal were allocated to the edible part.
The results of GHG emissions and land use of cultured meat production were also compared with livestock and vegetable products per unit of protein based on data from Nijdam et al. (2012).

Table 1. Conversion factors used to convert animal live weight or carcass weight to edible meat.

	Beef	**Pork**	**Sheep**	**Poultry**
Carcass weight of live weight	0.53	0.75	0.46	0.7
Edible meat of carcass weight	0.7	0.75	0.75	0.8

3. Results

The major energy input in the cultivation of cultured meat consists of heating energy required to heat the nutrition media and maintain the bioreactor temperature at 37 °C (Table 2).

Table 2. The results of energy requirements for hollow fiber bioreactor in the best and worst case scenarios.

	Best case GJ/FU	**Worst case GJ/FU**
Heating of reactors and media vessels*	8.12	14.60
Mixing media vessels	1.09E-04	1.95E-04
Aeration of media	0.07	0.13
Media pumping	1.93E-06	0.06
Total	**8.22**	**14.78**

*This is a balance of initial heating then maintaining the temperature of the media, and the energy released by the cells.

The results of the full LCA impacts of cultured meat are presented in Table 3. When comparing the feedstock source options, cyanobacteria had the lowest GHG emissions and land use, wheat had the lowest water footprint and corn the lowest primary energy requirement. Bioreactor energy use had the highest contribution to the energy input of cultured meat production. For GHG emissions, land use and water footprint, muscle cultivation and feedstock production had the highest contribution depending on the scenario.

When comparing the results of cultured meat with other livestock products, it was found that energy input requirement was at the same level with beef production, whereas GHG emissions and land use were lower than any of the livestock products (Figure 1). Water footprint was at the same level with poultry.

Table 3. Results of LCA impacts of cultured meat per functional unit (FU) of 1000 kg cultured meat.

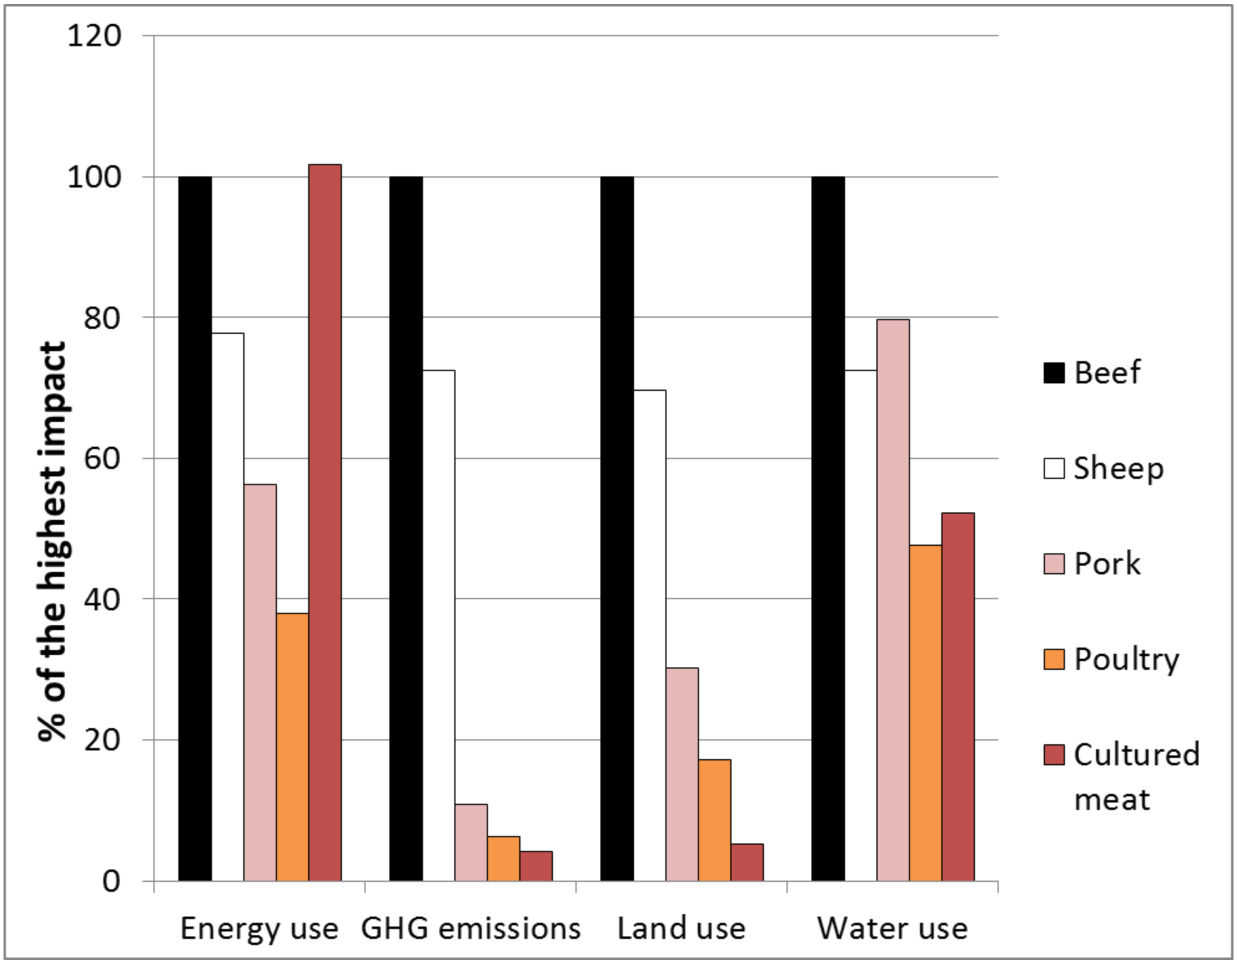

Figure 1. Comparison of environmental impacts of cultured meat with European livestock meat.

Figure 2 and 3 show the GHG emissions and land use of cultured meat compared with animal and plant based protein sources. The GHG emissions of cultured meat are at the same level with plant based protein and animal protein with the lowest carbon footprint. In terms of land use, cultured meat has the lowest land use requirements.

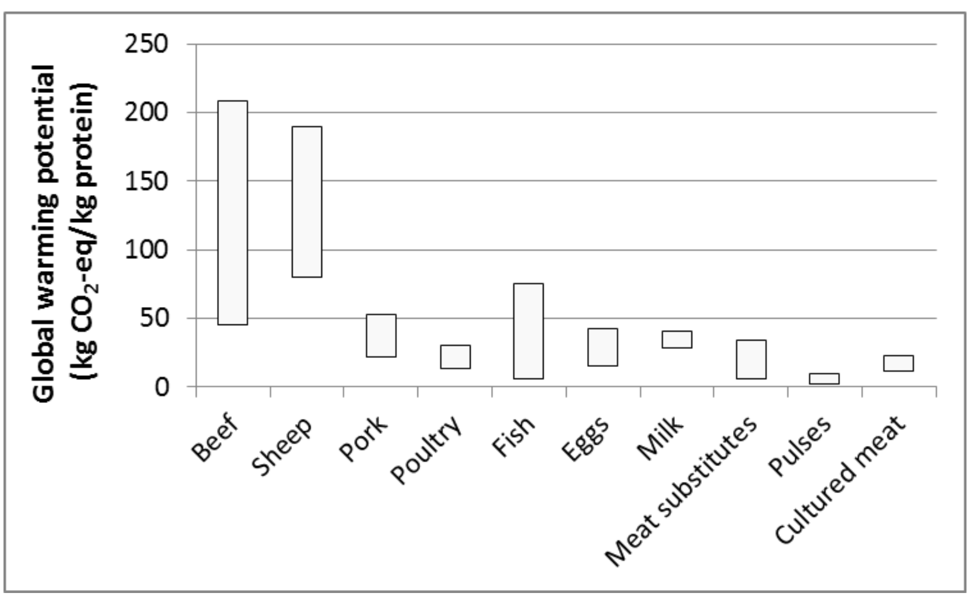

Figure 2. Comparison of GHG emissions of cultured meat with animal and plant based protein sources.

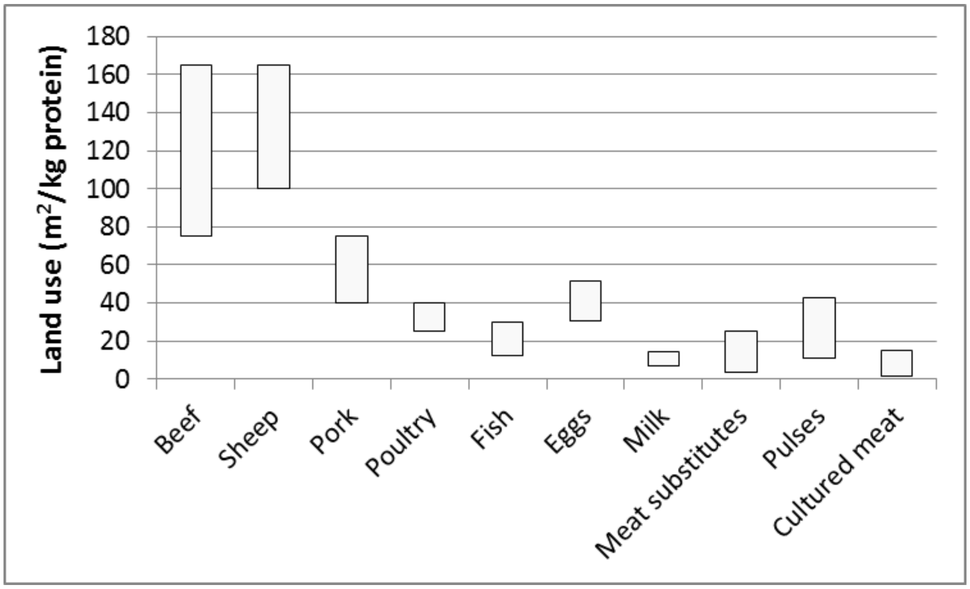

Figure 3. Comparison of land use of cultured meat with animal and plant based protein sources.

4. Discussion

As cultured meat production is still in research stage, the results presented in this paper have high uncertainty. The main uncertainty is related to the design of the bioreactor and composition of the nutrition media. Both have major impact on the environmental contribution of cultured meat production. The results of the hollow fiber bioreactor use are only preliminary hypothetical calculations. The energy requirement may be reduced by modifying the process, for example, by using heat exchangers. More research is required for developing suitable bioreactors for large scale cultured meat production.

Further research is also required for development of plant-based nutrition media for cell culturing. In this paper, only the impacts of producing the main ingredients of the nutrition media were included. More detailed assessment of impacts of producing the media should be performed once more information about a suitable plant-based media for cell culturing becomes available.

When comparing the current study with the results of Tuomisto and Teixeira de Mattos (2011), the main differences can be found in the energy input and water footprint results. The reason for higher energy input of cultured meat in this study is explained by more accurate modelling of the bioreactor and inclusion of bioreactor heating requirement.

The relative difference in the water footprint results is explained by updated methodology that includes only blue water footprint. Livestock production has high green water footprint, but relatively low blue water footprint.

5. Conclusion

We conclude that the uncertainties in the environmental impacts of cultured meat remain high. The alternative production scenarios compared in this paper help to better understand the sources of these uncertainty ranges. Regardless of the high uncertainty the results show that cultured meat could have substantially lower GHG emissions and land use when compared to conventionally produced meat. It is also important to take into account the consequential impacts of reduced land use requirements. If a large proportion of meat was produced by using cultured meat technology, land would be released from meat production for other uses. This land could potentially be used for provision of ecosystem services (e.g. for forests or natural conservation areas), which would increase the total environmental benefits of cultured meat production. More research on development of cultured meat technology is needed before more reliable estimates of the environmental impacts can be provided.

ABSTRACT

Eating healthier or vegetarian and vegan diets are suggested options to reduce the environmental impact of the current diet. In this paper we investigate different scenarios and assess the reduction of environmental impact after restoring the nutritional adequacy by replacements. We used Linear Programming to find solutions that are as close as possible to the current diet, first without any food groups' constraints and later by imposing constraints on meat, fish, dairy and eggs. Finally, we use a similar technique to search for the closest diet that achieves the same environmental reduction as the most restricted option (no meat, fish, dairy or eggs), without restrictions on products. We show that it is possible to find less restrictive solutions than vegetarian or vegan diets that satisfy all nutritional requirements and have less environmental impact than the current one. Most important, these are closer to the current diet.

Keywords: Linear Programming; Food Policy and Nutrition; Environmental Impact; Greenhouse gas emissions; Food patterns

1. Introduction

Global food production faces a big sustainability challenge, which comprises many aspects. Global agriculture is the main contributor to biodiversity loss, water resource depletion and soil degradation due to the extent of land occupation and current farming practices (Searchinger et al. 2013). Searchinger et al. (2013) states also that the production of crops and animal products today releases roughly 13 percent of global greenhouse gas emissions (GHGe); the conversion of forests, savannas, and peat lands to agriculture roughly accounts for an additional 11 percent of global GHGe and that the ongoing expansion of cropland and pastures is the primary source of ecosystem degradation and biodiversity loss. Naturally, these estimates are uncertain and better monitoring of agricultural emission is needed (Tubiello et al. 2014). However there is broad consensus that in order to decrease the demand for natural resources and reduce GHGe food consumption and production have to become more sustainable, especially because the world's population is still increasing rapidly. The Food and Agricultural Organization (FAO) estimates that by 2050 agricultural production has to be increased by 70 percent (FAO 2011).

The central question is how to decrease the impact of the food system. There are two complementary routes: improvements on the supply side and changes in the demand of foods. Sustainable intensification of crop production (FAO 2010) and implementing technologies and practices to reduce emissions from livestock production (Gerber et al. 2013) have huge potential, as can be illustrated by the differences in GHGe from dairy worldwide (Hagemann et al. 2012). Changing food patterns and reducing food spoilage at home are some of the more direct options at the demand side. This paper focusses on food patterns with a lower environmental impact.

Several authors suggested that, for example, making healthier choices or adopting to Mediterranean type diets could reduce the impact (Duchin 2008; Carlsson-kanyama and Gonzalez 2009; van Dooren et al. 2014). This was contradicted by Vieux *et al* (2013) who compared self-selected diets from a French dietary survey on GHGe. They also pointed out that this approach does not take into account the effort that consumers have to make to adopt these dietary changes. An elegant way to design alternative options is to apply Linear Programming (LP) to minimize the amount of necessary changes in the current diet (Maillot et al. 2010). At the same time the inclusion of nutritional restrictions in the LP model safeguards an adequate intake of nutrients and energy.

In this paper we study the environmental impact of a few scenarios. We start with the current average Dutch diet of women between 31 and 50 years of age and search for the closest healthy diet, which satisfies all nutritional requirements. This will show that just eating healthier is not a guarantee of a more environmentally friendly diet. We continue by analyzing three predefined dietary interventions in which different types of animal-based products are eliminated from the diet. In particular we look at two common vegetarian-type diets and a vegan diet that also excludes dairy and eggs. Finally, we compare the necessary changes in these scenarios with an optimal solution calculated by LP after imposing only a restriction on the total environmental impact, using the same target as can be reached maximally with the scenarios with product restrictions. Based on these analyses we obtain a good impression on how to find a food pattern which is not only healthy, but also low on environmental impact. Moreover, this diet pattern remains as close as possible to the current average situation.

2. Methods

2.1. Reference Profile and Nutritional requirements

As a case we have chosen a non-active woman between 31 and 50 years of age. This group was chosen because it has a relatively high requirement for iron, which can become critical if meat, an important source of iron, is removed from diets (Macdiarmid et al. 2012). Nutritional requirements were defined in close cooperation with the Netherlands Nutrition Centre (Voedingscentrum, The Hague) and are a compilation of the Dutch Food-Based Dietary Guidelines (FBDG) (Voedingscentrum 2011), national (Gezondheidsraad 2001; Gezondheidsraad 2006) and international recommendations (WHO et al. 2007) for energy and nutrients. To promote variation of diet, constraints were set on the maximum amount of each product in a weekly diet.

2.2. Current average Dutch diet

A simplified weekly current average Dutch diet is modelled with 207 products out of 1599 consumed by the survey population (n=3819) of the Dutch Consumption Panel (Rossum et al. 2011). This selection consists of the items contributing most to the total intake of the survey population (about 80% by weight). To compensate for the eliminated products, we scaled the remaining ones in such a way that the total amount within each product group was equal to the original average. The nutrient value of the observed average diet and our current diet was very similar[1].

2.3. Nutritional and Environmental data

Food composition data, including macro- and micronutrient content, was obtained from the Dutch Food composition table (RIVM 2011) while data on essential amino acids was collected from the United States Department of Agriculture Database (USDA 2012). Representative data on Greenhouse Gas Emissions (GHGe), Fossil Energy Use (FEU) and Land Occupation (LO) of all foods was collected from various sources and modelled from cradle to grave, including retail phase, the consumer phase and end of life of packaging materials (Kramer et al. 2013). Corrections were made for un-edible parts, raw to cooked ratios (RIVM 2012) and avoidable waste (Van Westerhoven and Steenhuizen 2010).

The individual environmental indicators were used to calculate a weighted score, based on the ReCiPe method (Goedkoop et al. 2013), which we call *p*ReCiPe. By combining the characterization, normalization and weighing factors of these three indicators we reach the following expression:

*p*ReCiPe=0.0459*GHGe+0.0025*FEU+0.0439*LO
GHGe = kg CO2-equivalents/kg
FEU = MegaJoules/kg
LO = m2*year/kg

We omitted other contributing midpoints, due to a lack of reliable and consistent inventory data for all products in scope and the fact that these 3 indicators are the most important contributors to the ReCiPe single score (Sevenster et al. 2010).

[1] Comparative tables are available upon request.

2.4. Linear programming and a metric for changes (penalty score)

Optimization of diets was performed with Optimeal®, a commercial Linear Programming (LP) tool developed by Blonk Consultants. The algorithm is described in detail elsewhere (Kramer et al. 2013). In the LP model amounts and deviations are expressed per serving (Voedingscentrum 2013). The goal of the LP is to minimize changes such that the solution diet satisfies all nutritional and, optionally, environmental constraints.

The metric for changes is operationalized by a penalty score which, in turn, reflects the popularity of foods. Any deviation from the current diet contributes to the penalty score, but the penalty contribution of each serving change is food and directional dependent. More specifically, the amount of serving changes in a given food is multiplied by a normalization of the total quantity (grams) consumed of that food during the dietary survey (RIVM 2012). In that way, the more popular a food is, the lower its penalty for increases is and the higher its penalty for decreases is. Conversely, the less popular a food is, the higher its penalty for increases is and the lower its penalty for decreases is. The penalty score can be interpreted as a measure of distance between diets.

The reasoning behind this modelling is the principle that diets which are more similar to the current one are more likely to be accepted by the majority of the population than more extreme diets. Also removal of popular products or introduction of unpopular products is not likely to be easily taken into practice. By comparing the penalty scores of different diets it is possible to measure how similar they are to the current diet.

2.5. Dietary Scenarios

We study 6 dietary scenarios. We start by the current average Dutch diet (*Current Diet*), modelled as described above and use it as the starting point of all optimizations. The other 5 dietary scenario are optimized diets (minimal penalty score) such that the nutritional constraints are always met, thus healthy diets. The difference among the diets is the (additional) constraints imposed. The first scenario, *Closest healthy* diet, does not add any product or environmental constraints. Next we study 3 commonly discussed diets in the context of defining sustainable diets (van Dooren et al. 2014): a *Vegetarian M* diet, which excludes meat products; a *Vegetarian MF* diet, which excludes meat and fish and a *Vegan*[2] diet, which excludes meat, fish, dairy and egg products. Finally we look at a diet with 30% less environmental impact (*30% less*), which instead of imposing constraints on food groups includes only a constraint on the environmental impact. We choose this target, because it was the largest reduction achieved by the other pre-selected diets, which was in fact the vegan diet.

3. Results

The current diet in the Netherlands does not meet all dietary guidelines (Rossum et al. 2011), as in many other countries (Mensink et al. 2013) (see numbers in bold in Table 1). For instance, it is too low in dietary fiber and several vitamins and minerals, whereas the intake of saturated fat is too high.

To obtain a healthier diet that is as close as possible to the current one, more products have to be added than deleted (Table 2). The *p*ReCiPe score remains the same. Both GHGe and LO decrease, whereas FEU increases. This is mainly due to a increase in the amount of fish[3], and fishing is energy intensive. Furthermore, the *Closest healthier* diet contains more fruit, vegetables and legumes. The latter supplies both fiber and vitamin B1, which were below the recommended intake in the *Current* diet. To reduce the intake of saturated fatty acids (SAFA) several types of sausage and cheese are reduced.

[2] In the two dietary scenarios which exclude fish, it is not possible to meet the dietary guidelines for DHA+EPA. We had, thus, to ignore this nutritional constraint is these cases.

[3] The involved species, such as herring and farmed salmon, are currently not overfished.

Table 1. Constraints (Lower and Upper) in the Linear Programming model and properties of the current diet (per day):

Property	Lower	Upper	Current[1]
Energy (kcal)	1890	2110	1993
Protein (g)	50	125	84
Fat (g)	44	89	79

Methionine (g)	0.8	-	1.9
Cystine (g)	0.3	-	1.0
Valine (g)	2.0	-	4.3
Histidine (g)	0.8	-	2.4
Vegetables (g)	200	500	**139**
Fruit (g)	200	500	**124**

[1] *Bold numbers indicate values outside the constraints*
[2] *FA = fatty acids*
[3] *EPA (Eicosapentaenoic acids), DHA (Docosahexaenoic acid): both omega-3 fish fatty acids*

If we subsequently add constraints on meat and optimize to find the closest adequate solution (*Vegetarian M*), both LO and GHGe are lower than the initial value of the current diet. The *p*ReCiPe is reduced by 17%. Omitting meat from the current diet (*Vegetarian M*) forces more changes, because it is an important source of several nutrients that are already below the lower limit in the current diet: e.g. B1, B6, selenium and copper. To replace these nutrients from meat substantial amounts of cheese, fish, legumes and meat replacers are added to the diet. This explains the relatively modest reduction of impact in this scenario. Because of their high sodium content soups (goodies) are removed to make space for cheese. When we subsequently restrict fish (*Vegetarian MF*) and dairy and eggs (*Vegan*) the environmental impact decreases. To replace the essential nutrients from fish (e.g. vitamin B12 and D), a fortified soy drink, eggs and nuts are added to the *Vegetarian MF* diet. The absence of dairy and eggs in the *Vegan* diet has an additional impact on the nutrient intake. Alternative sources of vitamin B12, calcium, essential amino acids and many other nutrients have to be found in compensation. For instance, brown rice as a source of Se and niacin, vegetables as a source of vitamin K and retinol equivalents and more fortified soy drink for vitamins B2, B12 and D.

The reduction in *p*ReCiPe obtained with the *Vegan* diet is 0.13 points or 30%. The same reduction can be realized without forced restrictions on animal-based product groups. Interestingly, this "*30% less*" diet shows lesser shifts in amounts per product group than the *Vegan* diet in comparison with the *Current* diet. Savings are not only found by reduction of meat, beverages and goodies[4] but also by making more sustainable choices within categories[5]. The contribution of meat in total savings is more than 60% in comparison with the *Closest healthy* diet. Within the meat category both beef and chicken are reduced, and mainly pork products remain. This is an interesting finding, because chicken has a lower environmental impact per unit. Most likely, the balance between nutritive value and environmental impact is less favorable in chicken. More specifically pork contains more of several critical nutrients like Fe, Cu, Se, B2 and B12 (RIVM 2011). Within the beverages group beer and wine are reduced. In the group goodies soups are reduced but some apple syrup is added. The latter is added due to the regular fortification with Fe, a nutrient likely to become critical when meat is reduced. Dairy (liquid and cheese) even increases, when expressed in milk equivalents (1 gram of cheese is equivalent to 8.4 grams of milk (Kramer et al. 2013).

Within the fruit category apple sauce is replaced by some banana and melon. Other replacements are cheese for buttermilk (dairy) and herring for salmon and mussels (fish).

The amount of changes relative to the current diet are reflected by the penalty score (Table 2). Quite some changes are necessary to make the diet just healthier (*Closest healthy*). The more animal-based products are restricted, the higher the penalty score is after restoring the nutritive value. These restrictive strategies have a higher penalty score than the optimal solution when the upper limit for *p*ReCiPe is set at 0.29 points.

To illustrate how complex the implementation of these dietary scenarios can be and how many other options are overlooked, we plotted (Figure 1) the environmental score (*p*Recipe) of the 6 studied dietary scenarios against their penalty score. The plot also contains a possibilities frontier line which is calculated as the minimum penalty score such that a given environmental score level is achieved.

[4] Non-staple foods, with a low contribution to the nutrient intake (Voedingscentrum 2011). These include, e.g., sugar, cookies, snacks, sauces, jam, candy, etc.
[5] Due to space constraints detailed tables with the breakdown were not included. These are available upon request.

Table 2. Quantities of foods and environmental indicator in diets. Amounts per day.

	Current	Closest healthy	Vegetarian M	Vegetarian MF	Vegan	30% less
Food groups						
Potatoes, pasta, rice, etc. (g)	136	136	136	136	217	136

Penalty Score	0	63.01	100.76	138.20	365.5	89.44

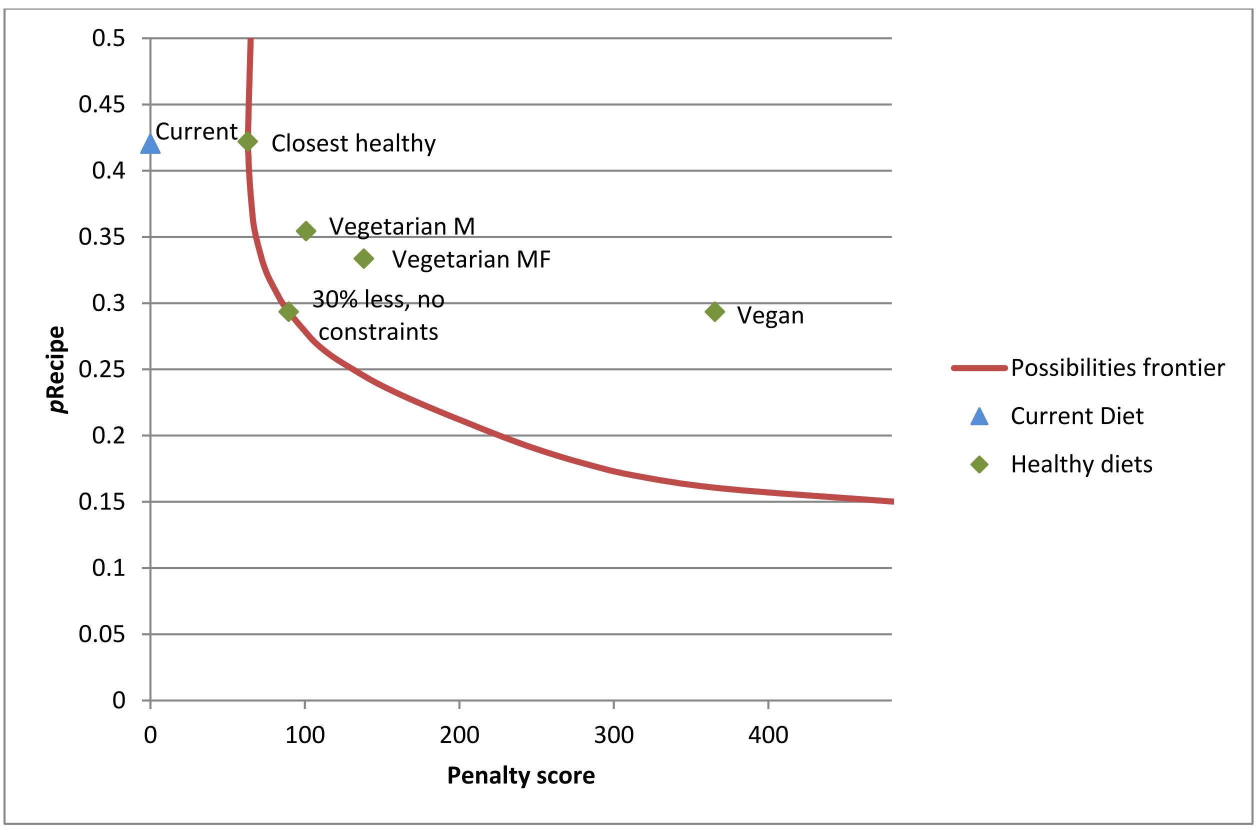

Figure 1. Penalty scores and environmental impact of the several dietary scenarios

In the figure, the closer a diet is to the frontier line, the more similar it is to the current a diet, while being healthy. The *Closest healthy* and the *30% less* are, by construction, on the frontier. Notice how much further the *Vegetarian* and *Vegan* diets are from the frontier. This does not indicate *per se* that a *Vegetarian* or *Vegan* options are not valid, but it does indicate that, if the goal is simply to reduce the environmental impact, there are many other options possible to reach the same environmental goal with less changes. These overlooked options still include animal-based products and are more similar to the current situation and, therefore, more likely to be accepted by a general population. Notice this diet resembles a so-called *Flexitarian* diet, which promotes the reduction of animal-based products, as a pre-defined intervention. This diet design is here, however, an outcome of a structured search procedure. Moreover, we selected the closest diet to the current which satisfies all nutritional requirements and achieves a 30% reduction of the environmental impact, the same level as the healthy *Vegan* scenario.

4. Discussion

4.1. Main observations

For the first time we compare different dietary scenarios using a metric for the distance between diets, taking popularity and environmental indicators into account. This improves on previous literature (Maillot et al. 2010). Our results indicate that just eating healthier is not necessarily beneficial for the environment. This supports the conclusions by Vieux *et al* (2013) who compared diet quality and GHGe from actual diets in France. The distance to the average current diet is larger when certain changes are enforced instead of left open. With relatively minor changes the environmental impact of a healthy diet (*Closest healthy*) can be improved with 30%. The optimal solution still contains 30% of the amount of meat quantity in the *Closest healthy* diet, whereas amounts of dairy (liquid and cheese), fish and egg almost remain constant. The reduced meat consumption is responsible for 60% of the reduction in environmental impact. Additional savings are realized in other categories like beverages and goodies. Our results also show that replacement scenarios of animal-based products should not be focused only on finding alternative sources of protein (Westhoek et al. 2011). To meet guidelines other nutrients like Fe, Ca, Se and vitamins B12 have to be replaced as well and might even be are more critical. In a comparison between the *Current* diet and the closest with 30% impact, reason for changes cannot be distinguished. Therefore, it is more meaningful to compare the *Closest healthy* diet with the closest with *30% less* impact. In this comparison all changes are induced by the restriction on the environmental indicator *p*ReCiPe. It shows that meat and beverages are still reduced, but also goodies (other than staple foods). Dairy (liquid and cheese) on the other hand even increases, when expressed in milk equivalents. Also legumes increase.

4.2. Validity and limitations

With the 207 products in the model we cover approximately 80% of the intake by weight. The other 20% represent 1392 products. It is possible that some of these products have a favorable nutritional and or environmental profile so that they would have been selected in the optimization. The quality and representativeness of included LCA data varies. For important product groups like meat, dairy, bread, legumes and vegetables we relied on data from a reviewed comparative LCA (Kramer et al. 2013). These data were obtained by applying a consistent LCA method regarding for instance allocation and system boundaries. Still, the quality of the LCI data in these studies varies. We are aware that data quality and variability could influence the outcome of the study..

Limitations of our environmental indicator are that it does not account for overfishing and makes no distinction between types of land use. We verified if this had an undesirable influence on the outcome, which was not the case. Overfished species were not increased. With regard to land use type, when this was taken into account a similar trend was found as in overall land occupation.

There is also variability in the food composition data we used but the present values represent the best estimate for products consumed in the Netherlands (Westenbrink and Jansen-van der Vliet 2013).

A limitation of the present study is that we only studied one group (women 31-50). We did not verify how different the outcome would be for men or other age groups. Differences could occur due to different nutritional requirements and due to different average diets. Another limitation is the lack of a good indicator for marine resource depletion. By ignoring this environmental impact a bias towards higher consumption of fish is introduced.

Finally, complex system inter-relations are not taken into account. For example, beef from the dairy production system and dairy products are not linked in the present model: they can be decreased or increased independently and different production systems are also not taken into account in this study. In the current system approximately 17 grams of beef is produced with every liter of milk. The diet with *30% less* environmental impact contains a quantity of beef that is higher than the amount associated with the suggested amount of dairy in the diet. The vegetarian diets, on the other hand, create a surplus of beef from dairy production. To incorporate these concerns an extended model, which is beyond the scope of this paper, would be necessary.

4.3. Sensitivity

The outcome of LP is sensitive to choices in restrictions and formulation of the objective function. Replacing the penalty score by a simple Euclidian Distance or the count of number of product changed, however, does not alter our qualitative analysis. The sensitivity to restrictions can be illustrated by the following observation. Some nutrients are almost exclusively delivered by one product group. In those cases the recommended amount of such a product group is very dependent on the level of one specific guideline. One example is the guideline for omega-3 fish fatty acids (DHA+EPA) in our model. Solutions without fish are therefore impossible and compared to the current diet, fish consumption should even increase to obtain a healthier diet. Wilson *et al* (2013) on the other hand, found optimized diets without fish because they did not include such a guideline.

4.4. General outcome

The average current diet in the Netherlands does not meet all dietary guidelines which are present as constraints in the Linear Programming (LP) model. The changes necessary to make it healthier, taking the popularity of products into account, does not change the environmental impact. Enforcing pre-defined dietary interventions, such as vegetarian or vegan diets has benefits for the environment, but results in an inadequate intake of omega-3 fish fatty acids when fish is left out of the diet. There is strong evidence that these fatty acids have a protective effect against fatal coronary heart diseases.

The choice for vegetarian or vegan diets in scenario studies can be argued to be arbitrary and ignore a whole set of possible diets which also satisfy nutritional constraints and yield a comparable or even lower environmental impact. The environmental improvement goal of 30% can be met by less drastic changes to the diet, if penalty scores of the different scenarios are compared. Another advantage is that substitutions are chosen based on objective criteria: a balance between nutritive value, popularity and environmental impact. Vegetarian diets have a systematic flaw because they contain dairy, but not the meat produced in dairy systems. Also solutions without fish have flaw, because they do not meet a guideline for omega-3 fish fatty acids. Our data shows that the reductions contributing most to the decrease of impact relative to the current diet are indeed in meat and cheese, and certain beverages like beer, wine and soft drinks, but they are all still part of the diet. On the other hand, legumes, fruit and vegetables are the most important additions to the current diet necessary to restore or improve the dietary quality.

The results we obtained when the constraints on groups were removed are quite similar to those obtained by MacDiarmid *et al* (2012). They also saw decreases in animal-based products and increases in plant-based foods. Because they ignored beverages, they missed the potential saving in this category. Because we observed similar trends we can confirm the validity of other studies that only used GHGe (Risku-Norja et al. 2009; Tukker et al. 2009; Stehfest et al. 2009; Vieux et al. 2012; Macdiarmid et al. 2012; Wilson et al. 2013). Only a few studies have addressed other impacts or used a single environmental indicator (Gerbens-Leenes and Nonhebel 2002; Tukker et al. 2009; Temme et al. 2013).

5. Conclusion

Within the Dutch context, eating according to nutrient requirements does not necessarily have a lower environmental impact. For women in the group of 31-50 we found that the closest healthy diet relative to the current diet in the Netherlands has the same environmental impact. It is possible however to find many other diets with reduced environmental impact which are healthier than the current situation, still includes meat, fish and dairy and eggs by using linear optimization. The method we propose is an innovative and systematic way of finding improved diets which are close to the current average diet satisfying all nutritional and additional environmental constraints.

Providing a diet that meets dietary requirements is a prerequisite for (sustainable) diets. Simply omitting animal-based products from the diet is not a valid option: other products have to be added to guarantee nutritional adequacy. In that respect, protein should not be the only focus, as an adequate intake of other nutrients supplied by animal-based products are also at risk.

The scenarios presented in this paper illustrate that omitting animal-based products from the diet require substitutions to meet dietary requirements. These, in turn, reduce the positive environmental impact change. For the general populations these scenarios seem less attainable than a scenario in which the desired reduction in impact is added as a binding constraint in the LP model. In that case reductions in meat (beef, chicken) and beverages (beer, wine) are making the most important contributions. Eating of legumes and (sustainable) fatty fish should be promoted. On the other hand, consumption of goodies should be discouraged, both for health and for the environment.

ABSTRACT

Food systems will have to provide increasing amounts of products at lower environmental costs. Life Cycle Analysis (LCA) is a methodology that can be used in agricultural systems to quantify input flows, materials and energy, as well as processes needed to obtain a food product. Selection of the appropriate impact categories and use of the corresponding indicators is of upmost importance to promote agricultural sustainability. A key aspect to guarantee the success of the concept and use of environmental impact thinking in agriculture is the involvement of farmers in the calculation of sustainability indicators. The objective of this work is to develop an online GIS-based platform for extensive crops with four decision-support tools (DST): crop varieties, fertilization, irrigation, and risk of plant disease appearance, at the same time that agricultural sustainability indicators can be calculated, in a plot basis. Selected indicators are: a) Carbon footprint, b) Water footprint, and c) Pesticide application pressure, ecotoxicity and human toxicity. Trade-offs among indicators are taken into account by using a per product unit or per area approach to balance out the caused impacts. In this way, we expect that main impacts of agricultural systems will be controlled at the same time that increasing crop productivity is achieved.

Keywords: LCA, GIS, Carbon footprint, Water Footprint, Pesticide toxicity

1. Introduction

At European level food (particularly, meat and dairy products) are among the sectors causing the majority of environmental impacts related to final consumption expenditure (Tukker et al., 2006). The manufacture of fertilizers and pesticides, farm operations, processing and transport of farm products, packaging, refrigeration, cooking, and end of life disposal options depend on natural resources and fossil energy. Most of investigations related to environmental aspects associated with agriculture focus on specific items, such as ammonia volatilization, nitrous oxide emissions, nitrate leaching, phosphorous fixation in soils as well as P losses, etc. However, in order to evaluate and compare the entire environmental burden related to agricultural production systems, it is necessary to consider all environmental impacts at the same time (Brentrup et al., 2001).

Sustainability comprises three pillars: economic, environment and social, and many indicators have been proposed to assess the state of the sustainability of agricultural production systems. Life Cycle Analysis (LCA) is a methodology used to measure the environmental impact of a product, process or system through its entire life cycle. In addition to identifying the impacts and potential improvement options of a product, LCA can aid in the selection of relevant indicators of environmental performance (ISO 14040:2006).

Looking at only one or a few indicators, important aspects of sustainability can be missed, so it is needed to choose a set of indicators that fit properly the system we are evaluating. Several schemes have been proposed in order to account for a balanced set of environmental indicators in agriculture; for example, under the GLOBAL 2000 scheme (Wildenberg, 2012), five field level-based indicators (N-balance, P-balance, humus-balance, pesticide use and energy intensity) and five indicators based on "material input per service unit" (carbon-footprint, biotic and abiotic material input, water input and area used) were chosen. With a focus on the on-farm activities, Agbalance™ Life Cycle Analysis combines environmental, social and economic sustainability indicators, calculates aggregated indices for the three types of indicators, and provides a single overall sustainability index (Schoeneboom et al., 2012).

In recent decades, LCA has been increasingly used for the assessment of agricultural impacts (Anielski Management Inc, 2010; Point, 2008; Renouf and Fujita-Dimas, 2013) due to its utility to inform strategic environmental programs, monitor progress, and most importantly, lead to a minimization of environmental burdens resulting from the provision and use of products and services (Guinée et al., 2002).

The life cycle inventory (LCI) is usually the most time-consuming and complicated stage of an LCA. In agricultural systems, the availability of quality data for the LCI is a challenge because a large amount of information needs to be gathered. The robustness of the indicators to be calculated will greatly depend on the accuracy of the data provided. Usually LCI data collection will involve interviews and surveys to farmers and advisory organizations, as well as looking for process data from LCI databases (Point, 2008). However, in late years the amount of information collected at agricultural systems in Europe is increasing. Common Agricultural Policy (CAP) aims to support farmers' incomes whilst encouraging them to produce high quality products and to adopt more sustainable practices. In order to follow up CAP objectives, a Land Parcel Identification System (LPIS) has been developed and information systems across the EU hold more than 135 million detailed land parcels, annually declared by 8 million farmers (JRC, 2014). At the Spanish level, the geographic information system for the management of CAP is known as SIGPAC. This system can be used to incorporate information about soil, crop, farming operations, etc., which can then be stored at the parcel level, thus providing unique data for different purposes. Moreover, climatic, meteorological, phenological, etc. data can be assigned to each parcel from the network of meteorological stations and from records in agricultural experimental stations. Using this system, Decision Support Tools (DST) can be developed in order to provide farmers with agricultural advice for the main agricultural operations.

Although the opportunity is arising, there are not many examples linking GIS with LCA, and the ones available provide only a partial integration. Falcucci et al. (2012) incorporated climate and agro-ecological zones in explicit GIS layers for elaborating LCA of greenhouse gas emissions from global livestock production. Hercule et al. (2012) studied how to use GIS data layers to standardize and simplify the choice of inventory for agricultural production: pumping energy required for irrigation, fuel inputs for cultivation (largely determined by clay content of the soil), etc.

As already mentioned, farmers need to collect information for different purposes such as to abide European regulations, to apply for CAP aids, etc. At European level a framework for achieving a sustainable use of pesticides has been developed (EC, 2009). Among the mandatory actions to be implemented, record keeping of any use of pesticides is included. Pesticide use, date, product and amount have to be recorded, so this information can be declared if the farmer is required to do so. Besides, the eco-conditionality aids for small farms are becoming more and more important, since the farmers' income is going to depend increasingly on aids, especially with decoupling. All this translates in record-keeping and report elaboration to benefit from these measures. In this sense, farmers will require standardized systems for collecting information and preparing mandatory reports. Besides, another important aspect of European agricultural policies is the recent inclusion of green payments and climate risk management tools proposed for the CAP for the period beyond 2013, which shows the European Commission's willingness to expand this climate component.

In summary, there is an urgent need to develop tools for increasing the efficiencies of food systems at a lower environmental cost. In this sense, precision agriculture at the interplot and intraplot level is gaining consideration for increasing agricultural productivity. The aim of the sigAGROasesor project (LIFE + 11/ENV/ES/000641) is to develop an online tool capable of displaying customised recommendations for extensive agriculture, in real time, and for specific parcels, on the basis of a series of detailed biotic and abiotic variables. Furthermore, it incorporates a set of environmental indicators to make farmers aware of the environmental impacts of their cropping management practices. It is based on GIS methodology to display the cropping units as well as the variables needed to run the DST, which provide agronomic advice to the farmers as well as alerts of disease appearance risks. An additional goal is to develop a DST for calculating environmental indicators to allow farmers and users of the AGROASESOR platform to measure key aspects of sustainable agriculture. It ultimately seeks to help farmers and farm managers to achieve the most efficient and sustainable crop production systems.

2.Methods

2.1. Platform AGROASESOR

The AGROASESOR platform is an on-line services platform, which comprises three pillars on which this expert system and decision-support tool is based: a) the application of modern GIS technologies for the management of geo-referenced information, making use of soil variability, climate and weather information, crop condition, plant health alerts, and biotic and abiotic risks in the decision-making process, b) Web-based Decision

Support Tools (DST) to systematise decision-making at the farm, and c) geo-referenced traceability, as a tool to register and manage historical records of Crop Management Units (CMU). In this way, the system will use all available information associated with each of the parcels of the farm incorporating it into decision making programs. In this way, farmers, advisors and cooperative managers will have an instrument for extensive field crops, which will provide specific advice, with precise handling tips (varieties, fertilization, irrigation, disease risk). With regard to sustainability, a specific area within the platform will allow the calculation of environmental indicators. The information generated by farmers and agricultural advisors and introduced at the CMU level to provide technical recommendations on the DST is the basis for calculating environmental indicators. Furthermore, through maps, algorithms, data tables, etc. we will incorporate the "extra" needed information (Figure 1). Therefore, the AGROASESOR platform will incorporate environmental criteria to guide economic and social farming practices towards more sustainable production models.

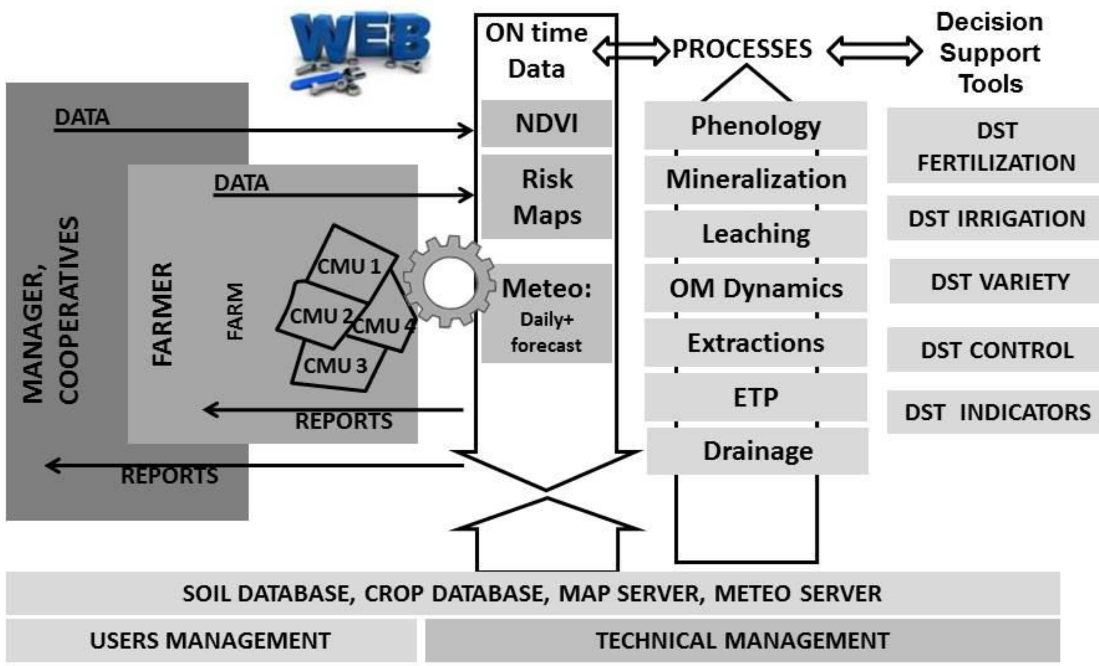

Figure 1. Operating system of the AGROASESOR platform: entities involved in the management of the platform, databases that support Decision Support Tools (DST), general processes performs for obtaining data for the DST. The DST INDICATORS is based on the data of farming operations, including all the inputs involved, as well as outputs in the form of yields from the Crop Management Unit (CMU).

2.2. Development of the environmental indicators at the spatial level

At the AGROASESOR platform, GIS is used to provide information at different levels and scales: a) soil properties (soil depth, texture, SOM, pH, etc.), b) weather variables, climate and meteorological data are assigned to each CMU through an algorithm, which identifies the most representative weather station, c) agricultural inputs and agricultural operations, d) factors needed to calculate the environmental impacts (GHG emission factors related to temperature values, regions with different companies providing electricity, etc.), e) factors needed to assess the environmental impacts, for example, to assess the impact of water consumption in different watersheds.

Besides, we are calculating Gross Margin of the CMU, and we have also selected Soil Organic Matter as an indicator of sustainable land use, which will be followed through time to assess soil quality. In this way we can balance out the different needs that agricultural systems have to take into consideration, maintaining an appropriate balance between economic goals and land maintenance, that is, we simultaneously raise the level of soil organic matter to a certain level and try to maximize benefits from the cropping system.

Carbon footprint calculation is based on a simplified LCA following ISO 14040 standard (ISO 14040:2006) and PAS 2050 (BSI, 2011) methodology; the boundary of the calculation is “cradle to gate”. Upstream processes such as the emissions related to the production of fertilizers and fuel were included, whereas manufacturing and maintenance of machinery and infrastructure were not taken into account within the Scope 3. In relation to the Scope 1, fuel consumption associated to fix and mobile combustion sources, as well as tillage and cultivation practices, were taken into account. Within farming operations the emissions of N_2O from the application of N fertilizers and soil cultivation were calculated using IPCC Tier 1 methodology (IPCC, 2006). Finally, within the Scope 2, electrical consumption was taken into account. Emissions of GHG from the production and distribution of a range of fertilizers, seeds and pesticides were taken from the Ecoinvent database 2.2 (Ecoinvent Centre, 2010). For compost and animal manure, ADEME (2010) and GES´TIM (2010) were used. The average Spanish electricity production mix was selected for calculating the environmental impact of electricity consumption.

Water footprint was calculated following the Water Footprint Network (Hoekstra et al., 2011) and ISO/DIS 14046 (2) methodology, adding its three components: the green, blue and gray water footprint. Although from the LCA standpoint there are some drawbacks in this approach as, for example, not taking into consideration the water footprint associated with the manufacture of raw materials, it has to be mentioned that data from the whole value chain, including all the suppliers, was impossible to get at this stage. Given that,quality changes in different environmental parameters are excluded in the volume based WFN approach and regional aspects are not included in sufficient detail, the Water Scarcity Index (WSI) was calculated as a measure of water use impact. The WSI was calculated based on Pfister et al. (2009), but using the water stress characterization factors values developed for 55 river basins in Spain (Núñez et al., 2013).

Pesticide indicators for pressure (number of applications), ecotoxicity (aquatic and terrestrial) and human toxicity were calculated using the most specific impact values derived for pesticide products. We used 1,4 Dichlorobenzene as an equivalent toxicity unit (Ecoinvent Centre, 2010).

3. Results

The main objective of building the DST INDICATORS at AGROASESOR has been achieved and been tested using a spread datasheet, which was developed previously to incorporate all the required farming operations, data and emission factors. Based on the calculations performed in the spreadsheet, programming was developed to accomplish the needed calculations, while taking into account that a great part of the primary and intermediate data is available in the platform. In this way, users include their management practices, taking into account the tractor, the equipment and the inputs, which are provided in top-down lists; besides, climate, weather, soil characteristics, biotic and abiotic factors are provided. However, the development of such a tool has to find a compromise between simplicity and accuracy, so that results are meaningful for the purpose of the tool and users are not discouraged to use the DST INDICATORS.

3.1. Development of the environmental indicators at the spatial level: assumptions and restrictions

3.1.1. Carbon footprint: Cut-off criteria, assumptions and limitations

The calculator has several sub-systems that decompose overall emissions by greenhouse gas emitted and crop management operations.

3.1.1.1. Fertilization

In the first step the user has to choose the mineral fertilizer, slurry or manure applied from the list that the tool provides. The mineral fertilizers, slurries or manures set out in this list have incorporated specific GHG emission factors from the production and distribution collected from Ecoinvent 2.2 (Ecoinvent Centre, 2010), ADEME (2010), or GES´TIM (2010) databases. Finally, the user has to enter the dose applied at each application. If the applied fertilizer does not appear in the list, the user has to enter the percentage of N, P_2O_5 and K_2O in the fertilizer. In this case, the calculator uses general GHG emissions factors from Ecoinvent 2.2 (Ecoinvent Centre, 2010) database.

Nitrous oxide (N_2O) and nitric oxide (NO) emissions related to fertilizer application were included according to IPCC Tier 1 method (IPCC, 2006), where it is assumed that 1% of applied N as mineral or organic fertilizer is emitted as N_2O. In relation with indirect fertilization-induced soil emissions, leaching is assumed to occur at a rate of 0.3 % of N applied (IPCC, 2006) for a moist climate zone. Although the tool calculates nitrate leaching in the DST fertilization, it is not feasible to use this specific leaching data in the DST INDICATORS in order not to cause an excessive time delay in obtaining the results for the indicators. Emissions of CO_2 from soil resulting from urea application or liming are also accounted for using the IPCC emissions factor (IPCC, 2006) of 0.20 and 0.12, respectively. Finally, the annual amount of N in crops residues (F_{CR}) returned to soil was calculated following IPCC 2006 Tier 1 approach (Eq. 1). The user has to answer the questions of what percentage of the plot is burned and what percentage of the residues is incorporated into the soil. We use the combustion factor (Cf) according to Chapter 2 of IPCC (2006):

$$F_{CR} = \sum_{T} \left\{ \begin{array}{l} Crop_{(T)} \bullet \left(Area_{(T)} - Area\,burnt_{(T)} \bullet C_f \right) \bullet Frac_{Renew(T)} \bullet \\ \left[R_{AG(T)} \bullet N_{AG(T)} \bullet \left(1 - Frac_{Remove(T)} \right) + R_{BG(T)} \bullet N_{BG(T)} \right] \end{array} \right\} \qquad \text{Eq. 1}$$

where,
$Frac_{Renew\ (T)} =$ Fraction of total area under crop T that is renewed annually equals one, because all the crops included are annuals.
$R_{AG(T)}$ = Ratio of below-ground residues dry matter, for cereals = 1.3, based on Spanish National Inventory of Atmospheric emissions.
$N_{AG(T)}$ = N content of above-ground residues, for cereals = 0.006, based on IPCC (2006)
$Frac_{Remov(T)}$ = Fraction of above-ground residues removed annually. If the answer to the question regarding the incorporation of crop residues into the soil is Yes, then we assumed that the factor equals 0, since residues are not removed. If the answer is No, the tool calculates the percentage of removed residues; in this case, we assumed that residues that are not burned are removed.

3.1.1.2. Pesticides

Although at usual application rates of pesticides the GHG emission from their fabrication and distribution is small, we wanted to give special emphasis to this section due to the importance of the effect of pesticide products on toxicology indicators as explained below. In this case, the tool provides a list of more than 2,000 pesticides based on the list published by the Spanish Ministry of Agriculture, Food and Environment, with all the trade names of the authorized pesticides. We compiled emission factors from Ecoinvent 2.2 (Ecoinvent Centre, 2010) for all the different active ingredients. For each trade name, their active ingredients were compiled and, when available, specific emission factors were incorporated into calculations; otherwise, we used the overall emission factor for insecticide, herbicide or fungicide.

3.1.1.3. Direct energy usage

To estimate the fuel consumption of machinery for farming operations such as tilling, drilling, seeding and harvest, we developed a list with the most common machinery used by farmers and we assigned to each machine fuel consumption (L ha^{-1}) according to the studies of the Spanish Institute for Diversification and Energy Saving (IDAE, 2005). Emissions of CO_2 from fuel consumption are accounted for using Ecoinvent 2.2 (Ecoinvent Centre, 2010) emission factors, of 3.066, 2.660 and 3.339 for diesel, petrol and biodiesel, respectively.

Only electrical consumption in irrigation systems has been considered (Sprinkler, 1.0 kWh; Pivot, 0.5 kWh and Drip, 0.3 kWh). We estimated the electrical consumption for each irrigation system according to Guide des valeurs Dia´terre v. 1.11 (2011). Specific emission factors of electricity were taken from the Spanish electricity production mix.

3.1.2. Pesticide application intensity, ecotoxicity and human toxicity

We build on Ecoinvent 2.2 (Ecoinvent, Centre, 2010) to get 1,4-DCB (kg eq.) factors for all the active ingredients available in this database (Table 1). These factors have been applied to the list of 2,000 authorized pesticides in Spain to calculate freshwater, marine and terrestrial ecotoxicity as well as human toxicity for each commercial pesticide.

Table 1. 1,4-DCB (kg eq.) factors for the different active ingredients available in Ecoinvent 2.2.

Active ingredient	Freshwater ecotoxicity	Seawater ecotoxicity	Terrestrial ecotoxicity	Human toxicity
2,4-D	0.058	0.064	0.002	3.747
Alacloro	0.132	0.111	0.005	6.696

Herbicide	0.132	0.111	0.005	6.696
Insecticide	0.350	0.167	0.006	8.053

Moreover, given the importance of reducing the number of applications, a second indicator is proposed: pesticide pressure defined as number of pesticide applications per plot.

3.1.3. Water Footprint

Taking into account that the purpose of sigAGROasesor is to encourage users to calculate sustainability indicators, in this first step, we have chosen a simplified calculation of water footprint to make it friendlier, as it has been mentioned in the Methods section.

The green water footprint is an indicator of the human use of so-called green water. Green water refers to the precipitation on land that does not run off or recharges the groundwater but is stored in the soil or temporarily stays on top of the soil or vegetation. The tool calculates the green water footprint according to the following equation (Eq.2):

$$WFgreen = \Sigma Pe/production\ (m^3/t) \quad \text{Eq.2}$$

where, Pe = The sum of the effective precipitation from seeding to harvest. These data are calculated on a daily basis from the meteorological data entered into the platform.

The blue water footprint is an indicator of the consumptive use of so-called blue water, in other words, fresh surface or groundwater. The tool calculates the blue water footprint by dividing the amount of the consumption of irrigation water by the production (m^3/t).

The gray water footprint is defined as the volume of freshwater required to assimilate the load of pollutants, based on natural background concentrations and existing ambient water quality standards. This water footprint is calculated by dividing the pollutant load (L, in mass/time) by the difference between the ambient water quality standard for that pollutant (the maximum acceptable concentration Cmax, in mass/volume) and its natural concentration in the receiving water body (Cnat, in mass/volume) and by the production. We assumed: L = Pollution load as N loss by leaching and runoff multiplied by the excess N. On one hand, we estimated a loss rate of 10 %. On the other hand, we calculated the excess of N as the difference between the nitrogen supplied (organic and mineral fertilization, and N supplied by irrigation water) and extractions. These values are compiled specifically from the DST fertilization.

- Cmax = It has an established legal maximum of 50 mg $NO_3\ L^{-1}$, according to the Water Framework Directive (EC, 1991).
- Cnat = 0, because of natural concentrations are not known precisely but are estimated to be low, and thus for simplicity one may assume Cnat = 0.

Finally, the sum of green, blue and gray footprints is the total water footprint.

3.1.3.1. Water Stress Index

Water stress is a condition where an imbalance occurs between water demand/need and water availability consumed for meeting the need (UNESCO, 2009). Determination of water stress in an area is calculated using the so called Water Scarcity Index (WSI). We used these values for 55 river basins in Spain as defined by Núñez et al. (2013). The Water Stress Index is calculated by multiplying the water scarcity index for a given area by the water footprint.

3.2. Reporting of the environmental indicators

Once the indicators have been calculated, the tool generates a report with the results for each indicator. As an example, the Water Footprint report is depicted in Figure 2.

In the case of Carbon Footprint, the report indicates total values and the contribution of each of the points to be taken into account (emissions from soil management, emissions from fabrication and distribution of fertilizer and pesticides, emissions from gasoil and electricity). For the Water Footprint, the result is expressed as the sum of the green, blue and gray water footprint and each one separately. In addition, it includes the result of the WSI indicator. Finally, in the case of pesticides, the report expresses the freshwater, marine and terrestrial ecotoxicity as well as the human toxicity and pesticide application intensity.

4. Discussion

One difficulty in the use of LCA, and corresponding environmental indicators, is the interpretation of the environmental impacts because results encompass different environmental impact categories. Methodologies as environmental footprint, which incorporates four environmental indicators: pesticides, greenhouse gas emissions, eutrophication and acidification, have been proposed (Lillywhite, 2008) to overcome the difficulties in interpreting LCA results; at the same time, aggregated indicators are useful for comparing different agricultural commodities in an easier and more comprehensive way. However, the main aim of the AGROASESOR tool with regard to sustainability is to inform farmers on what agricultural operations are causing the largest environmental impacts. So far, as above mentioned, we have incorporated three main indicators to the AGROASESOR platform: carbon footprint, water footprint, and pesticide ecotoxicity and human toxicity. In this way we account for the main environmental impacts of agricultural production. However, interpretation of the results is needed. Our approach is to place the results obtained in a relative scale, which can be built from literature values, or from the values that result from the use of the AGROASESOR platform by the farmers. In this way, a farmer can know how much impact causes in relation to other farmers in a similar production agroecosystem or in a more general scale. This will be helpful for the farmers to decide in which aspects of their production scheme to make favourable changes for the environment. At the same time, the AGROASESOR platform calculates an economic indicator, gross margin, and the farmer can also decide on the economic impact of the assayed agricultural operations.

In a cradle-to-grave analysis, trade-offs between improvements at one stage and increased impacts at another stage are identified (Cowell, 1999). However, AGROASESOR follows a cradle-to-gate approach, considering yield at the field border (CMU) as the product. This fact is partially overcome by assessing several environmental indicators, not only one as is the case for calculations of carbon footprint to measure the global warming potential, which is the objective of many studies.

We calculate indicators in a per production unit as well as in a per surface unit. We can look at a methodology to balance out these two types of calculations. The use of agricultural inputs, in particular, improved varieties, fertilizers, water, pesticides by increasing production in a synergistic way and at optimum adjusted rates by the AGROASESOR platform will allow increasing yields at the same time that decreasing agricultural inputs. In this way the impact per unit of product is expected to diminish. However, when considering impacts by surface unit, we get additional information on absolute amounts of impacts, regardless of production. Thus, we can choose absolute threshold values we do not wish to surpass, and also check that we abide the legislation regarding to the use of agricultural inputs or operations for a given geographical area. This is another contribution to the sustainability of the different production systems. Among the expected impacts of the project are the increase in yields (5%), fertilizer, water and pesticide product use efficiencies (+5%), while decreasing use in absolute values of irrigation water (-5%) and energy consumption (-5%). As mentioned above, Soil Organic Matter has been chosen as a reliable indicator of soil quality and the inner impact of agricultural production.

One of the advantages of the program with regard to environmental indicators is that when asking for reports, the level of aggregation for each indicator can be chosen: one CMU, a set of CMU, all the CMU with a given crop, all the CMU belonging to a farm, etc. In this way it is very easy to establish comparisons to take into account the interest of the farmer or the advisor. At the same time the administrators of the system can work in an integrated approach to answer more general questions regarding crops, inputs, or agricultural operations. Data variables and results can be exported through “csv” files, so by choosing the adequate parameters we can calculate environmental impacts for the variables we are interested, for example, comparing farmers that apply mineral fertilization with those that use mineral fertilizers combined with organic amendments. In this way, we can identify the effect of specific agricultural practices on whatever of the indicators we are interested in.

5. Conclusion

The AGROASESOR platform will allow the extension of the use of sustainability indicators to farmers. This is so because they will have available a web GIS software, which will facilitate the accomplishment of legal, administrative and technical requirements, at the same time that will provide them with the determination of environmental and economic indicators. As all the information needed for the different DST to work is introduced, calculations for the indicators are made easier, thus providing farmers and their advisors with a tool with multiple uses. Further inclusion of models to account for key processes is needed. Furthermore, it would be important to include more crops and indicators to account at the greatest extent with trade-offs at the agricultural level.

ABSTRACT

An LCA case study for water-related impacts on milk production in Finland is presented. Non irrigated feed crops were used in this "cradle-to-dairy" system. Impact assessment used methodology developed by Pfister et al. (2009). Result show that 5.75-5.85 liters of consumptive water is used to produce one liter of packaged skimmed milk. Results from previous studies range from about 1-250 l/kg. Drinking water for dairy cattle is the most significant factor in water consumption (44-45%). Also the volumes of washing water on farms and at dairy factories are substantial. Working practices and equipments affect water consumption on dairy farms, and variation among farms is considerable. Characterization factors for Finland differed significantly from the corresponding factors for geographically and socio-economically similar countries with abundant water resources. The characterization factors concerning Finland should be evaluated and developed to enable more accurate assessments of water-related impacts of products.

Key Words: life cycle assessment, water footprint, milk, animal production, environmental impact assessment

1. Introduction

The global water crisis demands that researchers include water issues in environmental impact assessments of products, particularly food products, which represent most of the world's water consumption. Two evolving methodological frameworks are helping practitioners conserve water resources (Boulay et al. 2013). Originally the water footprint referred to a method developed by Chapagain and Hoekstra (Chapagain et al. 2006, Hoekstra & Chapagain 2007) grounded in the concept of virtual water (Allan 1993, 1997). The evolving ISO Standard ISO/DIS 14046 on water footprint is based on a life cycle assessment (LCA) framework. Both methodologies take account of total direct and indirect water consumption and indicate its relevance (Boulay et al. 2013).

According to Shiklomanov and Rodda (2003), 66% of world water withdrawals and 86% of its consumption are for agriculture. At the local level the share of agriculture is much less in developed countries and in areas with rain-fed agriculture. It also heavily depends on whether imported foodstuffs are taken into account. In Finland agriculture is rain-fed, and the share of agriculture is only 3%, domestic use comprises 25% of water withdrawals and industrial withdrawal is 72% (FAO 2013). Only about 23% of Finland's freshwater consumption (technically introduced freshwater, "blue water") is based on national water resources, mostly because of virtual water content of imported foodstuffs (Mekonnen & Hoekstra 2011).

In the future, as a result of population and economic growth, the global demand for freshwater will increase by 40% more than the available water resources (McKinsey 2009). It was forecasted a decade ago (Shiklomanov & Rodda 2003) that in 2025 about 30-35% of the world's population will live in areas where water availability is very low or catastrophically low, at less than 1000 m^3 freshwater annually per capita. The relative water consumption of agriculture is likely to decrease, mostly due to growth in the industrial and domestic sectors. It is expected that by 2025 global withdrawals for agriculture will increase by 25%, for industry by 50% and for the domestic sector by 80% (Shiklomanov and Rodda 2003).

For these reasons everything possible should be done to ensure that food is produced without consuming local scarce freshwater resources in an unsustainable way. In Finland in practice all field crops are rain-fed, irrigation in the open is mainly used only for vegetables and potatoes (Tike 2012). Finland is one of the EU countries with a Water Exploitation Index WEI of less than 10% which is defined as a "no water-stress"-area (EEA 2003). In terms of water consumption, Finland might be a very good area for water-intensive food production. However, some other water-related environmental problems are very serious. In agriculture in Finland water eutrophication is considered worst environmental problem (Niemi and Ahlstedt 2013) and Baltic Sea is considered to be one of the world's most polluted seas (HELCOM 2007). Because of this, when assessing the environmental impact of food production, it is necessary to consider several water-related problems simultaneously.

In this paper we assess the data availability and quality and also methodological suitability for assessing water-related problems in circumstances of rain-fed agriculture in less used impact categories of water deprivation, and the impacts on human health, ecosystems and resources. We use milk as a case study because milk is, with other animal products, one of the foodstuffs that represent relatively high freshwater consumption during its production chain.

2. Materials and methods

2.1. Milk production system - background

The dairy industry and meat processing are the two main sectors in the Finnish food industry. Dairy products are also the most significant single product group in Finnish food exports, with cheese and butter representing 16% of the total food exports in 2012. Nevertheless, domestic milk consumption exceeds production (Niemi and Ahlstedt 2013). In 2012, still 50% of Finnish dairy cows were kept in tie-stall barns that are gradually being replaced by bigger free-stall barns, as the size of dairy farms increases (ProAgria 2012). More than 80% of Finnish beef production is based on animals originating from dairy herds (MMM 2013).

2.2. System boundary, functional unit and allocation

LCA was used as a framework to assess the water-related environmental impacts of Finnish milk. The system we included:

- feed crop and grass production with agricultural inputs fertilizers, lime, seeds
- industrial feed production
- dairy farms
- dairies, package production and municipal waterworks
- fuel and electricity included in all stages
- transport

Retailers and consumers were excluded from the study.

The functional unit (FU) was one liter of skimmed milk transported from the dairy to the retailer.

Allocation between milk and meat was done according to IDF (2010) methodology for carbon footprint calculation, when the allocation for milk was 87% and for meat 13%. Also allocation between dairy products was done according to IDF methodology, where different weighting factors are provided for electricity, heat, water and raw milk. Raw milk was allocated between dairy products in the basis of the milk solids. (IDF 2010)

2.3. Dairy farm model

Technologies, size of the herd and feed systems vary among dairy farms. We used a dairy farm nutrient management model (Nousiainen et al. 2011) to model fodder consumption in three different sized and technologically different farms (Table 1), where milk production was 8900 kg per dairy cow per year and dairy cow live weight 600 kg (ProAgria 2010). Feeding was based on grass silage, rape seed meal, and either home-grown grain from the farm or a commercial feed. Energy consumption in different farm types was based on figures from the literature (Posio 2010; Edström et al. 2005).

Table 1. Farm types in dairy farm model.

	Farm type 1	Farm type 2	Farm type 3
Technology	Tie-stall dairy barn, pipe milking	Free-stall dairy barn, milking parlor	Free-stall dairy barn, 2 voluntary milking robots
Animals	25 dairy cows, 10 heifers, 9 calves	60 dairy cows, 24 heifers, 22 calves	120 dairy cows, 48 heifers, 42 calves
Feed	Grass silage, own grain and rape seed meal OR Grass silage, commercial feed and rape seed meal	Grass silage, own grain and rapeseed meal OR Grass silage, commercial feed and rape seed meal	Grass silage, own grain, commercial feed and rape seed meal

We modeled all farm types for Southern, Northern, Eastern and Western Finland and combined farms according to statistics to average regional milk production from different sized farms (Table 2). Regional raw milk goes to a dairy located in the same region. Input-output data for different dairies was obtained from the dairy in question. Average Finnish milk production was modeled in relation to size of different dairies. The share of commercial feed (BIF) feeding regime was assumed to be used in 75% of total milk production and on-farm produced feed (OFPF) in 25%, based on expert opinion (Nousiainen 2014, personal communication).

Table 2. Farm types in four regions in Finland (Tike 2012)

	25 dairy cows	60 dairy cows	120 dairy cows
Southern Finland	69%	24%	7%
Western Finland	69%	24%	7%
Eastern Finland	73%	21%	6%
Northern Finland	71%	25%	4%

2.4. Feed production

According to the 2010 Finnish Agricultural Census (Tike 2012) the irrigated area was 0.07% for cereals, 0.03% for turnip rape and rape, and 0.2% for grasses (of the total crop area). The results from the 2010 census support the findings from earlier reports (Pajula and Triipponen 2003; Pajula and Järvenpää 2007) based on expert opinion. The only imported component in the dairy cattle feed concentrate was rapeseed meal, which originates from the Baltic countries (personal communication Raisio 2013), where rape is not generally irrigated (FAO 2013). Applying irrigation in Finland would result in bigger and better quality yields, but irrigation is profitable only in horticulture and for special crops. Irrigation in the open thus represents a marginal share of the water consumption in Finland (Tike 2012). In this study we assumed that no irrigation is applied in the Finnish milk production system.
Fuel consumption in crop cultivation was based on literature (Mikkola and Ahokas 2009). Water consumption in commercial feed production is based on data from industrial feed plant (Raisio 2013, personal communication).

2.5. Drinking water

Several formulas for exist estimating of drinking water intake in dairy cows. The most applicable for Finnish conditions was chosen by comparing the estimate given by a formula and the measured water intake values from the experiment of Kuoppala et al. (2004). The equation presented by Castle and Thomas (1970) had the closest values. It has also very easily measurable parameters (Eq. 1).

Drinking water intake (kg/day) = - 15.3 + 2.53 x milk (kg /day) + 0.45 x diet dry matter content (%) *Eq.1*

Water requirements of growing cattle are often expressed as total water intake, for example in McDonald et al. (1988). In this study, environmental temperature was assumed to be 16 °C, so the total water intake of calves less than 6 weeks of age was assumed to be 7.5 kg/kg DM intake and in older cattle 5.75 kg/kg DM intake. The feed water was calculated according to the dry matter content of a typical diet and drinking water by difference.

2.6. Washing water in dairy farms

The average types of machinery and equipment of the three different farm models were assessed based on the Finnish dairy herd recording system (ProAgria 2012). The database covers approximately 75% of Finnish dairy farms.

Water consumption in conventional pipeline milking systems in tie stall barns was assessed based on expert opinion (Mäki et al 2005). Milking parlors and automatic milking in free stall barns were assessed on the basis of Danish measurements (Rasmussen and Pedersen 2004, Lindgaard Jensen 2009) and on Swedish expert opinion (Gyllenswärd 2011). The sizes of the farm tanks and their wash water consumption and other water consumption in milk storage premises was assessed based on various expert opinions (Nyman 2013, personal communication; Korhonen 2013, personal communication and Gyllenswärd 2011). Other wash water consumption for different farm types was estimated on the basis of building regulations (MMM 2012) and German expert information (KTBL 2008).

2.7. Data sources in processing phase

2.7.1. Dairies

Water consumption data are based on data acquired from three dairies representing the entire dairy sector in Finland. Water consumption data include all freshwater consumption in dairy. Consumption includes milk truck washing. Energy consumption data (electricity and heating) were also based on dairy data.

2.7.2. Package production

Regular skimmed milk is sold in Tetra Rex cartons. We estimated the water consumption of package production on the basis of the Stora Enso Skoghall mill water footprint case study (Stora Enso 2011), for which the water consumption was 6 m^3 / tonne liquid packaging board. The inventory result is 0,164 l water / FU for a Tetra Rex carton.

2.7.3. Waterworks

Municipal waterworks produce water of which on average 18% is uninvoiced (Finnish Water Utilities Association 2012). Uninvoiced water includes water use by the fire department and other municipal use. The amount of unused water due to leakage and pipeline breaks varied according to site. Specific data from waterworks in those sites were used. Water losses in pipelines were calculated only for dairies and water losses in actual dairy sites were 12-15%. Dairy farms were assumed to acquire their water from their own well (Sorvala et al. 2006).

2.8. Other data sources

For electricity, fossil fuel production, fertilizers and lime we used inventory data from EcoInvent v. 2.2. Cooling water and water use in turbines for energy production were excluded. Diesel consumption for wood chips and peat production was assessed according to Mälkki and Virtanen (2003), Jylhä (2013) (wood) and Uppenberg et al. (2001) (peat).

2.9. Impact assessment

Environmental impact of freshwater was assessed according to a method developed by Pfister et al. (2009). Damage in three areas of protection was calculated: human health, quality of ecosystem and resources. Damage assessment was carried out according Eco-indicator-99 assessment framework (EI99) (Goedkoop et al. 2001).

Because production was located mostly in Finland and only minor parts in Baltic countries (rapeseed as part of the bought-in feeds), and no irrigation was used in rapeseed production, the same characterization factors were used for each phase in the production chain.

2.9.1. Water stress index and general impact

Water stress is defined by the ratio of total annual freshwater withdrawals to hydrological availability (WTA). The water stress index (WSI) determines the portion of consumptive water used which dispossess other users of freshwater. In the methodology developed by Pfister et al. (2009, Supporting Information), water stress indices for countries range from 0 to 1. WSI for Finland is relatively high at 0.416. At the watershed level most of Finland gets low WSI values, with some exceptions in the Varsinais-Suomi region, in some islands in the Gulf of Finland and in the Helsinki area. According to Pfister (written communication 2014) high total value in Finland is mostly due to water deficiency problems in the Helsinki area in 1960s and 1970s. Since then the problem has been solved by piping water from an external watershed to the Helsinki area.

Global average WSI (0.602) was used in the water footprint (general impact) calculations. The amount of consumptive water was normalized by dividing by 0.602 and expressed in H_2O equivalents (H_2Oeq).

2.9.2. Impacts on human health

For human health the pathway for water shortages for irrigation resulting in malnutrition is included in the method (Pfister et al. 2009). The Human Development Index (HDI) is an important part of the characterization factor $\Delta HH_{malnutrition}$ for human health. HDI is at high level (> 0.88) for Finland, and as such would cause $\Delta HH_{malnutrition}$ to be zero. There are rivers flowing from Finland to Russia and therefore the cross-boundary watersheds need to be included and CF for $\Delta HH_{malnutrition}$ for a country is calculated by counting up the watershed level results. The total CF for $\Delta HH_{malnutrition}$ for Finland is 4.4E -05 [10^{-6} DALY/m^3] (Pfister et al. 2009). Districts adjacent to Finland in Russia (Leningrad area, Republic of Karelia and Murmansk area) are developing, but still the HDI were in all of them <0.88 in 2013 (UNDP 2013).

2.9.3. Impacts on ecosystem

For places where plant growth is water-limited, withdrawals of so-called blue water may finally reduce the availability of green water and decrease vegetation and plant diversity. CF for ecosystem quality ΔEQ is 1.62E-01 [m^2•yr/m^3] for Finland (Pfister et al. 2009).

2.9.4. Impacts on resources

The renewable annual water resource in Finland is 106 km^3 (Shiklomanov & Rodda 2003) and total freshwater withdrawal 1.485% of actual renewable water resources (ARWS) (FAO 2013). In Sweden the corresponding percentage for ARWS is 1.503% (FAO 2013). The characterization factor for damage to resources in Finland is 7.42E-03 [MJ/m^3] and zero for Sweden (Pfister et al. 2009). According to Pfister (2014, personal communication) this is due to same artifact as the relatively high WSI for Finland. For that reason, CF for water resource impact (ΔR) should be zero and the impact on the resource is insignificant. Because of this, and also because there are only few relatively small areas with high WSI in Finland, and dairy production is located mostly in low WSI areas, we used a CF of zero for ΔR.

3. Results

3.1. Water consumption in production chain

Freshwater consumption for production of one liter of skimmed milk was 5.775 liters. In different feed regimes the results were 5.85 liters for cattle using on-farm grain in feed (OFPF) and 5.75 liters for cattle using commercial fodder as part of their feed (bought-in feed, BIF). The most water consuming phases were animal drinking (44-45%), water use in dairies (23-24%) and washing on the dairy farm (15-16%). Other water consumption in primary production included feed production, energy use and transportation and it comprised 6-7% of total use. Other water consumption in processing was respectively 9-10% and included package production, energy use in dairy, transportation and uninvoiced water in municipal waterworks.

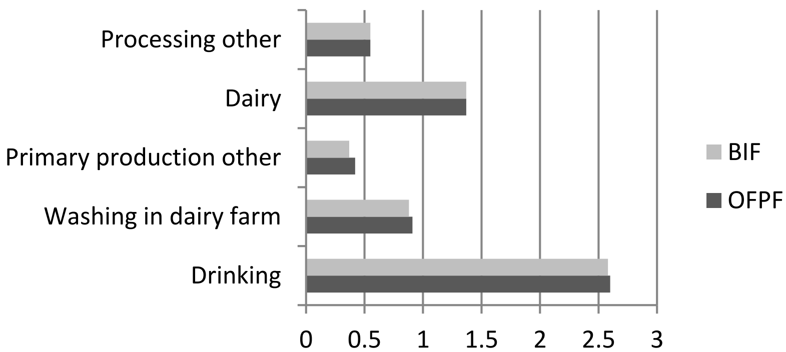

Figure 1. Total consumptive use of freshwater in production of skimmed milk ($liter_{water}$ / $liter_{milk}$) in production systems for on-farm produced feed (OFPF) and bought-in feed (BIF).

Dairy farm water consumption without drinking water was 1.25-1.33 liters/FU. Total water consumption from cradle to farm-gate was varying from 4.36-4.89 liters/FU. Washing the milking machines consumed most of the total amount without drinking water (Figure 2). Water consumption in feed production consisted of water consumption in agricultural input production (fertilizers, lime, fuels, electricity and seeds). After allocation in dairy-phase the total consumption from cradle to farm-gate was 3.8-3.9 liters/FU.

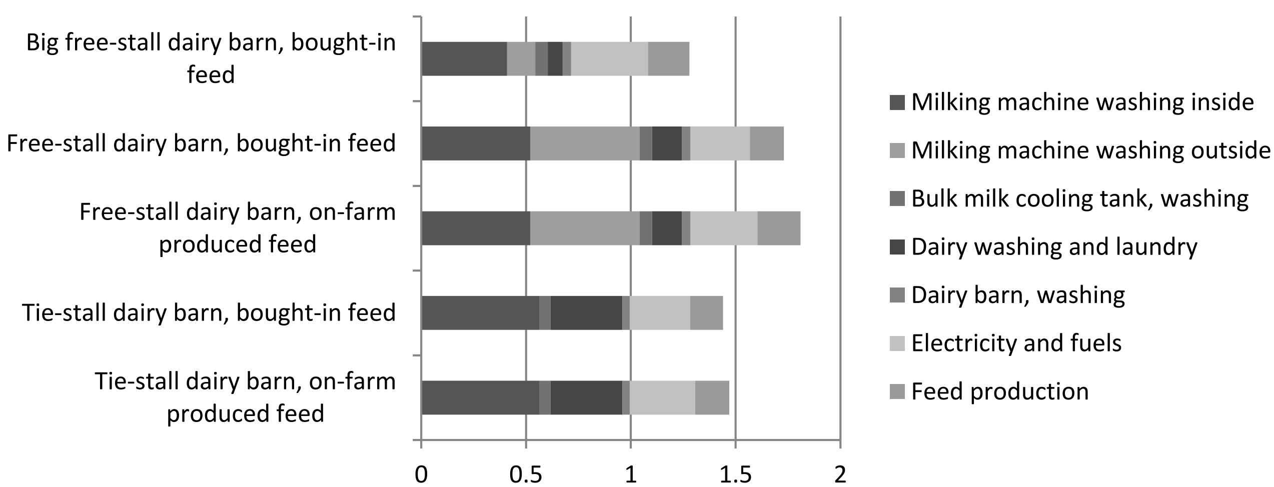

Figure 2. Consumptive use of freshwater in primary production without drinking water ($liter_{water}$ / $liter_{milk\ in\ dairy\ farm\ gate}$).

3.2. Impact assessment results

Impact assessment results were calculated in four impact categories (Table 3). Impact on resources was assumed to be zero (see 2.8.4). If calculated with current characterization factors, the impact would be 4.3E-05 MJ/l,$_{milk}$.

Table 3. Impact assessment results for one liter of skimmed milk.

Consumptive use l/l milk	Water deprivation H_2Oeq/l milk	Ecosystem quality ΔEQ m^2*year / l milk	Human health $\Delta HH_{malnutrition}$ DALY / l milk	Resources ΔR MJ / l milk
5.8	4.0	9.4E-04	2.5E-07	0

4. Discussion

4.1. Discussion of the results

Consumptive water use in milk production based on rain-fed feeds was 5.8 liters / liter skimmed milk. Drinking water for dairy cattle, water consumption in dairies and washing waters on farms were the most significant factors included in total consumptive water. Differences between feeding regimes are negligible in this case. Milking machine type makes a minor difference between farm types, but due to data quality no further conclusions are possible to draw about farm type differences. Numerical results indicate that total consumptive water use in milk production is low and water-related impacts are not in very high level in Finland.

The improvements in methodology (discussion in 4.4) might even decrease the impact assessment results in the future. However, in terms of other water-related impacts, dairy sector in Finland is considered to have high eutrophication impact: in Baltic Sea agriculture constitutes the largest share of the reported total diffuse nutrient loads to the sea (HELCOM 2011).

4.2. Comparisons with other studies

Worldwide water-related impacts of milk production have been studied by several researchers (i.e. Netherlands: De Boer et al. 2013, Australia: Ridoutt et al. 2010, New Zealand: Zonderland-Thomassen, M.A. and Ledgard, S.F. 2012). As shown in Table 4, results vary considerably. This is partly due to different local characterization factors, and as such, indicates the different impacts at various localities.

Production systems are very different, especially regarding irrigation, which affects results significantly. Irrigated feeds were used in the Netherland and New Zealand/ Canterbury cases. In the Netherland the consumptive water use was 66.4 liters in total, but only 5.7 liters without feeds. In New Zealand there was almost a 250-fold difference between the Waikato, with rain-fed feed production, and Canterbury cases.

However, there are several definitions for consumptive water. In New Zealand cases the consumptive water does not include all water withdrawn but water a) withdrawn and then evaporated, b) water returned to another catchment and c) water integrated in a product (see Table 4) (Zonderland-Thomassen, M.A. and Ledgard, S.F. 2012). Other studies include drinking water and irrigation water, if used, in total (De Boer et al. 2013, Australia: Ridoutt et al. 2010), and therefore it is not meaningful to compare the amount of consumptive water.

A huge variation in inventory data also affects the results, especially regarding the amount of water consumption on dairy farms, which varies considerably. In the New Zealand cases, the drinking water was 50 liters / lactating cow / day, in our study 73 liters and in Australia 150 liters. Milk production, feed dry matter and temperature have the biggest impact on cow water intake, and that probably explains the differences.

Table 4. Impact assessment results from previous studies on milk production from cradle to farm-gate. Milk produced by bought-in feed (BIF) in tie-stall dairy barn is used here as an example of Finnish milk.

Study milk from cradle to farm-gate	Consumptive use l/l, milk	Water footprint [3] H_2Oeq /l, milk	Ecosystem quality ΔEQ m^2*year / l milk	Human health $\Delta HH_{malnutrition}$ DALY / l milk	Resources ΔR MJ / l milk
Finnish milk	4.52[1]	3.12	7.32E-04	2.0E-07	0
De Boer et al. 2013 **Dutch milk**	66.4[1]	33.4	1.29E-2	8.0 E-08	6.7E-3
Ridoutt et al. 2010 **Australian milk powder**	14.1[1] (milk) 108[1] (milk powder)	1.9 (milk) 14.4 (milk powder)	-	-	-
Zonderland-Thomassen, M.A. and Ledgard, S.F. 2012 **New-Zealand milk** a) case **Waikato**	0.945[2]	0.165[4]	5.86E-05	0	0
b) case **Canterbury**	249.3[2]	11.1[4]	3.06E-02	0	0

[1]consumptive water includes drinking water and irrigation water, if used, as a whole
[2] consumptive water according to Water Footprint Network (Hoekstra et al. 2009, 2011) includes water withdrawn and then evaporated, water returned to another catchment and water integrated in a product
[3] Water footprint according to Ridoutt et al. (2010)
[4] blue water abstracted

Finnish milk seems to be associated with rather low consumptive water use. However, water footprint is higher than in Australia and New Zealand Waikato, because of the high WSI for Finland. Human health impacts exist, according to the method of calculation, in Russia. Both of these results are significantly affected by CF.

In general the huge variation in results from different studies indicates that the method of calculation is yet not completely established. Because of the local characteristic of water-related problems, it is natural that variation among inventory data is considerable. However, some differences may be due different definitions of consumptive water, different methods of data collection and also in cases of less-qualified data, as in this study (see 4.2), the likelihood of error increases. In addition to different inventory data sets in different studies, there might be differences in system boundaries and allocations. At the moment researchers have still only very few previous studies to compare with their own results.

4.3 Data availability

Good quality inventory data were not always available during inventory analysis. Data variations in other milk studies indicate this situation is not unusual, even though part of the variation is due to natural differences in production systems. Dairies measure their total water consumption, but no product-specific or production-line-specific data were available and therefore allocations were necessary. Water consumption in dairy farms had to be assessed by reviewing the literature thoroughly and canvassing expert opinion. There were some published data on water consumption using specific milking equipment and other equipment, but most studies used as data sources focused on research questions other than freshwater consumption. This definitely had a negative impact on data quality in this context.

Many dairy farms have their own well and no water meter making the assessment of water consumption a challenging task. Because it seems that in many cases that water consumption on dairy farms is very variable, depending on machine control and special practices, e.g. in frequency of washing, a more comprehensive study with rigorous consumption measurements would give interesting information.

4.4. Methodological gaps

4.4.1. System boundaries and allocation

The definition of consumptive water use seems to be very important question in terms of system boundary definition. Irrigation and animal drinking water are the most important phases of the milk production chain, and the results are different when in those phases all water withdrawals are included in inventory or only evaporated water, water returned to another catchment and water integrated in a product. Similar questions arise also in other phases of the production chain.

Municipal waterworks are not very often included in freshwater consumption inventory studies. We noticed that leakage of freshwater in pipelines has an impact, especially when the pipelines are long, and should be included in inventories. Another interesting case is the products of mining industry: lime and K- and P-fertilizers. There is always rainwater flowing into the mine and there is a need to pump it out. Should this water be included into the study or not? In some cases water is clean and available for many purposes like in lime mining, but not in all cases.

In terms of allocation, milk chain is a pretty complicated chain. At the moment a proper method for allocations in water related issues is missing. IDF (2010) recommends raw milk allocation in dairy in the basis of milk solids in climate change impact category, but regarding to water-issues, this should be re-assessed.

4.4.2 Impact assessment

Currently there are characterization factors that are defined using global models, but enhanced modeling tools for regionalized life cycle impact assessment are needed (Pfister et al. 2009). In this study we saw how global models may lead to misinterpretations at the local scale, as discussed in 2.8. In Finland, WSI and CF especially should be assessed again using up-to-date local data for impact their impact on the resource base. Also CF for impact on human health should be redefined, and good data should be found to detail the real impact pathway better to establish if there are connections between health impacts in Russia and water withdrawals in Finland.

5. Conclusion

As a first approach to apply LCA framework to food stuff in Finland, focusing on less used impact categories of water-related impacts, this study provides basic knowledge about suitability of the current methodology and data in this kind of assessments.

Impacts of water consumption in milk production were calculated, but further studies are needed to draw conclusions about water deprivation, human health and water resource impacts. At least WSI and CF for Impact on Resources should be redefined for Finland, using up-to-date local data instead of global models. Human health impact is due to the lower HDI in Russia, which affects the calculation, but there might be reasons to reassess the impact pathway.

Globally, variation in water-related impacts of milk production systems is huge due to location of production and i.e. production type (irrigated versus rain-fed agriculture) and the first thing to do is to point out hotspots of the production chains and magnitude of impacts. LCA framework is well suitable for assessing the consumptive water of food stuffs. We found out that consumptive water of milk production, in Finland, is relatively low. At the moment weaknesses in methodology and CFs based on global models are setting limitations for the impact assessment as well as poor quality of the data. Therefore, both a) improvements in methodology and b) more experience in water-related impacts included in LCA to gradually improve quality and quantity of the data are necessary. LCA is a strong tool to show several impact category results at once and to provide suitable quantitative information for improving the sustainability of the production chains, also when water-related impacts are in question.

ABSTRACT

Due to the significant contribution of the livestock sector to nitrogen (N) losses, improving N use efficiency (NUE_{-N}) along the life cycle of livestock products is one of the important step towards increasing production performance and reduction of its environmental impacts. We developed a comprehensive framework and novel metrics to assess NUE_{-N} along the livestock supply chain (i.e. "cradle-to-primary-processing"). Our framework was illustrated for the case study of mixed dairy production in Western Europe. Metrics developed included the life cycle NUE_{-N}; total N losses to the environment per unit of N in the final co-products; and the N hotspot index (NHI_{-N}), defined as the relative evenness of the N losses along the supply chain. Averaged across countries, the life cycle NUE_{-N} was 36±3.1%, N losses were 6.6±1.8 g N per g N in the final animal co-products, and NHI_{-N} of 1.0±0.1. The N losses and NHI_{-N} also revealed large differences in hotspots across supply chains, and allowed to identify priority areas where improvement actions are necessary to enhance the efficiency. We show that the combination of life cycle NUE_{-N}, N losses and NHI_{-N} gives valuable information to guide N management in livestock supply chains.

Keywords: life cycle, nitrogen use efficiency, hotspot, livestock, supply chain

1. Introduction

The livestock sector is identified as a significant contributor of nitrogen (N) losses into the air, water and soil, which can create environmental burdens including climate change, eutrophication, degradation of water and air quality (Erisman et al. 2007; Galloway et al. 2010; Xue and Landis 2010; Leip et al. 2013; Sutton et al. 2013). Due to an increasing world population and changing dietary patterns, driven by rising incomes and urbanization, especially in developing countries, the global demand for livestock products is expected to increase in the coming decades (Alexandratos and Bruinsma 2012). Acknowledging the need to improve its environmental sustainability, the livestock sector is increasing its efforts to improve nutrient management and nutrient use efficiency in livestock supply chains[1].

Several researchers proposed N use efficiency (NUE_{-N}) as a valuable metric to manage and benchmark N use and improve performance (Powell et al. 2010; Leip et al. 2011; Gourley et al. 2012a; Sutton et al. 2013). NUE_{-N} is generally computed at animal level (Powell et al. 2010) or farm level (Aarts et al. 2001; Gourley et al. 2012b; Godinot et al. 2014). Livestock supply chains, however, are increasingly long and complex, implying that NUE_{-N} at animal or farm level captures only a fraction of actual emissions. Potential inefficiencies taking place upstream or downstream from the farm are thus ignored. It is necessary to bring the life cycle approach to NUE_{-N}, in order to identify "hotspots" along the entire supply chain, and to avoid interventions that would result in shifting nutrient inefficiency problems from one production step to another.

Few studies have addressed nutrient use efficiency (NUE) at chain level (Suh and Yee 2011; Wu et al. 2014) and several challenges remain concerning the computation of a representative life cycle NUE_{-N}. The aim of this paper, therefore, is to present a comprehensive framework and related metrics to assess NUE_{-N} along the livestock supply chain, from "cradle-to-primary-processing." The framework will be illustrated with a case study.

[1] This research takes place in the context of a multi-stakeholder partnership gathering private, governmental and non-governmental organizations and aiming at developing methods and metrics relevant to guide the sustainable development of the livestock sector. See Livestock Environmental Assessment and Performance (LEAP) website: http://www.fao.org/partnerships/leap

2. Materials and methods

2.1. Description of the system

We propose a comprehensive method to assess the life cycle NUE_{-N} of livestock supply chains, from cradle-to-primary-processing-gate. This framework can be also used for other nutrients, such as phosphorus. To illustrate the computation and results from this framework, we apply it to mixed dairy systems in 28 countries of Western Europe. Mixed dairy systems were selected because of data availability, and the fact that they offer a relevant mix of inputs and outputs to test the framework. Mixed dairy systems are defined as systems combining dairy farming with other associated agricultural activities, such as feed cropping, other animal species production, and are characterized by an intensive exchange of products and services between these different activities (Oomen et al. 1998).

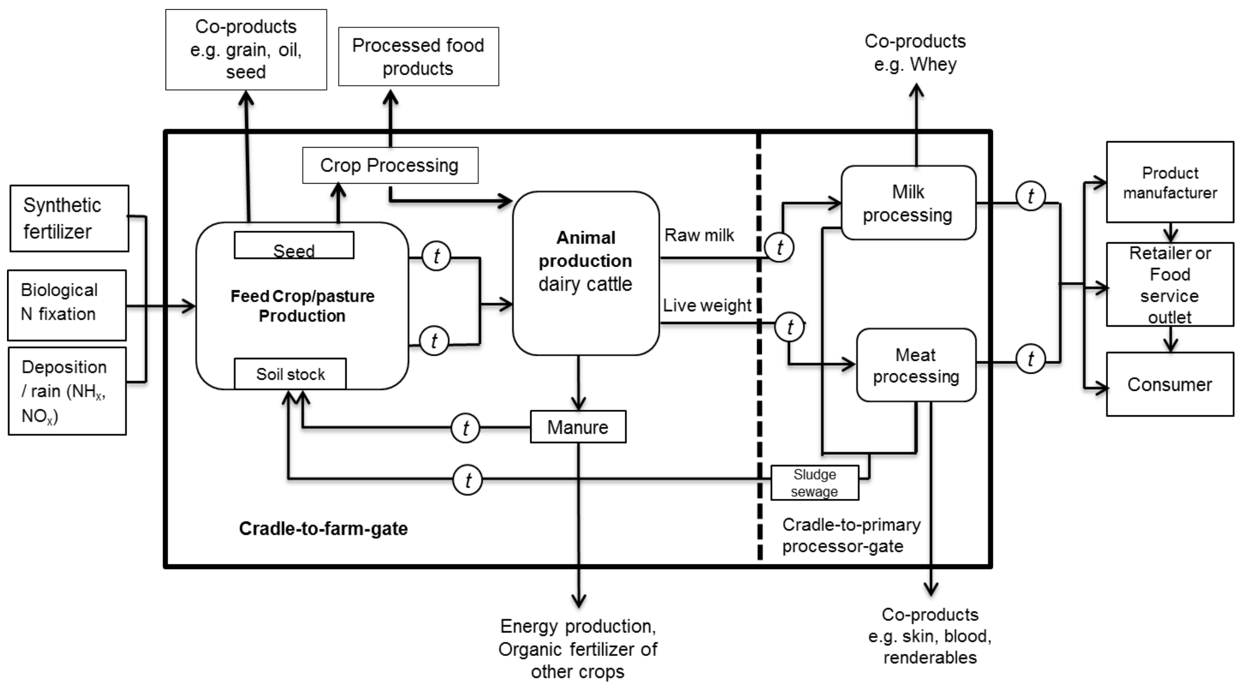

Figure 1. System boundary proposed for the life cycle of dairy cattle covering cradle-to-primary-processor-gate for two main products (milk, meat), the large box covering the cradle-to-primary-processing gate represents the stages covered by life cycle NUE_{-N} methodological framework. (*t*): refers to transportation.

2.2. System boundary

The framework assumes that all N flows occur during the same year, and the system operates in a fixed state. The system boundary illustrated in Figure 1 represents the cradle-to-primary-processing-stage of the life cycle. This choice of the system boundary is motivated by data availability. It includes three main stages, which are interconnected: feed crop/pasture production, animal production, and animal products processing. All N flows entering, leaving or within the system boundary are included in the assessment. Nitrogen flows enter the system mainly through synthetic fertilizer, biological N fixation (BNF), and atmospheric deposition (ATD) to produce feed crop and forage. Other inputs of N to feed crop/pasture are internal to the system and come from recycled manure (urine, dung and litter), crop residues or seeds. N inflows related to fossil fuel are excluded in this study because of lack of sufficient data on national and international transportation of feed stuffs and on-farm fossil fuel use. The N outflows are estimated based on products' yields. We assume that all outflows are separated after their excretion, which imply that, when a food crop, crop residue or by-product is used as feed, an economic allocation factor is only applied to split N losses between crop co-products. At the animal production stage, N flows are associated with feed, milk, live animals and manure recycled. Only milk and live animals are processed into final animal co-products, while manure is used as organic fertilizer in crop production. These final co-products mainly include milk, meat, leather, fat and other non-edible products. At each stage of the supply chain, the fundamental principle of mass balance conservation is applied: "N inflow = N product + N loss + δN stock." N product includes all co-products delivered at each stage, whereas N loss refers to N lost via volatilization, run-off and leaching.

2.3. Metrics

We propose to calculate three metrics based on the analysis of the N flows along the chain, i.e. NUE_{-N}, the N losses and the N hotspot index (NHI_{-N}). NUE_{-N} is a relatively common metric, but it is calculated here for the entire supply chain, following a life cycle perspective. The "N losses" indicate the amount of N lost to produce 1g of N in the final co-product. NHI_{-N}, on the other hand, is proposed as a new metric that qualifies the evenness of inefficiencies along the supply chain.

2.3.1. Computation of the life cycle NUE_{-N}

NUE_{-N} refers to the total N outflow excluding losses to the total N inflow within each stage or subsystem of the supply chain. The calculation model includes three interconnected stages: feed crop/pasture production, animal production and processing, to ensure that an intervention arising from a particular stage of the chain is transferred throughout the supply chain. This concept was previously defined in Suh and Yee (2011) and Wu et al. (2014).

Feed crop and pasture production

At the level of the cropping system, NUE_{-N} is estimated for all crops and pastures produced. NUE_{-Nc} is defined as the ratio of N outputs (harvested in plant biomass) plus the variation of the mineral N in soil stock pool to N inputs (inorganic fertilizers, livestock manure, crop residues, ATD, and BNF). Furthermore, it is assumed that extra N which is not up-taken or lost; is stocked as mineral N in the soil pool. NUE_{-Nc} is estimated as follows:

$$NUE_{-Nc} = \frac{\sum(O_c + \delta S_c)}{\sum I_c} x100 \qquad \text{Eq. 1}$$

where O_c is the total N in harvested crop or pasture; δS_c is the change of the stock of N in soil (either as accumulation or removal of mineral N in soil); I_c is the total N input materials to feed crop/pasture production.

Feed ration

Feed assessment requires the identification of all feed component used in animal ration. We estimate the average NUE_{-N} of ration (NUE_{-Nf}) based on proportion of each feed component in the ration. Feed ration may vary during the year or over a period of a year. It is assumed that animals of the same cohort are fed a similar ration the whole year. In this study, the country specific feed rations are extracted from the Global Livestock Environmental Assessment Model (GLEAM) (Gerber et al. 2013). NUE_{-Nf} is estimated as follows:

$$NUE_{Nf} = \sum_{i=1}^{k} (NUE_{Nci} x \, \beta_i) \; (k = 1,2, \ldots, k) \qquad \text{Eq. 2}$$

where NUE_{-Nci} is the N use efficiency of feed component i, β_i is the proportion of feed component i in the ration, k is number of feed component used. NUE_{-Nf} is calculated at herd level.

Animal production

At the level of the animal production system, NUE_{-N} refers to the capacity of animals to incorporate N in feed into animal products. After the ingestion, N intake is partitioned into edible protein (e.g. meat, milk) and inedible protein (e.g. leather, blood, offal) as well as in animal excreta according to Powell et al. (2013). We considered manure as a valuable product of the animal production system, contrary to most studies that examine N balances of livestock systems (Segato et al. 2010; Leip et al. 2011; Oenema et al. 2012). N losses associated with manure management are estimated using GLEAM (Gerber et al. 2013). We assume that manure managed in mixed dairy systems is used either as organic fertilizer or for energy production. Similarly to crop production, NUE_{-N} in animal production (NUE_{-Na}) is defined as the ratio of N in co-products to N in inputs (feed intake), and is estimated as follows:

$$NUE_{-Na} = \left[\frac{O_a+\delta S_a}{I_a}\right] x100\% \qquad \text{Eq. 3}$$

where O_a is the N in product including edible and non-edible products such as manure; δS_a is the change of N stock in animal herd related to calving or input of new animals; I_a is the total N intake.

Processing

After the farm gate, live animals and primary animal products are processed. The inedible products from processing may be used as compound feed (e.g. blood, bones) for other animal species, as input to industrial processes (e.g. leather, cosmetics, food or pharmaceutical industries) or other use such as fertilizer. N concentration in manure produced during transportation or during stalling of animals at the slaughterhouses and in waste water, which is not treated at factory level, is considered a pollutant to the environment, therefore, is included in the estimation of N losses. NUE_{-Np} is defined as the ratio of N content in final animal co-products to N entering the processing unit and is estimated as follows:

$$NUE_{-Np} = \left[\frac{O_p}{I_p}\right] x100\% \qquad \text{Eq. 4}$$

where O_p is the total N in final animal co-products at primary processing and I_p is the total amount of N in animal production output which equals to O_a (Eq. 3). It is assumed that no stock exists in processing plants.

Supply chain

The entire life cycle NUE_{-N} is estimated as the product of NUE_{-N} of each stage of the supply chain, and is estimated as follows:

$$\text{Life cycle } NUE_N = \prod_{i=1}^{n} NUE_{-N_i} (i = f, a, p) \qquad \text{Eq. 5}$$

Where NUE_{-Ni} represents NUE_{-N} of stage i of the supply chain.

2.3.2. Nitrogen losses

"N losses" is defined as the total N losses to the environment that occur for the production of one unit of the final co-product. N losses are estimated as N in output products plus stock change minus N inputs. The reference unit used to report the N losses is 1 g of N in final animal co-products at the primary processing gate. N losses may occur through volatilization of NH_3, emissions of N_2O, NO, and nitrates leaching and run-off at every stage of the supply chain. They are estimated based on tier-1 equations from IPCC guidelines (IPCC 2006).

2.3.3. Nitrogen hotspot index (NHI_{-N})

NHI_{-N} is defined as the relative evenness of the N losses in the supply chain. NHI_{-N} is calculated as the standard deviation of N losses divided by the average N losses of all stages of the supply chain, and, therefore, quantifies the relative evenness or concentration of losses along the chain. A high NHI_{-N} implies that the occurrence of major hotspots of N losses in the chain, whereas a low NHI_{-N} implies that N losses are evenly distributed. NHI_{-N} is estimated as follows:

$$\mathrm{NHI_N} = \frac{\sigma}{\mu} \qquad \text{Eq.6}$$

where σ is the standard deviation of the N losses at the different stages of the supply chain; μ is the corresponding average of N losses.

2.4. Data and parameters

Country average data regarding crop and livestock activities were extracted from the GLEAM database. GLEAM was developed to assesses the environmental performance of livestock supply chains at global level (Gerber et al. 2013). GLEAM is a Geographical Information system (GIS) based model which represents processes and activities, from the production of inputs into the production process to the farm-gate. It is composed of five main modules: herd module, manure module, feed module, system module and allocation module. GLEAM relies on IPCC Tier 1 and Tier 2 approaches and emission factors to estimate the greenhouses gas emissions and thus the N flows. The Tier 1 approaches are used in this study for the estimation of N_2O emissions. Additional data on N ATD were obtained from global maps of atmospheric N deposition (Dentener 2006), while BNF data are estimated from Herridge et al. (2008). The fourteen feed components considered were different types of fresh grass, legumes, cereals, and by-products (soybean cake, maize gluten meal, etc.) according to Opio et al. (2013). The data represented the year 2005.

2.5. Sensitivity and statistical analysis

The descriptive statistics and sensitivity analysis were performed with R software (R Core Team 2013). The sensitivity analysis of key data was carried out to identify the most sensitive parameters to the life cycle NUE_{-N} result. Each key data of the input has been changed by 10% and the corresponding change in life cycle NUE_{-N} was evaluated.

3. Results

3.1. Overall NUE_{-N} and N losses at different stages of the supply chain

The country-level NUE_{-N} and N losses of mixed dairy supply chains for Western European countries are summarized in Figure 2. Of the 11 Tg N applied annually to feed crop and pasture, only 0.79 Tg N were found in final animal co-products and 2.5 Tg N were recovered as manure available for recycling. The NUE_{-N} is higher at processing stage: 79% compared to 61% and 76% at the biophysical stages of feed crop/pasture production and animal production, respectively. The lower NUE_{-N} in feed crop/pasture production is related to the relatively large amounts of N lost via volatilization, leaching and run-off during the process of application of synthetic fertilizer and manure and manure deposition during grazing. On the other hand, the relatively higher NUE_{-N} in animal production is explained by the large proportion of manure that is estimated to be recycled. About 3.9 Tg N were lost during feed crop/pasture production representing 74% of total N losses in supply chain. The amounts of N losses in animal production and processing stage were lower: 1.1 Tg N and 0.18 Tg N, respectively.

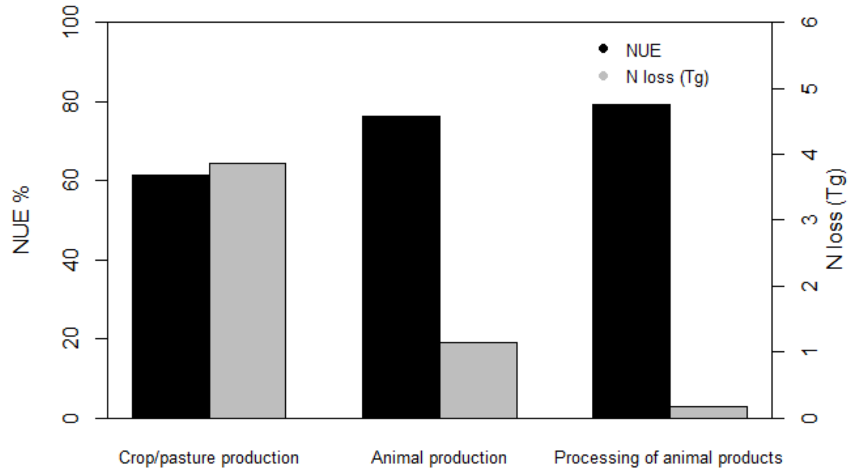

Figure 2. The NUE$_{-N}$ and N losses for every stage of the mixed dairy cattle supply chains for Western European countries.

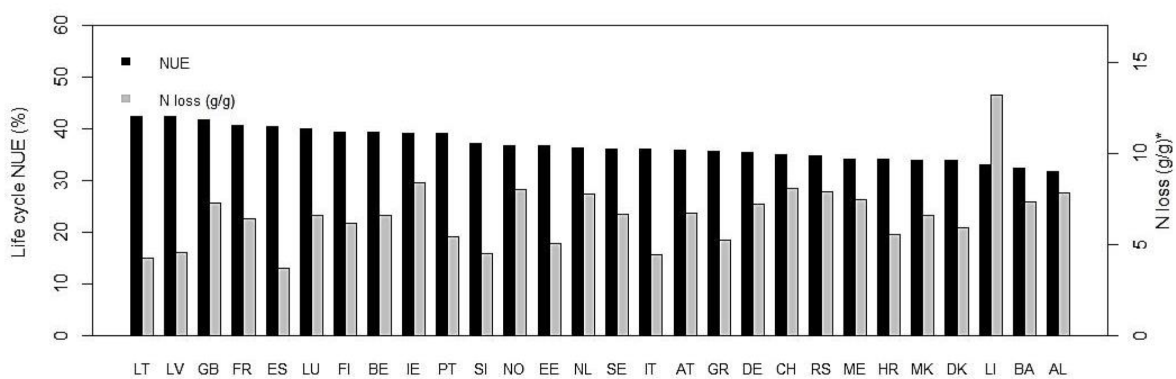
3.2. Life cycle NUE$_{-N}$, NHI$_{-N}$, and N losses

The average life cycle NUE$_{-N}$ and N losses of mixed dairy supply chains for Western European countries are summarized in Figure 3, whereas results of NHI$_{-N}$ are presented in figure 4. There were large differences between countries in average life cycle NUE$_{-N}$ which ranged from 32% to 43%, with an overall average of 37±3%. Depending on the country, N losses per g of N in final co-product varied from 3.7 g N per g N to 13 g N per g N with an average of 6.6±1.8 g N per g N. NHI$_{-N}$ varied from 0.61 to 1.4, with an average of 1.0±0.1. These results show that the countries with higher life cycle NUE$_{-N}$ do not necessarily have lower N losses per unit of product or NHI$_{-N}$ or vice-versa. For instance, the United Kingdom (GB), and the Spain (ES) have a similar life cycle NUE$_{-N}$ but the dairy cattle system in GB has a higher N losses than in ES. This is because in GB the feed system is dominated by forage (around 62% of total feed), whereas this material plays a less important role in the feed rations of ES (around 42% of total feed) and that fodder production is characterized by a lower feed use efficiency.



AL: Albania, AT: Austria, BE: Belgium, BA: Bosnia and Herzegovina, CH: Switzerland, DE: Germany, DK: Denmark, EE: Estonia, ES: Spain, FI: Finland, FR: France, GB: United Kingdom (of Great Britain and Northern Ireland), GR: Greece, HR: Croatia, IE: Ireland, LI: Liechtenstein, IT: Italy, LT: Lithuania, LU: Luxembourg, LV: Latvia, MK: Macedonia, NO: Norway, NL: Netherlands, PT: Portugal, ME: Montenegro, MK: The former Yugoslav Republic of Macedonia, RS: Republic of Serbia, SE: Sweden, SI: Slovenia.
* N loss is expressed as g N losses per 1 g of N in final animal co-products (edible and non-edible).

Figure 3. The life cycle NUE$_{-N}$ and N losses of mixed dairy cattle supply chains for Western European countries.

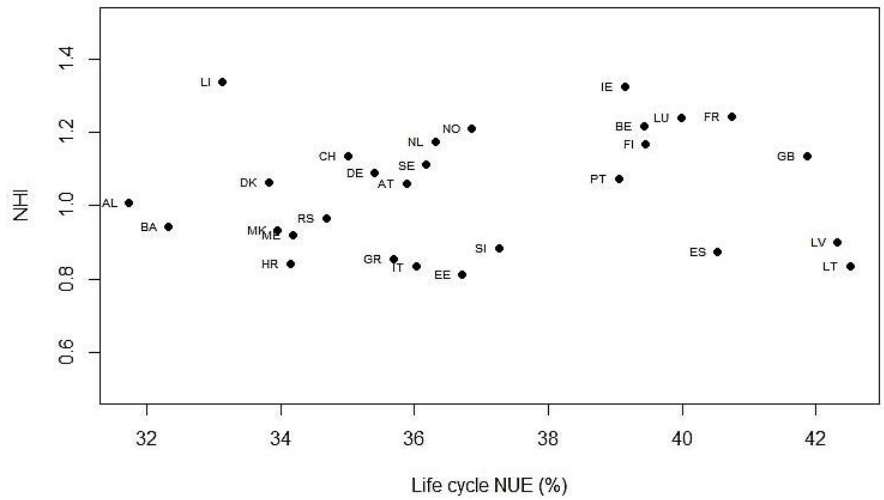


Figure 4. NHI_{-N} and life cycle NUE_{-N} of mixed dairy cattle supply chains for Western European countries.

Around 15 countries have a NHI_{-N} greater than the average (1±0.1), indicating the presence of hotspots in the supply chains. All countries irrespective of their life cycle NUE_{-N}, the feed crop/pasture is the stage with higher N losses due to the over-fertilization. NHI_{-N} also allows comparison of supply chains with equal life cycle NUE_{-N}. In this case, for example, Norway (NO) and Estonia (EE) have similar life cycle NUE_{-N} but the lower NHI_{-N} in EE implies that N losses are similarly spread along the supply chains than in NO where there is a presence of a hotspot in the feed crop/pasture production.

4. Discussion

4.1. Sensitivity analysis and methodological limitations

Data used in this study were mainly extracted from GLEAM and literature. Obviously, these data are subject to various degrees of uncertainty. A partial sensitivity analysis was thus carried out to identify the most sensitive key data to the life cycle NUE_{-N} result. A 10% increase/decrease in the synthetic fertilizer use resulted in a 0.3% increase/decrease in the life cycle NUE_{-N}, whereas it resulted in 1% increase/decrease when applied to feed N intake. On the other hand, the 10% change on manure use resulted in 7% decrease/increase of life cycle NUE_{-N}, which shows the largest range among the key data tested. Any change of this parameter impacts also the NHI_{-N} and N losses. Other sources of uncertainty are related to the modeling of soil mineral N stock change which is simplified in this assessment, and based on a mass balance approach. In addition, the use of Tier 1 and Tier 2 approaches presents a limitation to the accuracy of quantification; more research is needed to develop Tier 3 approaches that improve the accuracy and precision of computation.

The main challenge of computing NUE_{-N} at each life stage of the supply chain compared to computing a unique overall efficiency, is obviously the high data requirements and the dependence on data quality and uncertainty. Therefore, the exploration of minimum data requirement to perform a representative regional or global life cycle NUE_{-N} is crucial. The other limitation is related to the difficulty to estimate mineral N stock in the soil pool. Leip et al. (2011) assumed a soil stock change of zero to simplify the calculation. In contrast, the framework we propose, considers that the extra N which is not uptaken or lost through leaching, run-off and volatilization is stocked as mineral N in the soil pool. The long-term accumulation of N may however result in high leaching with impacts on water quality and aquatic ecosystems. Further improvement of the framework should thus aim at estimating the maximum storage capacity of the soil to avoid the under-estimation of N losses to the environment.

4.2. Comparison with other studies

This study computes NUE_{-N} in a life cycle dimensions of mixed dairy production systems in Western Europe. It shows that, for production of final animal co-products, the life cycle NUE_{-N} was on average 36±3.1%. The country-level life cycle NUE_{-N} computed in this study is not directly comparable with previous results computed at animal or farm level. Nevertheless, partial validation is possible by comparing the NUE_{-N} in different stages of the supply chain with actual quantifications. The average NUE_{-N} at feed crop/pasture production (61%) is comparable to the average of soil NUE_{-N} of 59% estimated for all crops in fifteen countries of European Union (OECD 2001). In animal production, the NUE_{-N} is 76%, which is higher than previous estimates of about 22% in dairy production system (Powell et al. 2013). The difference is related to the N outflows included in the quantification. Powell et al. (2013) only considered the raw milk as output whereas in this study, raw milk, live animals, and recycled manure were included as products, which increased considerably the NUE_{-N} in this stage. The high performance at the processing stage in terms of NUE_{-N} is related to the technological control of flows, treatment of waste water and re-use of organic wastes usually applied at industrial level.

The average N losses calculated in this study are not comparable to the N footprint defined by Leip et al. (2013), which focuses on the total direct N losses to the environment per unit of food product. The N footprint, therefore, is higher than the estimated N losses which are related to the unit of N in the final animal co-product. Furthermore, livestock supply chains deliver non-edible final co-products which constitute raw material for other industries e.g. leather, cosmetics, pharmaceutical industries, etc. Therefore, the harmonization of the quantification methods and interpretation of the results are essential to allow the comparability.

4.3. Relevance and comparative advantages of the proposed framework

The proposed framework relies on the computation of three indicators. Complementarily to life cycle NUE_{-N}, NHI_{-N} facilitates the design of interventions, by giving information on the presence of hotspots. Furthermore, N losses gives information on the likely environmental impacts, although pathways aren’t described in this assessment. At crop/pasture level, this framework may support the improvement of land management, and precision of N application. At the animal production level, increasing feed digestibility and manure management are suggested options. Although further research is needed to explore their applications in contrasting farming systems (Oenema and Tamminga 2005; Erisman et al. 2007; Oenema et al. 2012; Sutton et al. 2013). Relatively high values of NHI_{-N} indicate that interventions can be targeted to few hotspots, which may well improve their cost-effectiveness; whereas designing and implementing interventions for supply chains with lower NHI_{-N} would require greater monitoring and evaluation efforts.

The life cycle approach applied to N use allows to account for the use, recycling and disposal of different agricultural resources such as crop residues and manure. The proposed framework provides indications on potential N pressure on the environment but does not give direct information on the impacts e.g. on water quality. Assessing impacts and evaluating the possibility to use life cycle NUE_{-N} as a potential proxy of impact, requires an approach that takes into account the N migration and transformation pathways in the environment. This requires detailed data on soil types, climate, water catchment, hydrology, drainage capacity of the soil, altitude, intensity of mechanization, as well as the interaction of livestock activities with other agricultural supply chains (Schulte et al. 2006).

Compared to life cycle assessment (LCA), the proposed framework requires less data and assessment steps, while supplying relevant information to support decision making. It is therefore proposed as a tool that can support the design and monitoring of N management in livestock systems that is less data demanding than LCA.

5. Conclusion

The life cycle NUE_{-N} provides information on N performance in livestock supply chains. It explores the capacity of livestock supply chains to convey N contained in inputs into products for human use. The life cycle NUE_{-N} considers the ability of livestock stakeholders to recycle, reuse and dispose of nutrients to limit the continuous importation of “new nutrient” in the supply chain. The combination of life cycle NUE_{-N}, N losses and NHI_{-N} provides relevant information to improve production technology and practices for a better management of nutrients. The framework requires less data than LCA but global and regional assessment would still require much information. Further work is thus needed to evaluate the minimum data requirement of the framework, ensuring wider applicability.

ABSTRACT

In the Euro-Mediterranean countries the sheep milk production is a significant sector that is currently going through a deep structural crisis. Since eco-sustainability of production systems and mitigation of climate change are European priorities, optimizing the environmental footprint of dairy sheep farms could become the access key of farmers for receiving financial support and achieve a more environmentally-sound agriculture. The main objectives of this paper were to compare the environmental impacts of sheep milk production from three different dairy farms in Sardinia (Italy), characterized by different input levels, and to identify the hotspots for improving the environmental performances of each farm, by using an LCA analysis. The LCA conducted using different functional units (1 kg of Fat Protein Corrected Milk and 1 ha of Utilized Agricultural Area) and different assessment methods (IPCC, ReCiPe, and Blue Virtual Water) led to a more objective evaluation of the environmental performances of farms.

Keywords: dairy sheep farming systems; environmental impacts; Life Cycle Assessment; agriculture multifunctionality; eco-sustainable livestock.

1. Introduction

The dairy sheep production is a significant sector for the European Mediterranean countries. Sardinia (Italy) is the most important EU region for sheep milk production, with more than 3.2 million ewes – about 3.5% of the EU total (EUROSTAT, 2012) – and a milk production of about 330.000 t year^{-1} (Osservatorio Regionale per l'Agricoltura, 2012), which represents more than 12% of the total European production (EUROSTAT, 2012). More than half of Sardinian sheep milk production is addressed to cheese industry for "Pecorino Romano PDO" (Protected Designation of Origin, European quality label) production (Furesi et al., 2013). "Pecorino Romano PDO" is one of the main Italian PDO product (ISMEA, 2012) and 95% of its production derives from Sardinian cheese factories (Idda et al., 2010). The dairy sheep farming system in Sardinia presents different degrees of intensification, depending basically on the geographical location of farms, which affect key-traits such as arable land availability, soil fertility and possibility for irrigation (Caballero et al., 2009; Porqueddu, 2008). In the last decades, Sardinian sheep production systems suffered a serious and continuous loss of competitiveness, due to several internal and external factors that caused a deep structural crisis in this traditional sector.

As production systems' eco-sustainability and climate change mitigation are on top of the European agenda, minimizing the ecological footprint of farms represents a key factor for farmers to obtaining public incentives and for enhancing the multifunctionality of agricultural systems. Therefore, the optimization of environmental performances could be a crucial factor to improve competitiveness of sheep farming, particularly in marginal areas. For this purpose it is essential to assess the environmental footprints of these livestock systems and to identify the weak points of the production chain where to take actions for reducing the farm's environmental impact (FAO, 2010). The environmental impacts (including greenhouse gases emissions) of animal production systems can be evaluated by using the Life Cycle Assessment (LCA) approach (De Boer, 2003). However, when applied to agriculture, the LCA analysis presents some challenges due to the intensive nature of required data, their limited availability and the multiple-output nature of production (FAO, 2010). Most of the research literature has been focused on intensive livestock systems of dairy cattle (Milani et al., 2011). To our knowledge, very little research studies have been conducted on life cycle assessment of sheep milk. A good example is given by Michael (2011), who made a detailed analysis of the resource use and emissions of sheep milk production in Australia, as part of a wider study on selected "new animal products" industries. On the other hand, several studies have been conducted to evaluate specific impacts of dairy sheep farming systems on soil, water, biodiversity, etc. (Molle et al., 2008; National Research Council, 2010; Peyraud and Delaby, 2006; Shepherd et al., 2007).

This study was conducted with the main aim of contributing to fill in these knowledge and data gaps and with the specific objectives of (i) comparing the environmental impacts of sheep milk production from three different dairy farms located in Sardinia and characterized by different input levels, and (ii) identifying the hotspots to improve the environmental performances of each farm, by using an LCA analysis.

2. Methods

2.1. Case studies

During 2011, data were collected from three different dairy farms located in the Province of Sassari, North-western Sardinia, Italy. The three studied farms fall into a homogenous agro-climatic area, with climate conditions typical of the central Mediterranean area, an average annual rainfall of approximately 550 mm, mean monthly temperatures varying from 10 to 26 °C, and elevation ranging from 60 to 350 m a.s.l. Rural landscape is characterized by dairy sheep farms with a mosaic of feed resources mainly represented by annual forage crops, cereal crops, improved and natural pastures.

The three farms differed mainly in stocking rate, size of grazing areas and concentrates consumption (Table 1), mostly covering the range of input levels for Sardinian sheep livestock (ARAS, 2013). We considered as low input farm (LI), the farm with the lowest stocking rate (1 ewe ha^{-1}), the largest grazing area (95 ha) and the lowest consumption of concentrates (1 t per year). On the opposite, the high input farm (HI) showed the highest stocking rate (5.5 ewes ha^{-1}), the smallest grazing area (12 ha) and an annual consumption of concentrates of about 200 t. Mid-input farm (MI) was characterized by intermediate levels of input. Farms had also different market strategy: LI and HI farms sold the milk to the cheese industry for “Pecorino Romano PDO” production, while MI uses its own milk for small-scale on farm cheese production, “Pecorino di Osilo”, which is included in the Italian list of typical agri-food products. Moreover, MI was the only farm that used the aseasonal lambing technique.

Table 1. Main characteristics of production system in low- (LI), mid- (MI), and high-input (HI) dairy farms. Data refer to 2011.

	Low-input (LI)	**Mid-input (MI)**	**High-input (HI)**
Utilized Agricultural Area (ha)	125	70	67
Heads (number)	120	320	370
Stocking rate (ewes ha^{-1})	1.0	4.6	5.5
Milk production (kg $year^{-1}$)	25,000	79,655	110,000
Milk pro-capita annual production (kg ewe^{-1} $year^{-1}$)	208	249	297
Pastures - grazing area (ha)	95	52	12
Arable land – cereals and annual forage crops (ha)	30*	18	55
Concentrate feed annual consumption (t) **	1	121	204
Mineral N-fertilizing (kg ha^{-1})	0	21	45
Mineral P_2O_5-fertilizing (kg ha^{-1})	0	72	32
Irrigation	no	yes	no
Milking system	manual	mechanical	mechanical

*10% of the arable land production is used for sheep feeding; the remaining part is sold as hay and grain.
** LI produces all concentrates on farm, MI imports all concentrate feed needed, and HI imports about 86% of total requirements.

2.2. Life Cycle Assessment methodology

The methodology used to carry out the LCA study is consistent with the international standards ISO 14040-14044 (2006 a, b). The analysis was conducted using two different *functional units* (FU): 1 kg of Fat and Protein Corrected Milk (FPCM) and 1 ha of Utilized Agricultural Area (UAA). The use of these two FU allows to define and to combine productive and economic results with depletion of natural resources. All inputs and outputs referred to 1 kg of FPCM were partitioned (*impact allocation*) between milk and the other co-products on the basis of the economic value of products (economic allocation), since the “main product” (milk) of all three farms had an economic value much higher than the other co-products (wool and meat) . When co-products were obtained from the same field (e.g., triticale-barley grain and stubble), mass-based allocation was applied, since the amounts of the individual co-products were interdependent in a physical relationship.

The life cycle was assessed "from cradle to gate", including in the *system boundaries* all the input and output related to sheep milk production. All modes of transportation and distances covered within the system were also taken into account. The model system was divided into two subsystems: a) Flock, and b) Farm Impact.

a) Flock - Processes linked with the productive life of livestock.

They include all the processes related to i) the use of agricultural soil and the cultivation operations required for the production of different forages; ii) the feed input, including the consumption of forage from pastures and feed concentrates; iii) livestock operations such as shearing (once a year) and milking (performed twice a day if mechanical, once a day if manual). Each of these processes has been applied to the different categories of sheep, depending on the breeding techniques adopted by each farm, having as primary reference points the quantity and quality of sheep diet. Therefore, LCA model includes ewes and rams, each subdivided into lambs, replacement animals and adults. The ewes were grouped by physiological and productive phase (maintenance, dry and lactation).

b) Farm Impact - Processes linked with the farm structure.

They include infrastructures (milking parlour, barns, etc.), agriculture machineries and devices (tractors, ploughs, milk cooler, pumps, etc.), water and energy consumption, and consumable materials like detergents, veterinary drugs, spare parts, etc.

About 70% of life cycle inventory data were collected through 12 visits *in situ*, interviews and a specific questionnaire (farm-specific data for year 2011). The remaining data (e.g., enteric methane emissions, supplement chemical composition, etc.) were collected from available literature and databases (mostly Ecoinvent v. 2.2 developed by Swiss Centre for Life Cycle Inventories).

With the aim of assessing in a more comprehensive way the environmental performances of the case studies, three different *evaluation methods* were used: 1) IPCC, Intergovernmental Panel on Climate Change (2006), which provides estimates on greenhouse gases emitted in the life cycle of products (Carbon Footprint), expressed in kilograms of CO_2-equivalents with 100-year time horizon; 2) ReCiPe that provides a more comprehensive assessment of life cycle environmental performances (Ecological Footprint), considering 17 different categories of environmental impact, which are calculated and harmonized obtaining a single eco-indicator (Ecopoint, Pt) (Goedkoop et al., 2009); 3) Blue Virtual Water that estimates the (virtual) water content incorporated (Water Footprint) into a product, as the volume of water, expressed in l-equivalents, consumed or polluted during the entire life cycle of the product (Hoekstra et al., 2011).

The life-cycle analysis was performed under the following *simplified assumptions*: the analysis included only the amount of forage (fodder crops and pastures) consumed by flocks, after cross-checking estimated and/or measured forage production and estimated nutritional needs based on gender, age, weight, physiological stage and production level of animals. National inventories of emissions by ISPRA (2011) for CH_4 and by IPCC (2006) for N_2O were used to quantify flocks’ enteric emissions. Irrigation impacts of MI were estimated by Ecoinvent v. 2.2. Life cycle assessment calculation was made using LCA software SimaPro 7.3.3 (PRé Consultants, 2011), which contains various LCA databases.

A Monte Carlo analysis was also performed to quantify the effects of the data uncertainties on the final results and to weight the differences between the environmental performances of the three farms.

3. Results and discussion

3.1. Evaluation of the environmental performances

The main results of the environmental impact assessment are shown in Fig. 1 by farm (LI, MI, and HI), method (IPCC, ReCiPe and Blue Virtual Water), and functional unit (1 kg of FPCM and 1 ha of UAA).

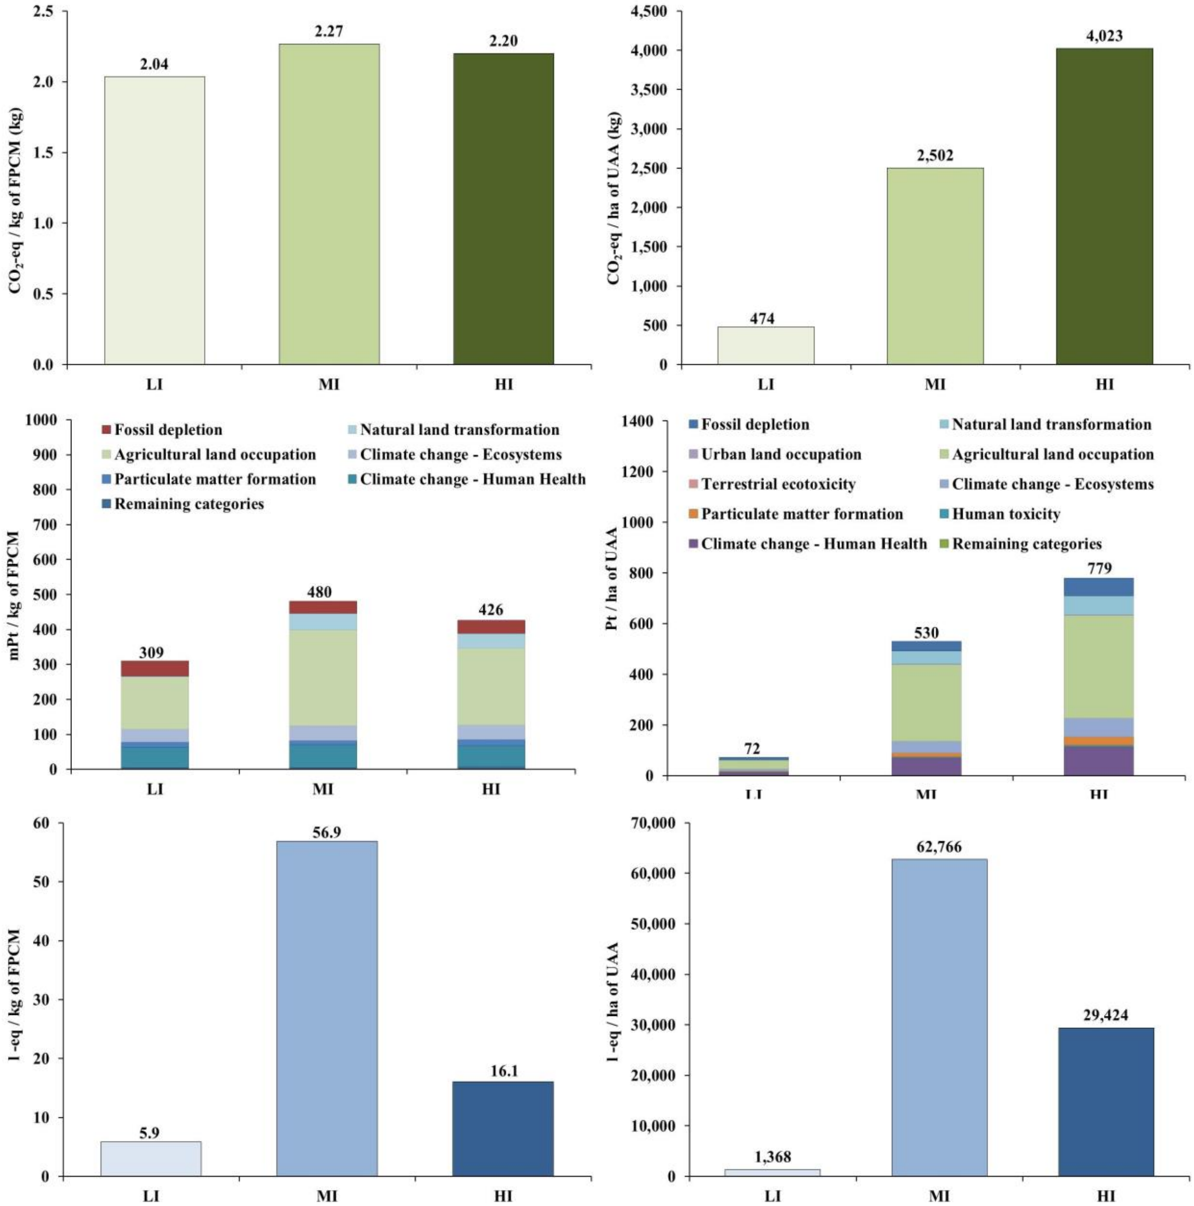

Figure 1. Main LCA results for three farms (LI, low input; MI mid input; HI, high input) using IPCC (plots at the top of the figure), ReCiPe (middle plots) and Blue Virtual Water (bottom plots) methods and two different functional units (1 kg of Fat Protein Corrected Milk, left plots, and 1 ha of Utilized Agricultural Area, right plots).

3.1.1. IPCC

The estimated life-cycle greenhouse gases (GHG) emissions of 1 kg of FPCM (plot on the left at the top of Figure 1) were slightly higher in MI. The GHG emissions per kg of FPCM from the observed production systems showed a slight variation ranging from approximately 2.0 (LI) to 2.3 (MI) kg of CO_2-eq. This result seems to contradict the findings reported in previous research studies (FAO, 2010; Hayashi et al., 2006; Michael, 2011). These authors showed that the degree of the environmental impact of farming systems referred to the quantity of product is negatively correlated with the intensity level in the inputs. The average Carbon Footprint of the three farms was equal to 2.17 kg CO_2-eq/kg FPCM and was about 61% lower than that estimated by Michael (2011) on a typical Australian dairy farm, where the Carbon Footprint was equal to 3.57 kg CO_2-eq/kg FPCM. However, the analysis of Michael (2011) was conducted on a more intensive dairy sheep farming system characterized by different sheep breed (East Friesian), and amounts of enteric methane emissions and stocking rate twice the amounts estimated in our case studies.

When the environmental impact assessment was performed using as functional unit 1 ha of UAA, the Carbon Footprint of the three studied farms showed relevant differences, indicating a strict positive relationship between the environmental impact of farms and the intensity level in the inputs (plot on the right at the top of Figure 1). The HI farm had the largest value (more than 4,000 kg of CO_2-eq), with LI and MI showing GHG emission amounts equal to about 12% and 62% of HI Carbon Footprint, respectively. Therefore, the highly extensive system of LI, with an UAA value almost twice compared to MI and HI and a stocking rate equal to 18% of HI (Table 1), was crucial in determining the environmental performance calculated per 1 ha of UAA.

3.1.2. ReCiPe

The results from the ReCiPe method assessment followed a trend similar to IPCC method for both FU (plots in the middle of Figure 1). To facilitate the interpretation of results, Fig. 1 shows only impact categories with scores higher than 10 milli-ecopoint (mPt) and 1 ecopoint (Pt) per 1 kg of FPCM (left side of the figure) and 1 ha of UAA (right side of the figure), respectively. When 1 kg of FPCM was used as functional unit, the farm with the lowest score was LI, with about 300 mPt per 1 kg of FPCM (approximately 36% and 27% less than MI and HI, respectively). When using 1 ha of UAA as functional unit, LI showed again the lowest value, with about 72 Pt per ha of UAA, which represents 14% and 10% of MI and HI impacts, respectively. It's interesting to note that the utilization of two FU led to different ranking of the three dairy farms and to a different weight of the impact categories on the life cycle assessment. Moreover, the use of 1 ha of UAA as FU determined a range of environmental impacts much higher than those assessed for 1 kg of FPCM. Agricultural land occupation was the impact category that showed the main contribution to the total environmental impact. The contribution analysis of the Agricultural Land Occupation impact category allowed to complete the description of the farming systems and to better understand the differences among the three farms in terms of input levels. The extensive land use represented more than 60% of the Agricultural Land Occupation in the LI, compared to 41% and 17% in MI and HI, respectively. On the other hand, the intensive land use was near 60% of Agricultural Land Occupation in HI, and around 35% for both MI and LI. In the latter case, the unexpected large percentage of intensive land occupation can be explained by the very limited arable land destined to forage production for sheep feeding. However, the contribution of the occupation of arable land on the total Agricultural Land Occupation was larger than 20% in MI and HI, and equal to about 1% in LI farm. Agricultural land occupation and, more generally, land use impact category are critical aspects of LCA analysis, in particular when the agricultural sector is investigated (Schmidinger and Stehfest, 2012). In this case, the impact category "land use", currently included in the most widely used LCA methods (like ReCiPe), quantifies mainly the potential impacts of land use on biodiversity, excluding other relevant land use impact categories, such as depletion of productive land area and changes in soil quality (Mattila, 2012).

3.1.3. Blue Virtual Water

Mid input farm (MI) was the only one that applied irrigation for crop production. The use of water for irrigation in MI determined, for both FU, a large Blue Virtual Water consumption compared to the other farms. The results of the Blue Virtual Water impact assessment method for 1 kg of FPCM indicate that the Water Footprint of MI was approximately 3.5 to 10 times larger than the Water Footprint observed in HI and LI, respectively (bottom plots of Figure 1). When the Water Footprint was calculated using 1 ha of UAA as functional unit, MI showed an impact value that is more than twice the HI value and about 46 times larger than the LI. In addition, the direct water consumption of MI for producing the annual total amount of FPCM was approximately 3,600 m^3, with about 65% being consumed for irrigation. The direct water consumption of HI amounted to 1,279 m^3, with an indirect consumption equal to 448 m^3. Conversely, the Blue Virtual Water consumption for LI derived mainly from indirect consumption, which represented, with 122 m^3, the 82% of the total consumption.

3.2. Contribution analysis

A detailed contribution analysis is reported in Table 2, which illustrates all processes that contributed with more than 1% to the total environmental impact of all farms for the three different evaluation methods adopted, using 1 kg of FPCM as functional unit. Similar results were also obtained for the functional unit 1 ha of UAA. In general, the analysis of the contributions of individual processes for the three farming systems showed a relevant role of enteric methane emissions, field operations (mainly tillage), electricity and production of agricultural machineries. In MI and HI, feed concentrates in the diet (in particular soy production) showed a relevant contribution, with percentages ranging from 16% for HI (IPCC method) to 30% for MI (ReCiPe method). The natural and improved pasture utilization resulted in relevant contribution only for the ReCiPe assessment method (31% in LI, 40% in MI and 34% in HI), essentially for the effect of the Agricultural Land Occupation impact category. The contribution of agrochemicals was generally low (always less than 3%), due to their very limited use in all the three farms. However, the incidence of contribution of each process varied with the evaluation method utilized. For example, the enteric methane emission is the most important impact (an overall average of 42% of total impacts) for the IPCC method, but when the estimate is performed using the ReCiPe method, the impact of the enteric methane emissions amounted on average to 11%, representing only the fifth highest-ranked impact. The complementary use of the three methods offered a multiple analysis perspective, resulting in a more comprehensive assessment of impacts. From a methodological point of view, there are many similarities between the different footprints, but each has its own peculiarities related to the uniqueness of the substances considered.

The analysis of contributions has been also useful for identifying more specific strengths and weaknesses of each dairy sheep farming system, in order to improve their environmental performances.

Enteric methane emissions represented the most important environmental impact factor for all the farms when IPCC method is used. This result is consistent with the actual knowledge about the role played by the enteric methane fermentation in ruminant livestock emissions, which are estimated to represent approximately 18% of the global anthropogenic GHG emissions (FAO, 2006). Few practical strategies can be followed for reducing enteric methane emissions of grazing animals (Hegarty et al., 2007), mainly by regulating the quantity and quality of feed consumed (Pelchen and Peters, 1998) or utilizing inhibitors of enteric fermentation (Martin et al., 2010; Nolan et al., 2010; Puchala et al., 2005; Tiemann et al., 2008; Wallace et al., 2006). However, further research studies are needed to carefully analyse the complexity of relations among breeding techniques and enteric gas emissions (e.g., methane and nitrous oxide).

Beside the crucial role of enteric methane emissions, the major contributions to the environmental impact of LI are due to land use on natural and improved pastures (i.e., field operations, ranging from 21% to 34%, for ReCiPe and Blue Virtual Water, respectively), electricity (from 8% to 16%, for ReCiPe and Blue Virtual Water, respectively), and agricultural vehicle's equipment (from 8% to 10%, again for ReCiPe and Blue Virtual Water, respectively). The power consumption of LI depended mainly on milk cooling and therefore an improvement of the environmental performance of this farm could be achieved choosing the proper size of the cooling tank and/or adopting a more efficient cooling system, possibly powered by renewable sources. In addition, LI showed a relevant contribution to the overall impact determined by tractor and other devices, such as pick-up and generator diesel (10%, 8%, and 26% for IPCC, ReCiPe and Blue Virtual Water methods, respectively). This contribution is at least double compared to the contribution observed in the other farms and it can be likely due to the use of over-dimensional and power-consuming equipment compared to the farm needs.

The contribution of field operations (tillage and sowing) to the total environmental impact of the productive cycle of 1 kg of FPCM was largely lower in MI (with values never exceeding 8%) than in the other farms, for all the adopted methods. This result could be probably due to the minimum tillage practice used by MI for sowing of pasture mixtures. However, the environmental performances of MI could be improved by reducing the purchase of feed concentrates and consequently increasing the amount of pasture and self-produced hay in the diet of flock. To achieve this result, an increase of the total surface sown with well adapted and high quality pasture mixtures may be suggested (Franca et al., 2008; Porqueddu and Maltoni, 2005). The overall high consumption of electricity suggests to introduce a farm strategy based on renewable source power supply. Finally, it may be appropriate to assess a proper sizing of the machinery stock, in relation to the needs of MI.

The contribution of concentrate feed was particularly large in MI, despite lower total annual consumption compared to HI (0.38 t ewe^{-1} versus 0.55 t ewe^{-1}). It's important to note that HI produced about 24% of its concentrate needs on-farm and had a larger annual milk yield per ewe compared to MI, which imported all concentrate. In HI, the improved pastures and annual forage crops represented the most relevant contribution to the overall environmental impact. Taking this result into account, a possible strategy to reduce the Carbon and Ecological Footprint of HI could consist in increasing the agricultural surface area utilized for permanent semi-natural pastures and finding proper pasture management strategies (i.e., deferred grazing during spring to allow self-reseeding). Moreover, improving power supply strategy could represent an effective way to enhance the HI environmental performance, as well as for the other farms.

Table 2. Percentage contribution of processes to the total environmental impact of low- (LI), mid- (MI) and high-input level (HI) farms, using three evaluation methods (ICPP, ReCiPe, and Blue Virtual Water) and 1 kg of FPCM as functional unit. The process category "Remaining processes" includes all the processes with a percentage contribution lower than 1% for all methods and farms.

	IPCC			**ReCiPe**			**Blue Virtual Water**

3.3. Monte Carlo analysis

Uncertainty results from the Monte Carlo simulations showed different implications depending on the functional unit and the evaluation method used (Table 3). Blue Virtual Water method showed significant differences between the three production system case studies, due to the large differences in water consumption (LI and HI water consumption were respectively 4% and 43% than MI) with relatively low uncertainty intervals (16%, 14%

and 4-5% for LI, MI and HI, respectively). No significant differences were found between the environmental performances of the three farms when using 1 kg of FPCM as functional unit and IPCC and ReCiPe evaluation methods. For both methods the uncertainty interval did not exceed 16% and the probability of a farm to have an Ecological or Carbon Footprint greater than or equal to the footprint of another farm did not exceed 22%, on average. As expected and regardless of the method used, the Monte Carlo analysis confirmed that the differences between the environmental impacts of the three farms calculated using 1 ha of UAA as functional unit were significant.

Table 3. Monte Carlo simulation output for each assessment method, functional unit and farm with low- (LI), mid- (MI), and high-input (HI) levels. Average values and uncertainty intervals for P≤0,05 (between brackets) are reported.

Farm /FU/ Method	LI		MI		HI	
	1 kg FPCM	1 ha UAA	1 kg FPCM	1 ha UAA	1 kg FPCM	1 ha UAA
IPCC (kg CO_2-eq)	2.0 ± 10%	474 ± 11%	2.3 ± 13%	2,502 ± 13%	2.2 ± 13%	4,023 ± 0%
ReCiPe (Pt)	0.3 ± 13%	72 ± 13%	0.5 ±16%	530 ± 16%	0.4 ± 15%	779 ± 15%
Blue Virtual Water (l-eq)	5.9 ± 16%	1,368 ± 16%	56.8 ±14%	62,766 ± 14 %	16.1 ± 4%	29,424 ± 5%

4. Conclusion

In this work, LCA approach was used for comparing dairy sheep production systems and for identifying the hotspots to improve their environmental performances. The LCA conducted with two different functional units (1 kg of Fat Protein Corrected Milk and 1 ha of Utilized Agricultural Area) and three different assessment methods (IPCC, ReCiPe, and Blue Virtual Water) led to a more objective evaluation of the environmental performances of three case studies, taking into account both the economic dimension and the environmental role of dairy farming systems.

The environmental performances of the studied farming systems were similar when using 1 kg of FPCM as functional unit, regardless of the assessment method used. On the other hand, the environmental impacts were significantly different when the assessment was based on the functional unit 1 ha of UAA. Moreover, the contribution of each process to the environmental performances of dairy sheep systems depended largely on the method used for the evaluation. However, this study shows the relevant role played by enteric methane emissions, tillage, electricity and machineries in the overall environmental performances. Feed concentrates in the diet (in particular soy production) showed a relevant contribution in MI and HI. The natural and improved pastures utilization resulted in relevant contribution only for the ReCiPe assessment method. The contribution of agrochemicals was generally low, due to their very limited use in all the farms.

Certainly, LCA represents a valid approach for developing an eco-design strategy at farm level aimed to exploit the multifunctionality of extensive Mediterranean livestock systems. Further studies and knowledge are needed to overtake the limits of the LCA methodology when applied to agriculture sector. In particular, a certain degree of weakness derives from the lack of both site-specific datasets on Mediterranean farming systems and appropriate methods to assess comprehensively the “land use” impact category.

Acknowledgements

This study was conducted under the Project CISIA “Integrated knowledge for sustainability and innovation of Italian agri-food sector”, coordinated by the Department of Biology, Agriculture and Food Science of the National Research Council (CNR-DISBA) and partially funded by MEF - Ministry of Economy and Finance of Italy. The authors wish to acknowledge Mr. Daniele Nieddu for the technical help.

Construction cost of plant compounds provides a physical relationship for co-product allocation in life cycle assessment

ABSTRACT

Although, according to the ISO 14044 standard, economic allocation should be the solution of last resort, it is frequently used in LCA studies of agri-food systems because of the inadequacy of solutions preferred by ISO. We calculated allocation factors for a range of plant co-products used as feed ingredients according to three methods: energy allocation (En), economic allocation (Ec) and allocation based on plant physiological construction cost of plant compounds (Cc). Compared to En and Ec, Cc yields higher allocation factors for protein-rich co-products and lower factors for lipids. Whereas the difference between En and Cc is modest (up to 5 percentage points), the difference between Ec and Cc is more variable and can be large (up to 18 percentage points). For plant co-products, Cc is an attractive option, as it is based on the physiological mechanisms involved in plant growth rather than on a common property of the co-products.

Keywords: economic allocation, energy allocation, plant co-products, (biophysical mechanism)

1. Introduction

For a long time, the topic of allocation has been the subject of methodological debate in Life Cycle Assessment (LCA) studies. The International Organisation for Standardisation (ISO) 14044 standard (ISO 2006) for LCA defines allocation as "partitioning the input or output flows of a process or a product system between the product system under study and one or more other product systems". Allocation is about attributing the relative shares of responsibility for environmental impacts to several co-products (Suh et al. 2010; Pelletier and Tyedmers 2011).

The ISO 14044 standard defines the following procedure for allocation:

1. Wherever possible, allocation should be avoided by
   a) dividing the unit process to be allocated into two or more sub-processes and collecting the input and output data related to these sub-processes, or
   b) expanding the product system to include the additional functions related to the co-products.
2. Where allocation cannot be avoided, the inputs and outputs of the system should be partitioned between its different products or functions in a way that reflects the underlying physical relationships between them.
3. Where physical relationship alone cannot be established or used as the basis for allocation, the inputs should be allocated between the products and functions in a way that reflects other relationships between them. For example, input and output data might be allocated between co-products in proportion to the economic value of the products (ISO 2006).

Agri-food systems contain many multiple output processes, e.g. the transformation of soybeans yielding meal and oil, or the production of milk, calves and cull cows by a herd of dairy cows. How to best allocate impacts to co-products has been the subject of much debate (Suh et al. 2010; Ardente and Cellura 2011; Pelletier and Tyedmers, 2011). Although, according to ISO guidelines, economic allocation should be the solution of last resort, it is frequently used in LCA studies of agri-food systems because of the inadequacy of the solutions that should be preferred according to the ISO decision hierarchy.

Avoiding allocation by dividing the unit process often is not possible, as for instance in the case of the transformation of soybeans in meal and oil. Avoiding allocation by expanding the system is feasible for those co-products that can be produced by other processes. However, for agricultural products this approach is often problematic. For instance, in the case of a dairy herd producing milk, cull cows and calves, we may want to identify a process that yields a product similar to cull cows, i.e. animals that can be transformed into beef. One can identify a suckler cow herd as an alternative producer of animals that can yield beef. However, on close examination this is not satisfactory, as beef from a suckler system is of a different (better) quality than beef from culled dairy cows. Finding an alternative production process for cow milk is even more difficult. One might turn to processes producing goat milk or soy "milk", but these are obviously very different products. As a consequence, as system expansion applied to LCAs of agricultural products often fails to identify alternative processes producing the same products; it generally resorts to choosing alternative processes yielding products used for the same purpose, i.e. insuring functional equivalence. LCA studies will for instance consider that suckler cow beef can be considered equivalent to dairy cow beef (Nguyen et al. 2013), or that pork is equivalent to beef (Thomassen et al. 2008a). Considering that low and high quality beef are equivalent, or that pork is equivalent to beef may, for a variety of reasons, not only seem quite far-fetched to most people, it also introduces major arbitrariness and additional uncertainty in the LCA study. Last but not least, the system expansion approach causes the LCA model to get larger and more complicated, requiring the collection of more data (Curran 2013).

When allocation can not be avoided either by dividing the unit process or by expanding the product system, then the next best option, according to ISO 14044, is to allocate the inputs and outputs between the products in a way that reflects the underlying physical relationships between the products. In their eloquent but in parts hard-to-understand paper “An ecological economic critique of the use of market information in life cycle assessment research” Pelletier and Tyedmers (2011) critique the use of economic allocation and plead for the use of physical or biophysical properties of products in allocation. They admit however that biophysical allocation is harder to justify when it is necessary to allocate burdens between co-products with divergent functions, for example when soy processing co-products are used as meal for animal nutrition and as oil for biodiesel. In such a case, finding a common physical or biophysical property adequate for both functions is difficult. Furthermore, even when one can find such a property, one may wonder to what extent the identification of a common physical or chemical property of the co-products can be equated to the existence of an underlying physical relationship between the co-products as mentioned in the ISO 14044 standard. Although this seems to have been accepted as a common interpretation of the ISO standard in many published papers on the subject, it remains quite a puzzling assumption to the authors of this paper.

So, since both avoiding allocation as well as allocating according to a physical relationship rarely seem to work satisfactorily for agri-food multi-output systems, it should not come as a surprise that many LCA studies of such systems end up allocating inputs and outputs to co-products in proportion to their economic value (Ardente and Cellura 2011; Brankatschk and Finkbeiner 2014). For many authors, economic allocation is attractive as it is the value created that causes the process. However, economic allocation is not without difficulties. It is based on the one hand on the relative masses of the co-products produced and on the other hand on the relative economic values of these co-products. While the former are generally quite stable, the latter tend to fluctuate with time and place in response to changes in supply, demand, regulation, subsidies, culture (Pelletier and Tyedmers 2011) and technological developments. As a result allocation factors will fluctuate, affecting the credibility of the results of the LCA. This problem can be reduced by averaging product prices over several years which will smooth short-term variations

In this paper we want to contribute to this debate. We first present an inventory of the use of methods to attribute impacts to plant co-products used as animal feed in recent LCA studies to quantify the relative importance of these methods as they are actually used in studies published in peer-reviewed publications. Secondly we propose a new way of allocating impacts to plant co-products according to the underlying physical relationships between the co-products. We compare this method to two current allocation methods.

2. Methods

2.1. Attribution of impacts to plant co-product in LCA studies

We found 24 LCA studies from peer-reviewed scientific journals and scientific reports for the 2000-2013 period that attributed impacts to plant co-products used as animal feed. These studies used either system expansion or allocation according to co-product mass, energy content, nitrogen content or economic value, or several of these methods. This allowed us to establish the relative share of co-product handling methods used in “real life”, so to say.

2.2. Comparison of three allocation methods

This case study focused on plant co-products used as ingredients for animal feed. We compared three methods for the allocation of impacts to plant co-products: energy allocation, economic allocation and the new allocation method (presented in this paper) according to the construction cost of plant compounds.

Energy allocation is often used to allocate impacts when one or more of the co-products are used as biofuels (ADEME 2010). Energy allocation is generally based on the lower heating value (LHV) of the co-products. For some plant co-products not associated with biofuel production (e.g. wheat middlings) LHV data are not available in the literature. Furthermore, in many biofuel studies, LHV values used for the various co-products are taken from several literature sources, introducing methodological heterogeneity for these data. In order to obtain a coherent set of LHV values for the co-products we studied we estimated their LHV values from their gross energy values taken according to INRA (2004; 2007). Gross energy is defined as the heat produced during the complete combustion of an organic component in a calorimeter in the presence of oxygen (INRA 2007). Given this definition, a gross energy value therefore corresponds to a higher heating value (HHV). It has been observed that the LHV of co-products used as animal feed is 6 to 7% lower that their HHV (Hofstrand 2008). We assumed a 6% difference to estimate LHV from gross energy values, as we thus obtained LHV values that were closest to those found in literature sources.

For economic allocation we used average annual prices for the 2005-2009 period. These were world market prices for oils and meals from soybean, rapeseed, sunflower, linseed, oil palm, and for corn oil (ISTA 2009; 2011); for wheat and maize co-products other than corn oil these were prices for the United States of America (USDA 2012), for sugar beet co-products these were prices for France (AGRI C5 2013; I. Bouvarel pers. Comm. 2013). These prices were used to calculate so-called “Olympic averages” i.e. for each co-product we took the five annual average values for the 2005-2009 period, eliminated the highest and lowest values, and averaged the values for the remaining three years.

We propose a new allocation method for plant co-products based on physiological mechanisms involved in plant growth rather than on physical or chemical characteristics of the co-products. Plant biomass results from photosynthesis. Plants convert glucose, the prime product of photosynthesis, into other plant compounds such as carbohydrates, proteins, lipids, lignin and organic acids. These groups of compounds differ in their construction costs, i.e. g of glucose/g of compound (Poorter, 1994). Plant co-products (e.g. soybean meal and soybean oil) differ in their contents of these compounds and consequently have different construction costs. We propose biomass construction cost as a characteristic for physical allocation.

Construction cost was estimated according to Poorter (1994) using the following equation:

$$CC = (-1.041 + 5.077 * C_{om}) * (1\text{-}M) + (5.325 * Norg)$$

Where:
CC: the total cost to produce one gram of plant biomass (g glucose/g dry weight)
C_{om}: the carbon content of the biomass (g/g dry matter)
M: the mineral content of the biomass (g/g dry matter)
N_{org}: the organic nitrogen content of the biomass (g/g dry matter)

The carbon content of the biomass was estimated according to Vertregt and Penning de Vries (1987) using the following equation (ignoring organic anions):

$$C_{om} = 0{,}444 * \text{carbohydrates} + 0{,}535 * \text{protein} + 0{,}774 * \text{lipids} + 0{,}667 * \text{lignin}$$

All components as well as C_{om} are expressed as g/g dry matter (DM). Carbohydrate, protein, lipids, lignin and mineral contents of co-products were taken from INRA (2004; 2007), from the Feedipedia (2013) website and from ANSES (2013).

The calculation of allocation coefficients for the three methods requires extraction rates (the proportion of the processed product obtained from the parent product). Extraction rates for soybean, rapeseed and sugar beet were from Jungbluth et al. (2007), for sunflower from FAO (2002), for linseed from unpublished INRA data, for oil palm from Schmidt (2007), for wheat and maize from Würdinger et al. (2002).

3. Results

3.1. Attribution of impacts to plant co-product in LCA studies

In the studies surveyed, economic allocation was used in 19 out of 24 cases (Table 1). Energy allocation was used in three studies, system expansion and mass allocation were used in two studies, while nitrogen content was used in one study. This illustrates the popularity of economic allocation among scientists dealing with LCAs involving plant co-products, in spite of ISO 14044 recommending economic allocation as a last resort.

Table 1. The use of methods to attribute impacts to co-products used as animal feed in LCA studies published in peer-reviewed journals in the 2000 – 2013 period.

3.2. Lower heating value, average price and construction cost for the co-products

The lower heating values (in MJ/kg DM) that we calculated from gross energy values were 36.9 for oils and fat, for oilseed meals they ranged from 18.1 for rapeseed meal to 18.5 for soybean meal; for the other co-products they ranged from 14.5 for beet molasses to 18.9 for palm kernel (Table 2). Prices for oils (in $/t gross product) ranged from 626 for palm oil to 1028 for linseed oil; for oilseed meals they ranged from 178 for sunflower meal to 321 for soybean meal; for the other co-products they ranged from 69 for corn gluten feed to 585 (Euros) for beet sugar. Construction costs (in glucose/kg DM) were 2.89 for oils and fat, for oilseed meals they ranged from 1.54 for sunflower meal to 1.67 for soybean meal; for the other co-products they ranged from 0.99 for beet molasses to 2.20 for palm kernel.

Table 2. Lower Heating Value (LHV), Olympic average price for 2005-2009 and construction cost of plant co-products used for animal feed

Co-product	LHV (MJ/kg DM[1])	Price 05-09 ($/t gross product[2])	Construction cost (kg glucose/kg DM)
Soybean oil	36.9	694	2.89
Soybean meal	18.5	321	1.67
Ratio oil/meal	1.99	2.16	1.73
Rapeseed oil	36.9	874	2.89
Rapeseed meal	18.1	184	1.59
Ratio oil/meal	2.04	4.75	1.82
Sunflower oil	36.9	851	2.89
Sunflower meal	18.2	178	1.54
Ratio oil/meal	2.03	4.78	1.88
Linseed oil	36.9	1028	2.89
Linseed meal	18.2	293	1.58
Ratio oil/meal	2.03	3.51	1.83
Refined palm oil	36.9	626	2.89
Palm kernel	18.9	-	2.20
Fodder fat	36.9	-	2.89
Wheat flour	15.4	313	1.42
Wheat bran	17.8	82	1.34
Wheat middlings	17.9	82	1.39
Feed grade wheat flour	17.8	82	1.40
Maize starch	16.5	319	1.22
Corn gluten feed	17.6	69	1.32
Corn oil	36.9	760	2.89
Corn gluten meal	21.7	370	2.07
Beet sugar	15.7	585[3]	1.21
Pressed sugar beet pulp	16.0	134[3]	1.13
Beet molasses	14.5	160[3]	0.99

[1] Dry Matter
[2] Product at its reference humidity content
[3]€/t gross product

For LHV oil/meal ratios for the four oilseeds (soybean, rapeseed, sunflower and linseed) varied little and ranged from 1.99 for soybean to 2.04 for sunflower (Table 2). For prices the ratio varied widely, ranging from 2.16 for soybean to 4.78 for sunflower. For construction cost the ratio varied moderately, ranging from 1.73 for soybean to 1.88 for sunflower. For soybean oil/meal ratios varied least across the three methods (1.73 to 2.16), whereas for the other three oilseeds these ratios varied much more across methods: rapeseed: 1.82 to 4.75, sunflower 1.88 to 4.78 and linseed 1.83 to 3.51.

Construction cost was strongly correlated with LHV, price was correlated with both LHV and construction cost, but the correlation was weaker (Table 3).

Table 3. Correlation coefficient (r) between lower heating value (LHV), Olympic average price for 2005-2009 and construction cost of plant co-products used for animal feed

	LHV	Price 05-09	Construction cost
LHV	1.0	0.697	0.987
Price 05-09		1.0	0.722
Construction cost			1.0

Table 4. Allocation factors according to energy content, economic value and construction cost for plant co-products used for animal feed

Raw material	Energy content	Economic value	Construction cost
Soybean oil	35.3	34.2	32.1
Soybean meal	64.7	65.8	67.9
Rapeseed oil	60.0	75.6	57.3
Rapeseed meal	40.0	24.4	42.7
Sunflower oil	63.0	78.1	61.2
Sunflower meal	37.0	21.9	38.8
Linseed oil	46.9	57.5	44.3
Linseed meal	53.1	42.5	55.7
Refined palm oil	85.0	81.8	80.5
Palm kernel	11.5	15.0	16.1
Fodder fat	3.6	3.2	3.4
Wheat flour	76.7	93.6	79.8
Wheat bran	13.6	3.8	11.6
Wheat middlings	4.0	1.1	3.5
Feed grade wheat flour	5.7	1.6	5.1
Maize starch	62.5	79.2	61.0
Corn gluten feed	24.9	6.4	24.6
Corn oil	6.4	7.5	6.5
Corn gluten meal	6.3	6.9	7.9
Beet sugar	67.3	72.8	69.4
Pressed sugar beet pulp	22.8	23.0	21.6
Beet molasses	9.9	4.2	9.0

3.3. Allocation factors for the co-products

For soybean, energy (En) and economic (Ec) allocation factors were close (Table 4). For the other oilseeds Ec allocation had higher factors for oil than En allocation, but for oil palm Ec allocation had a lower factor for oil than En allocation. For co-products from wheat, maize and sugar beet Ec allocation had higher factors for the main product (flour, starch and sugar, respectively) than En allocation.

Relative to En allocation, construction cost (Cc) allocation had a lower factor for oil for the four oilseeds as well as for oil palm. For wheat co-products, Cc had a higher allocation factor for flour and a lower allocation factor for bran than En. For maize and sugar beet co-products En and Cc allocation factors were quite close.

4. Discussion

The survey on the application of the different approaches for the attribution of impacts to plant co-products yielded quite sobering results, as it revealed a large gap between the normative propositions on co-product handling in the ISO guidelines and the actual practice by scientists publishing LCA studies. Clearly neither avoiding allocation nor allocation according to a physical relationship proved satisfactory for plant co-products to most LCA practitioners. There may therefore be interest among LCA scientists for a new approach to allocation of plant products.

Allocation according to the underlying physical relationships between the co-products, as recommended in the ISO 14044 standard, is generally done by identifying a common physical chemical property of the co-products such as mass or energy content (Pelletier and Tyedmers 2011). However, the identification of a common property such as mass or energy content does not really establish or reflect a common relationship between co-products. Any two products in the world have a mass and an energy content, but this does not mean they are related. The relationship between co-products is their common origin, so a physical allocation method should not be based on the physical properties of the co-products, but rather on the mechanism reflecting their common origin, as this is the basis of their relationship.

The new method proposed in this paper corresponds in our view to a more appropriate interpretation of the ISO 14044 standard, as it is not based simply on a physical property of the co-products, but on their construction cost, i.e. the common plant physiological mechanism at the origin of the different compounds that make up plant biomass. Although construction cost is strongly correlated with LHV, it is not identical. Whereas for LHV oil/meal ratios for the four oilseeds analyzed in this paper are around 2, these ratios vary between 1.73 and 1.88 for construction cost. As a result, relative to allocation factors based on energy content, allocation factors based on construction costs are higher for meals than for oils

5. Conclusion

Although, according to the ISO 14044 standard, economic allocation should be the solution of last resort, it is frequently used in LCA studies of agri-food systems because of the inadequacy of solutions preferred by ISO. Allocation according to the underlying physical relationships between the co-products is generally done by identifying a common physical chemical property of the co-products, but this does not really reflect a relationship between the co-products. We propose construction cost of plant compounds making up the co-products as an allocation criterion which is truly based on a relationship between the co-products.

ABSTRACT

Our study quantifies the historical Dutch diet of 80 years ago, based on a cultural history research. We calculate the greenhouse gas emissions (GHGE) and land use (LU) of this diet, using actual LCA data for 206 most consumed products, and the health score, based on ten nutritional characteristics. In order to meet the current requirements, we optimize this diet for adult males using linear programming. We compare the diet with the present Dutch, Mediterranean and New Nordic Diet. An optimized Low Lands Diet has the same healthy nutritional characteristics as the Mediterranean and the New Nordic Diet, and results in a lower environmental impact. The diet consists mainly of products with a high nutrient density. An adaptation of this historical diet, which fits more into the eating habits, climate and agricultural tradition of the Low Lands, is assumed easier to achieve than a transition into a foreign European diet.

Keywords: Greenhouse gas emissions, historical Dutch diet, New Nordic Diet, linear programming, health impact

1. Introduction

The present Dutch diet is not in line with the dietary guidelines (Health Council 2006; WHO 2003). Regarding the health impact, the diet has an unfavorable fatty acid composition, which increases the risk of cardiovascular diseases. Besides, only 5% of the Dutch population adheres to the recommended fatty acid composition through fish consumption. Insufficient consumption of fruit and vegetables increases the risk of coronary heart diseases, stroke and some forms of cancer (lung, breast and stomach cancer) (Van Kreijl et al. 2006). The increased intake of energy-dense foods that are high in fat has resulted in a worldwide doubling of obesity since 1980. In The Netherlands 30% in the population aged 4 years and older are moderately overweight. Another 10% has severe overweight (obesity) (CBS, 2012). Overweight and obesity are major risk factors for a number of chronic diseases, including diabetes, cardiovascular diseases, and cancer. The unfavorable dietary composition contributes approximately twice as much to the total mortality as overweight: 10% versus 5% of the annual deaths in the Netherlands (Van Kreijl et al. 2006).

Current trends in food production and consumption are considered unsustainable. For example, approximately one-third of human influence on greenhouse gas emissions (GHGE) and land use (LU) is related to our diet and the food chain (Vringer et al. 2010). The average Dutch diet is less sustainable, in terms of GHGE and LU, than eating according to the Dutch dietary guidelines. Further improvements are within reach, we conclude in a recent paper (Van Dooren et al. 2014a).

To reach these improvements, policy makers are exploring the possibilities to develop guidelines for healthy diets that are also low in environmental impacts (Health Council 2011). These guidelines are still qualitative and quite general. The aim of this paper is to define more in detail a nutritionally healthy, environmentally friendly and culturally acceptable diet for the Low Lands. In theory it is possible to define an optimal diet, according to criteria both for health and environmental impact (Van Dooren et al. 2014b). However such optimized diet may have difficulties being broadly accepted by consumers. Therefore, we seek dietary solutions that fit into the historical and cultural context, and climate of the Netherlands and Flanders, called the Low Lands Diet[1]. We build on the experience gained by scientists who recently explored and defined the Mediterranean diet (MD) (Bach-Faig et al. 2011; Fidanza and Alberti 2005), and the 'New Nordic Diet' (NND) (Bere and Brug 2009; Bere and Brug 2010; Hahnemann 2010; Mithril et al. 2013; Mithril et al. 2012; Uusitupa et al. 2013). Our hypothesis is that through clever combinations we can define an optimal diet for the Low Lands of Europe, comparable to the MD and NND.

[1] *Low Lands refer to the Rhine-Meuse delta, mainly characterized by fertile flat land at North Sea level, a temperate climate, and a sober, tolerant, former Calvinist, Dutch speaking culture.*

2. Methods: approach

In order to substantiate our hypothesis and reach our aim, we first describe our method to quantify the nutritional health (section 2.1) and environmental impact of different diets (2.2). To calculate the environmental impact, we need the GHGE and LU data of food products. Reliable data are sourced; using actual Life Cycle Assessments for 206 most consumed Dutch products (2.3). We apply this calculation methods to diets found in literature (2.4).

2.1. Calculating the Health Score

The health benefits and impacts of diets are highly complex and under continual debate and not easy to quantify. Insight in and impact of different indicators are relative and change overtime. Fortunately, different health organizations such as WHO (2003), World Cancer Research Fund, RIVM, and the Dutch Health Council (2006) have been using more or less the same indicators. The existing concept of the US Healthy Eating Index (Kennedy et al. 1995) to quantify overall diet quality is useful, but not directly applicable to Europe due to differences in cultural habits (serving sizes) and nutritional guidelines. Therefore, we developed a related score relevant to the European context. This Health Score is described elsewhere (Van Dooren et al. 2014a). The Dutch Health Council (2006) has translated and quantified the ten indicators towards a recommended intake in the Dutch population. These indicators reflect preventive factors for different food-related diseases, such as obesity, heart disease and cancer. We calculate the scores of diets, based on the ten indicators, with the following formula: Eq.1.

Health Score = (g vegetables/200g + g fruits/200g + g fiber/30g + g fish/37g + 30 en%/en% total fat + 10 en%/en% saturated fat + 1 en%/en% trans-fat + 10 en%/en% free sugars + 6 g/g salt + 2500 kcal/kcal energy)/10 **Eq. 1** (Van Dooren et al. 2014a)

2.2. Calculating the Sustainability Score

In 2010 the FAO agreed upon a definition for sustainable diets (FAO 2010): *Sustainable Diets are those diets with low environmental impacts which contribute to food and nutrition security and to healthy life for present and future generations.* 'Low environmental impacts' –as part of the definition of sustainable diets- need to be quantified using different parameters. Energy use and GHGE can be considered good proxies for this total environmental impact (Dutilh and Kramer 2000). LU and land use change are good proxies for loss of biodiversity (Pereira et al. 2010). In the score, we therefore used LU and GHGE as indicators to quantify -in relative terms- the environmental impact of the diets, because together they cover at least the top 4 of the impacts identified by Rockström et al. (2009). Our Sustainability Score is defined in an earlier study (Van Dooren et al. 2014a). We used the 2020 European Commission goal of a 20% GHGE reduction in the food chain (compared to 1990) as a reference value, although it is a political, arbitrary choice. The GHGE of the Dutch diet in the 1990s was 4.09 kg CO_2eq/day; the 2020 goal is 20% lower or 3.27 kg CO_2eq/day. This level was allocated a score of 100.

For LU we have no single reference value. The present LU in the Netherlands, according to the WWF (2012), is 3.20 global hectares. Publications about the ecological footprint (WWF 2012) suggest that the worldwide available biocapacity calculated in LU is 1.78 global hectares, which is 44% below the present use. We used as a reference a 44% reduction in the food chain applied for LU. From 5.34 m^2*year/day (the LU of the 1990s Dutch diet) to 2.97 m^2*year/day is a 44% reduction. This value was indicated as 100. The Sustainability Score was defined as the average of the GHG and LU score per diet. The score was calculated with the following formula: Eq.2.

Sustainability Score = (3.27 kg/ kg CO_2eq GHG + 2.97 m^2*year/ m^2*year LU)*100 /2
Eq. 2 (Van Dooren et al. 2014a)

2.3. Life Cycle Assessment of food products

Our calculation of GHGE and LU for the most consumed products in the diets is based on Life Cycle Assessment (BSI 2008; JRC 2010). The LCA methodology for agricultural products we use is described in 'The Agri-footprint method; Methodological LCA framework, assumptions and applied data, Version 1.0' (Blonk et al. 2011). The life cycle boundary is from raw materials acquisition and natural resources to final disposal, including food waste, and some estimate of energy use for cooking and preparation at home. In LCAs of agricultural products, the main contributors to the end score are GHGE, LU, and fossil energy use (Sevenster et al. 2010). Two of these are covered. In the scope of this study, it was not possible to carry out an extensive assessment to determine standard deviations for the parameters. LCA experts assume a general uncertainty of 10% to 20% in the results (Blonk et al. 2011).

2.4. Literature research

Using literature research, we define European examples of diets which are mentioned as both nutritionally healthy and low in environmental impact. We focus on recent publications exploring the Mediterranean and New Nordic Diets. In order to compare these diets with the Low Lands Diet, we quantify also the historical Dutch diet of about 80 years ago (1900-1940), based on a cultural history research (Jobse-Van Putten 1995; Van Otterloo 1990).

3. Results

3.1. Defining the Mediterranean Diet (MD)

The MD has been the subject of many studies (Trichopoulou et al. 2005) and we have previously studied this diet (Van Dooren et al. 2014a). The MD is characterized by a high intake of vegetables, pulses, fruits, and cereals (in the past largely unrefined); a moderate to high intake of fish; a low intake of saturated lipids but high intake of unsaturated lipids, particularly olive oil; a low to moderate intake of dairy products, mostly cheese and yogurt; a low intake of meat; and a modest intake of alcohol, mostly as wine (Willett et al. 1995). The best quantitatively defined description of this historical diet is probably published by (Fidanza and Alberti 2005).

Harvard Medical School further translated the dietary pattern into a more Western, culturally acceptable, diet with concrete recommendations (Willett 2001) and Willett published together with Oldways in 2009 the Mediterranean Diet Pyramid (www.oldwayspt.org). A consensus meeting recently updated the Mediterranean diet pyramid (Bach-Faig et al. 2011). Buchner et al. (2010) published the Double Pyramid and compared the ecological footprint of foods with their health-related position in the pyramid. They concluded that foods that are recommended for health reasons generally have lower environmental impacts as well. In contrast, foods with lower recommendations are those with a higher environmental impact. In an earlier climate diet study the Willett diet was also evaluated (Stehfest et al. 2009). In Table 1 we compare three ways to quantify the MD. The last column has been used for this study.

Table 1. Quantification of the Mediterranean Diet.

(Fidanza and Alberti 2005) *(% of energy)*	**(Bach-Faig et al. 2011)** *(servings (s))*	**(Van Dooren et al. 2014a)** *(grams per day)*
cereals (48%–52% of energy)	1-2 s pref. wholegrain every meal	210 g wholegrain bread
		100 g grain products (pasta)
extra virgin olive oil (14.5%–16.6%)	olive oil every meal	45 g vegetable oils
vegetables (5%–7%)	>= 2 s every meal	300 g mainly fresh vegetables
	potatoes <= 3s weekly	25 g potatoes
pulses (4.4%–6.6%)	>= 2 s weekly	75 g pulses
fruit (2.0%–2.6%)	1-2 s every meal	250 g fruits
fish (1.6%–2.0%)	>= 2 s fish/seafood weekly	2 times a week*
red wine (4.2%–6.0%)	wine in moderation	150 ml red wine (1 glass)
	1-2 s olives, nuts, seeds daily	
	herbs, spices, garlic, onions daily	
meat (2.6%–4.0%)	< 2 s red meat weekly	once a week beef or pork*
	<= 1 s processed meat weekly	
	2 s white meat weekly	once a week chicken*
milk and dairy products (1.3%–1.8%)	2 s dairy daily (pref. low fat)	300 ml milk or dairy products
		15 g cheese
eggs (0.8%–1.4%)	2-4 s weekly	3 eggs a week*
animal fats (1.0%–2.0%)		
	<= 2 s sweets weekly	200 kcal non-basic products
		**100 g animal products total*

Epidemiological evidence suggests that a traditional MD may be beneficial to health (Keys 1980). The term ‘Mediterranean Diet’ originated from the 1960s when studies suggested that people living in Crete and South Italy were having a lower incidence of coronary heart disease (Keys 1970). The Health Score of the MD is 122, which is higher than the recommended guidelines (Table 3), and the Sustainability Score for males (86) is below the guidelines. The question is: Is this healthy, cultural accepted Southern European diet transferrable to Northern European areas?

3.2. Defining the New Nordic Diet (NND)

We find an answer as we look into the Nordic Diet. Although the Mediterranean cuisine is also popular in Western European countries, food patterns differ significantly throughout different countries. We came across a Scandinavian variant of the Mediterranean diet, the NND. This Northern European diet consists of many local Scandinavian traditional products such as fish, berries, cabbage, rapeseed oil, rye, oats and game (Hahnemann 2010). Dietary components with substantial evidence of health-promoting properties that are part of the Nordic Nutritional Recommendations 2012 (Norden 2014) are naturally included in the NND; e.g. fruits, vegetables, potatoes, whole grains, nuts, fish and shellfish (Mithril et al. 2012). The diet is quantified in Table 2. The ‘New’ diet is also based on long local traditions; in the Middle Ages foods such as fresh herbs, legumes, cabbage and root vegetables played a major role in the Nordic Diet, but their use has decreased significantly over recent decades (Mithril et al. 2012).

Table 2. Quantification of the New Nordic Diet according to Uusitupa and Mithril.

Healthy Nordic Diet (Uusitupa et al. 2013)	**New Nordic Diet (Mithril et al. 2012)**
500 g/week wholegrain pasta and rice (25 en% whole grains)	
210 g bread/d (6 slices)	275 g wholegrain bread and cereals
>50% as rye, barley or oat	
150-200 g berries	75 g berries
175 g fruits	250 g fruits
175 g vegetables	150 g root vegetables
	30 g cabbages, 240 g other vegetables
	45 g legumes
	175 g potatoes
rapeseed or sunflower oil (2/3 unsaturated fats)	15 g rapeseed oil
soy oil based margarines	10 g butter
nuts and seeds unsalted	30 g nuts and seeds
	6 g wild plants, mushrooms, herbs
2 portions/d low-fat milk and cheese	450 g low-fat milk (+50 g other dairy)
	25 g cheese
3 portions fish/week (2 fatty)	43 g fish and shellfish (5g seaweed)
white meat, poultry, game	100 g meat (4 g game)
	25 g eggs (1/2)
50 g apple juice	
	75 g extras
	15 g sugar
	1000g coffee, tea, water (600g)

The NND can be described by overall guidelines: (a) more calories from plant foods and fewer from meat; b) more foods from the sea and lakes; and c) more foods from the wild countryside (Mithril et al. 2012). According to studies by Bere and Brug (2009, 2010), this diet has a positive health impact, and a low environmental impact, similar to the MD. Bere and Brug advise moderation of beverages such as coffee, soft drinks, fruit juice and alcohol, and fatty and sweet extras in between meals in order to increase the scores.

Our calculation results in a higher Health Score of 134 for the NND and results in the same Sustainability Score of 86 (see Table 3), compared to the MD. There is some research that confirms the health impact of the NND. Uusitupa et al. (2013) for instance investigated the effects of an isocaloric healthy Nordic diet on insulin sensitivity, lipid profile, blood pressure and inflammatory markers in people with metabolic syndrome. Uusitupa et al. concluded that a healthy NND improved lipid profile and had a beneficial effect on low-grade inflammation. In 2009, OPUS was launched as a comprehensive research project for optimal well-being, development and health of Danish children through a healthy NND. The preliminary results of the scientific research on the correlation between weight loss and the NND show that eating Nordic food is an effective way to curb obesity in the Danish population (Thorson et al. 2013).

Mithril et al. (2012) concluded that the principles and guidelines of the NND could be applied in any region. In the next section we will look if an application to the Low Lands is reasonable.

3.3. Defining the Low Lands Diet (LLD)

Although the Scandinavian culture stands closer to the Low Lands than the Mediterranean, it still differs significantly. The challenge is to define and investigate a LLD, with comparable qualities to the MD or NND. A similar health effect as the NND can be expected in the Low Lands with a traditionally, predominantly plant-based diet (semi-vegetarian), also with lots of fresh and regional vegetables, fruits and whole grains (bread, pancakes, porridge), a local vegetable oil, supplemented with limited amounts of fish, eggs, meat, and milk.

The Dutch diet from the beginning of the 20th century (1900-1940) is well described by Jobse-Van Putte and fit into this description. Research was done by interviewing older people from different areas and analyzing official documents. There are no quantitative diet surveys available prior to the 1960s. Other sources confirm the findings from Jobse-Van Putte (1995) (Knibbe 2001; Van Otterloo 1990). The following issues are typical for the LLD:

- People constrain themselves, especially to price of food. It should be cheap, fast and easy.
- There is an international, cosmopolitan mind-set, because the area is in between three cultural circles: Roman, Anglo-Saxon and German/Scandinavian. Culture, as well language, and foods are borrowed from different cultures.
- The Protestant-Calvinistic religion has resulted in an ethical relation towards food and abstinence, temperance, and pleasure, and an attitude towards food as a way to survive.
- The democratic, liberal and caring government is comparable to the Scandinavian countries, with comparable values towards food as a necessity, combined with a natural, balanced, and nutritious proposition.
- Due to an open trading economy, there is a lot of tolerance towards food habits of immigrants (Chinese, Indonesian, Jewish, Italian, Greek, Turkish and Moroccan) and an early adaption of coffee, tea, rice and spices (Albala 2003; Jobse-Van Putten 1995).

A general, typical LLD is described in Table 4. Some available statistics were used, on the consumption of bread, pulses, potatoes, milk, meat and fish between 1930 and 1950 (CBS 2001). Due to the low income situation, no food was wasted (Jobse-Van Putten 1995). This LLD is plant based and includes a maximum energy percentage (en%) of 30% deriving from an animal origin. In the countryside most of the people were self-sufficient. They had a vegetable garden and an acre with rye or other grains and a pig. Once a year the pig was slaughtered and the pork and grease was consumed until lent. Bread was baked once a week. Farmers in the lower grassland -clay and moor- areas (river sides, lake sides and coastal area) owned cows. One cow was available per four inhabitants. The butter was mostly sold and buttermilk was for own use. Porridge cars went by homes on a daily basis to sell porridge made of buttermilk and barley. People living in the eastern sand areas consumed a more rye based diet. In the cities more wheat was consumed. Typical for the culture is the cooking of hot meals in one pot (‘*stamppot’*) and for several days. Thanks to the trade connections, rice, spices, coffee and tea were common at an early stage. Fresh fish was only available in coastal zones; fresh water fish consumption was dropped in the 18th century, due to overfishing. Beef, poultry and game were not regular on the menu.

The Health Score of 106 and the Sustainability Score of 97 of the LLD (Table 3) are comparable to the recommended guidelines (Health Council 2006), but the Health Score is lower and the Sustainability Score higher than the MD and NND. The scores of the traditional LLD are higher than the present diet. Now we look for an interactive method to improve the suboptimal intake of vegetables, fruits, fiber and fish and to lower the salt consumption in the LLD.

Table 3. GHGE, LU, Sustainability Score, nutritional characteristics, and Health Score of the present Dutch, Mediterranean, New Nordic, historical Low Lands, and optimized Low Lands diets (males 31-50y).

		dietary guidelines	**present Dutch**	**Mediterranean**	**New Nordic**	**historical Low Lands**	**optimized Low Lands**
1	GHGE (kg CO_2-eq)	3.07	3.52	3.24	3.82	3.24	**2.60***
2	Land use (m^2*year)	3.08	4.15	4.15	3.42	3.18	**2.86**
	Sustainability score	101	82	86	86	97	**115**
1	Vegetables (grams)	200	119	300	**420**	179	215
2	Fruits (grams)	200	82	250	**350**	145	277
3	Fatty acids (en%)	25	34.5	**20.5**	21.5	25.2	24.2
4	Saturated fatty acids (en%)	10	12.7	6.9	**6.7**	8.4	7.3
5	Trans-fats (en%)	1	1.0	0.5	0.4	0.3	**0.2**

4. Methods: Linear programming

Although it cannot be assumed that a healthy diet will always have lower GHGE (Macdiarmid 2013), we do expect that linear programming will make it possible to find a diet with lower impacts than those diets found in literature. This is confirmed in a paper that is currently under submission (Van Dooren et al. 2014b). Several studies in other countries - for instance UK, France and New Zealand - have also successfully used linear programming for diet optimization.

Linear programming is a mathematical technique that allows the generation of optimal solutions (Dantzig G and M. 1997). The method we use for linear programming in this study is very similar to the one used by (Macdiarmid et al. 2012). This mathematical method optimizes an outcome which is a linear function of several variables that can be controlled (e.g. the amount of food eaten), while subject to a number of constraints (e.g. dietary requirements) (Macdiarmid et al. 2011). The linear programming algorithm minimizes the absolute changes in terms of portions to the present diet (see also Maillot et al. 2010); weighted by a proxy of popularity, while satisfying a number of constraints. Due to the weighing, it penalizes positive deviations from the present diet differently from negative deviations. More specifically the optimization weights are constructed from the normalized value of the total food consumption based on weight (n=206, based on (Van Rossum CTM et al. 2011)) for male adults (31-50y). In other words: Diets are improved by keeping as much as possible products from the starting point, and by adding products that are popular at the moment, in order to create a culturally acceptable diet.

The total GHGE of a diet consisting of amounts of n food products (x_1, x_2, ., x_n) and the associated GHGE of each food product per unit weight ($GHGE_i$) is as follows: Eq.3.

$$GHGE_{diet} = \sum_{i=1}^{n} x_i GHGE_i \qquad \textbf{Eq. 3}$$

In addition, the diet has to satisfy the energy and nutrient requirements (constraints) and, when applicable, an upper limit for total GHGE. Each constraint can be denoted as b_1, b_2, .., b_m, and with each food product i contributing a_{ij} per unit weight to requirement j, a set of j dietary constraints was established such that: Eq. 4.

$$b_j \geq \sum_{i=1}^{m} a_{ij} x_i \qquad \textbf{Eq. 4}$$

Optimization is done by linear programming using the newly developed Optimeal® software of Blonk Consultants and the Netherlands Nutrition Centre, which runs with MATLAB Compiler 7.16 and Microsoft Access Runtime. During optimization we use 33 nutrients and GHGE as constraints. Adequate intake levels and dietary guidelines of 33 nutrients are given by the Netherlands Nutrition Centre (2008) and the Health Council of the Netherlands (Health Council 2001; 2006; 2009) as the first constraint. The 33 nutrients and nutritional indicators are: energy, protein, carbohydrates, total fat, saturated fatty acids, trans fatty acids, polyunsaturated fatty acids, cholesterol, dietary fiber, alcohol, water, sodium, calcium, phosphorus, magnesium, iron, copper, selenium, zinc, iodine, retinol, vitamin D, vitamins B1, B2, B6, B12, folic acid, vitamin C, n-3 fatty acids (EPA + DHA), fruit consumption and vegetable consumption. Secondly, the upper boundary for climate impact (GHGE) is set to 2.60 kg CO_2eq/day. This represents a 20% reduction of the present GHGE of the Dutch diet (males 3.52 kg CO_2eq/day (Marinussen et al. 2012)), as feasible target.

5. Results: an optimized LLD

Optimization of the historical LLD resulted in an increased content of vegetables, fruits and dietary fibers, and a decrease in salt. Table 4 shows the result of the historical research into the LLD and the results of optimization by linear programming. Due to the constraints and penalty rules, the optimization resulted in a diet which is palatable and in line with the traditional diet. Various elements of this diet are in use at the moment, for instance a high consumption of potatoes and wheat bread compared to other European countries, the preference for cabbage, root vegetables and local fruits (apple, pear), the level of milk consumption and the habits of drinking coffee, tea and beer.

Table 4: Quantification of the historical and optimized Low Lands Diet for male adults, by historical research and linear programming.

historical Low Lands diet	**optimized Low Lands diet**
350 g potatoes	350 g potatoes
180 g vegetables (leafy, roots, cabbages)	215 g vegetables (extra lettuce and kale)
145 g fruits (apple, pear, berries)	277 g fruits (extra pear)
18 g legumes	51 g legumes
	24 g nuts
35 ml soup	35 ml soup
210 g rye and wheat bread (6 slices)	210 g rye and wheat bread (6 slices)
30 g rice and 10 g other grain products	10 g other grain products
2 portions porridge incl. 250 ml buttermilk and 150 ml full fat milk	2 portions porridge incl. 325 ml skimmed milk and 150 ml full fat milk
20 g cheese	no cheese
40 g butter, rapeseed oil, margarine	40 g butter, rapeseed oil, margarine
25 g fish	37 g oily fish
55 g meat (pork, beef and chicken)	48 g meat (pork and chicken)
300 ml coffee, 250 ml tea	300 ml coffee, 250 ml tea
300 ml beer, 6 ml wine	300 ml beer
	300 ml water
32 g extras (sugar, jam, chocolate, syrup, cake)	32 g extras (sugar, jam, chocolate, syrup, cake)

Furthermore, this optimization placed the LLD scores in between the Health Scores of the MD and NND, but resulted in the highest Sustainability Score (i.e. lowest environmental impact, Table 3). GHGE is 2.60 kg CO_2-eq per day and LU 2.86 m^2*year. The sustainability scores (Table 3) of the Nordic, Mediterranean, traditional LLD and recommended dietary guideline are on the same level of about 100. Only the optimized LLD is higher. An unexpected result is that the Health Score of the optimized LLD is close to the high score of the NND. Both are higher than the MD, which is generally considered as very healthy.

The optimization results in a diet within the 33 nutritional constraints and with low GHGE and LU (or high Sustainability Score). To reach this diet, the consumption of (local and seasonal) fruits, vegetables and legumes has to increase. Nuts should be added to the diet. The consumption of fish and white meat should be increased and the intake of cheese and beef has to be reduced. The optimized LLD seems to be a cultural acceptable option, which amply meets the nutritional and environmental constraints.

6. Discussion

In this paper we were able to define a nutritionally healthy, environmentally friendly, and culturally acceptable Low Lands Diet. The historical quantification of the diet before 1940 is subject to uncertainties. Changes in starting point will result in other optimal solutions. The qualities of the LLD are in line with the benefits of MD and LLD, based on the quality of historical diets from decades ago. In order to give relevant recommendations both historical, cultural patterns and present consumption have to be taken into account.

Both gastronomists and nutritionists are beginning to believe that there is a shared route to creating regional diets and an opportunity to develop a healthy diet that bridges gastronomy, health and sustainability (Mithril et al. 2012). Eating according to the Dutch dietary guidelines is one way to get to a healthier and a lower environmental impact than the present Dutch diet (Health Council 2011). However, further improvements in health scores, GHGE, and LU are within reach, we concluded in (Van Dooren et al. 2014a). We demonstrated that the MD is generally the health focus option with a high Sustainability Score. On the other hand, this paper demonstrates that the NND is also a prototype regional diet taking health, food culture, palatability and the environment into account. The principles and guidelines can indeed be applied in any region (Mithril et al. 2012). We demonstrated the possibility to apply this to the Low Lands.

This study confirms that if we combine the strong points of historical diets, with optimization on health and sustainability parameters, then even a local diet with higher scores is possible. Although the NND has the highest Health Score, a higher Sustainability Score is found in the optimized LLD.

Earlier, Swedish (Livsmedelsverket 2009) and Finnish governments (Steering Group 2010) have put together committees to give policy advice on environmentally effective diets. In line with these recommendations, four simple considerations for environmental impact were used in the formulation of the NND:

- Focus on locally grown foods.
- Focus on foods from organic food production.
- Focus on composing a proportion of the diet from foods sourced from the wild countryside, encouraging biodiversity and minimizing use of fertilizers and pesticides.
- Focus on minimizing waste and utilizing all of every food purchased (Mithril et al. 2012).

Saxe et al. (2013) confirmed that the climate impact of the local, organic NND is lower than the average and recommended diets. The four considerations mentioned above are also transferrable to and in use in the Low Lands, although the size of wild countryside in the Low Lands is much smaller, even a century ago. These Scandinavian recommendations and guidelines have a qualitative character. In this study we have quantified the sustainability in a combined score of GHG and LU. We also demonstrate that the NND is not optimal in the Sustainability Score. The reason is a relative high amount of meat, fish, vegetables and fruits. The optimized LLD showed that with smaller quantities of these products comparable nutritional health can be achieved. It is important to mention the common ground of the results for MD, NND and LLD. All diets consist of basic food products, which are high in nutrient density and most of the time low in energy density. Most of the volume is plant based products, such as whole grains, fruits, vegetables, oils, pulses and nuts. All include animal products in moderate quantities.

When interpreting the results it is important to consider that the methodology used to score health and sustainability is based on a limited number of parameters. Other parameters, such as fossil energy use, water use, and ReCiPe-score were outside the scope of this study. The data are not based on dietary assessments, but on a general description from the literature about different diets. This results in some uncertainties. Sustainability scores are based on Dutch data on LCAs of common food products. Most of these products are familiar to the Mediterranean and Nordic cuisine, but difference in transport and agricultural methods would result in slightly different calculations of GHGE and LU. On the other hand, the results reflect a hypothetical situation where these NND and MD are transferred to the Low Lands. Because of the limited number of products (206) used in the calculations, no detailed results of the diets could be given. For instance some traditional products were missing and replaced by comparable products (e.g. oats and barley by wheat). Furthermore, the study should not be interpreted as a retrospective study on the sustainability impact of the situation before 1940. Surely, energy intensity, processing and yields differ significantly over time. The calculation of the traditional LLD reflects the situation if male adults from our area were to eat as our ancestors and grandparents did 80 years ago. Rather than trying out diets recommended in the literature, this study confirms the usefulness of linear programming to improve existing or culturally relevant diets.

7. Conclusion

An optimized Low Lands Diet has the same nutritional characteristics as the Mediterranean and the Nordic Diet, and results in a lower environmental impact and a higher sustainability score. These results are relevant because an adaptation of the historical diet, which fits better into the present eating habits, climate and agricultural tradition of the Low Lands, is assumed to be easier to achieve than a transition into a foreign Southern or Northern European diet.

Optimising land use and consumption of livestock products in the human diet with an increasing human population in the Netherlands

ABSTRACT

Land use related to food production is generally quantified using product-based life cycle assessments. We, however, quantified land use of diet scenarios with a land use optimization model. Energy and protein requirement of human populations, varying from 15 to 30 million people, were met with the consumption of arable crops, meat and milk. Diet scenarios explored contained 0% up to 80% of animal protein. First findings show that a limited contribution of animal protein in the diet resulted in lowest land use per capita, because of utilization by livestock of products inedible for humans. Moreover, utilization of land unsuitable for crop production provides the opportunity to sustain a larger population compared to a situation in which these soils were not used to produce food.

Keywords: human diet, land use, land optimization modelling, crop production, animal production

1. Introduction

Currently, about 40% of all terrestrial land area in the world is used for agriculture (FAOSTAT 2013). Non-agricultural land area consists of (tropical) forest, desert, mountains and tundra, but also of cities, industrial areas and roads. Pressure on land will increase, because of increasing land degradation (Stringer 2008) and increasing demands for food, biofuel, biomaterials, housing and infrastructure for an increasing population of 9.6 billion in 2050 (United Nations 2013). Simultaneously, there is need for preservation of nature (Smith et al. 2010, The Royal Society of London 2009, TheWorldBank 2007).

One way to feed an increasing world population with a limited land area is to increase productivity per hectare, commonly referred to as sustainable intensification (Tilman et al. 2011). Other ways to feed an increasing world population with a limited amount of land area include reducing the amount of food waste along the chain (Gustavsson et al. 2011, Kummu et al. 2012) or a change in human diets towards food products requiring less land area (Meier & Christen 2013).

Various scientific studies have assessed the impact of a change in human diet on land use (Collins & Fairchild 2007, Gerbens-Leenes & Nonhebel 2002, Peters et al. 2007, Rabbinge & Van Latesteijn 1992, Risku-Norja et al. 2008, Stehfest et al. 2009, Thibert & Badami 2011, Wirsenius et al. 2010). These studies support the general conclusion that plant-based diets require less land than animal-based diets (Meier & Christen 2013, Stehfest et al. 2009, Van Kernebeek et al. 2014, Wirsenius et al. 2010). Some studies even propagate to substitute ruminant meat by monogastric meat to lower land area requirements for food production (Collins & Fairchild 2007, Stehfest et al. 2009, Wirsenius et al. 2010). However, compared with diets of ruminants, diets of pigs and poultry are relatively rich in products such as cereals, that humans could consume directly (De Vries & De Boer 2010). Moreover, in a situation where arable land is limiting, ruminant production on land being unsuitable for crop production may contribute to global food security (Peters et al. 2007).

To avoid competition between humans and animals for land and products, such as cereals, we could stimulate to feed by-products from crop cultivation or the food industry to animals, and to feed grass from land less suitable for crop cultivation to ruminants. Peat soils in the Netherlands, for example, are not suitable for production of arable crops, such as grain or potatoes, but are valuable for grass-based livestock production. The objective of this paper is to examine the relative contribution of livestock production in a human diet, with an increasing human population, given a limited land area in a region. We used the Dutch agricultural system with different population scenarios as an illustration, assuming no import and export of food and feed.

2. Methods

To fulfil our research objective, we assessed agricultural land area required to feed a growing population in the Netherlands with various dietary choices, using linear programming. We varied population sizes from 15 million people, which is the approximate current Dutch population size, up to the maximum number of people that could potentially be fed, with steps of 5 million people. Diet scenarios ranged between 0% animal protein in the diet up to 80% animal protein, with steps of 5%.

The system studied was directed at production of food (i.e. energy and protein) for a given human population in the Netherlands, assuming no import and export of food and feed. We distinguished cultivation of food crops (grains, root- and tuber crops, oil crops and legumes), feed crops (maize silage) and grass. Crops could be cultivated on clay and sandy soils. Peat soils could be used for cultivation of grass. Our system also included dairy and pig production. Land area for animal production consisted of feed production. In the modelling study, we assumed typical, current agricultural yields for both crop and animal production (PPO 2009, 2012, Vermeij 2012). We excluded products from fisheries and aquaculture as these are not land-based systems. We also excluded products from greenhouses as these do not require agricultural land. For the same reason, we did not account for land required for infrastructure and production sites for, e.g., artificial fertilizer and machinery.

The objective function of our optimization model was to minimize the use of land for the defined crops and grassland on clay, sand and peat soils, whilst meeting human nutritional requirements. Current existing agricultural land area in the Netherlands was set as physical boundary.

Daily per capita human requirements were defined as 2000 kcal, 57 grams of protein and a maximum of 90 grams of total sugars (EFSA 2009, 2012).

2.1. Production of crops and crop products

Crop production and yields were based on typical current agricultural practices in the Netherlands. We distinguished between crop production on clay, sand and peat soil. We used multiple-year average yields for each soil type. Apart from differences in yields across soil types, no further geographical differences in yields and inputs were assumed, as the Netherlands is a small country with a relatively homogeneous climate. We accounted for 2-7 percent land area requirement for the production of seeds and tubers.

We distinguished four groups of food crops: grains, root- and tuber crops, oil crops and legumes. From each group, we included the crop with the largest land area in the Netherlands as a model crop, except for the group of root- and tuber crops, where we included two model crops. We included wheat as model crop for grains, potatoes and sugar beet for root- and tuber crops, rapeseed for oil crops and brown beans (Phaseolus vulgaris) for legumes. In addition, we included maize silage and grass as forage for dairy cattle.

Crops are grown in crop rotations. We used rotation schemes as provided by Van Ittersum et al.,(1995). Grass and silage maize were considered as mono crop rotations, whereas the other crops were considered in four to six year rotations.

Agricultural area in the Netherlands totals 1,842 x 10^3 hectares in 2012 (CBS 2013). Based on the land use map by Lesschen et al. (2012), we attributed the total agricultural area to three soil types:

779 10^3 hectares of clayey soils, 839 10^3 hectares of sandy soils, and 224 10^3 hectares of peat. Due to the vulnerability of peat to soil subsistence and oxidation after tillage, we assumed that these soils can only be used for grass production to feed cows.

We included various post-harvest processes to convert harvested products into human edible products and feed ingredients. Processes included were: dry milling of wheat, wet milling of potato, peeling of potato, sugar processing and crushing of oil seeds. The nutritional value of the output products were taken from (PDV 2011) for feed and (RIVM 2013) for food products.

2.2. Animal production

We modelled the pig and dairy production system using the concept of an animal production unit (PU), based on typical current management (Vermeij 2012). A PU consisted of one animal unit per year for an average Dutch farm, including associated breeding animals and offspring. Per PU, we defined output in terms of meat and milk. We computed associated nutritional requirements in terms of energy, protein and fiber. Moreover, other feeding constraints, e.g. daily intake capacity, were defined. The optimization model, finally, composed the feed ration.

For the pig production system, a PU comprised a fattening pig unit, including the associated rearing gilts and breeding sows. Per PU per year, 3.26 fattening pigs were slaughtered, producing 170 kg pork per year.

For the dairy production system, a PU comprised one milking cow, including associated young stock. A Dutch dairy cow PU produced on average 8120 kg milk (8586 kg FPCM; Fat and Protein Corrected Milk) and 141 kg meat per year (LEI 2013, PDV 2012) available for human consumption.
We assume no impact of ration composition on production parameters such as protein content in milk, dressing percentage and carcass quality.

2.3. Losses and waste

Losses and waste of arable and animal products were modelled on weight basis using Gustavsson et al. (2011) and Biewenga et al. (2009). These include losses in the feed chain during conservation and feeding, losses during transport and distribution, and waste by the consumer.

3. Results

The first findings of our analysis show the agricultural land area for diets varying in percentage of animal protein for various population sizes (Figure 1).

Diets containing no animal protein had slightly higher land use compared to diets that contained a modest amount (5-30%) of animal protein. This is due to the utilization by animals of products that cannot be consumed by humans, such as wheat straw and sugar beet molasses. At higher levels of animal protein, additional feed crops are produced, which results in increasing land use. Besides, with increasing percentage of animal protein, peat soils are taken into use for the production of grass for dairy cows.

The figure also shows that, at higher population numbers, a vegan diet cannot provide sufficient food to sustain the population. Crop production on clay and sandy soils does not produce sufficient protein for this large population size. Due to the utilization of peat soils by dairy cows, an extra number of people can be fed potentially.

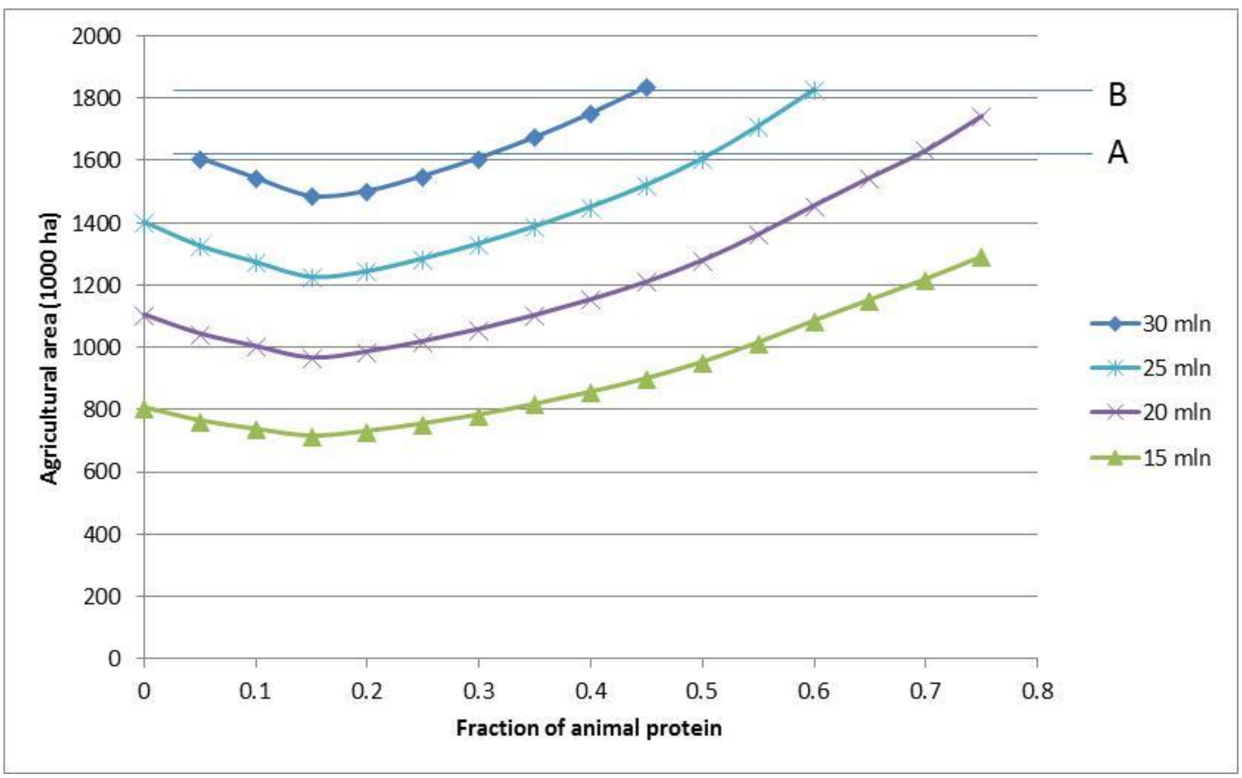

Figure 1. Agricultural land use (ha) in the Netherlands with increasing population, for diets differing in the amount of animal protein. The current Dutch population is 17 million. The Netherlands has around 1.8 x 10^6 hectares of agricultural land; we assumed no import of food. A: total agricultural area on clay and sandy soils. B: total agricultural area on clay, sand and peat soils.

4. Discussion

Our analysis was limited to land use. We did not consider economic effects of dietary choices. Besides, land area requirement is only one of many impact categories that should be accounted for when assessing overall sustainability of human diets. In the Netherlands, high crop yields partly result from high levels of inputs, which may reduce required land area at the cost of long-term sustainability in relation to, e.g., ecosystem services (Foley et al. 2005). Western diets contain in the order of 70% animal protein (Van Kernebeek et al. 2014). A reduction of animal consumption in affluent diets could help reducing land use, as well as greenhouse gas emissions (Hedenus et al. 2014).

Because we do not use allocation in our optimization model, it was not possible to express land use per kg of product or per kg of protein, as is often seen in literature (De Vries & De Boer 2010). However, we were able to compare land use of the diets with results from literature (Meier & Christen 2013, Terluin et al. 2013). Land use required for diets reported by Terluin et al. (2013) varied between 470 and 1000 m^2/capita/year. Land use required for diets reported by Meier and Christen (2013) varied between 1000 and more than 2000 m^2/capita/year. Land use required for diets in our study varied between about 500 and 1000 m^2/capita/year.

5. Conclusion

The ability of animals to utilize products that cannot be consumed by humans can help to reduce land use for food production. Moreover, utilization of land unsuitable for crop production, in our case peat soils, provides the opportunity to sustain a larger population compared to a situation in which these soils are not used to produce food.

ABSTRACT

We evaluated the impact of feeding and breeding strategies to reduce greenhouse gas (GHG) emissions from dairy farming. A whole-farm optimization model was combined with mechanistic modeling of enteric fermentation and LCA to determine the impact on GHG emissions and farm income. Feeding strategies included supplementation of extruded linseed (56% linseed; 1 kg/cow/day in summer, 2 kg/cow/day in winter), supplementation of nitrate (75% nitrate; 1% of dry matter intake), and reducing grass maturity. In case of breeding, the impact of one genetic standard deviation improvement in milk yield (687 kg/cow/year) and longevity (271 days) was assessed. Supplementing linseed reduced emissions by 9 kg CO_2-equivalents (CO_2e)/ton fat-and-protein-corrected milk (FPCM), supplementing nitrate by 32 kg CO_2e/ton FPCM, and reducing grass maturity by 11 kg CO_2e/ton FPCM. All strategies reduced farm income. Increasing milk yield and longevity reduced emissions by 27 and 23 kg CO_2e/ton FPCM, respectively. Both strategies increased farm income.

Keywords: dairy farming, greenhouse gas mitigation, linear programming, economic analysis, life cycle assessment

1. Introduction

Dairy cattle, producing milk, meat, and non-edible products (e.g. manure), are responsible for about 30% of global greenhouse gas (GHG) emissions produced by the livestock sector (Gerber et al., 2013). About half of these GHG emissions is related to enteric fermentation. Other important sources of GHG emissions are feed production and manure management. Two important areas of interest to reduce GHG emissions from dairy farming are feeding strategies to reduce emissions from enteric fermentation, and breeding strategies to improve animal productivity.

Examples of feeding strategies to reduce emissions from enteric fermentation are dietary supplementation of fatty acids, dietary supplementation of nitrate, and reducing the maturity stage of grass herbage and grass silage (Martin et al., 2008; Van Zijderveld et al., 2011; Brask et al., 2013). Examples of breeding strategies to improve animal productivity are increasing milk yield and longevity (Bell et al., 2010). Increasing milk yield per cow reduces GHG emissions per kg milk by diluting emissions from production and fermentation of feed related to maintenance. Increasing longevity reduces GHG emissions per kg milk by reducing the number of female replacements contributing to GHG emissions during maintenance and growth, without producing milk, and by increasing lifetime milk yield per cow, diluting emissions related to rearing.

Most studies that evaluate the potential of feeding and breeding strategies to reduce GHG emissions from dairy farming do not account for emissions other than enteric methane (CH_4), do not account for changes in farm management to adapt the farm optimally to the particular strategy, or do not account for consequential effects in other parts of the milk-production chain. To understand which strategies can contribute to reducing the net contribution of dairy farming to global GHG emissions, an integrated approach is required that accounts for all changes in farm management and includes all changes in GHG emissions along the chain.

The aim of this study was to analyze the impact of several feeding and breeding strategies to reduce GHG emissions from dairy farming on GHG emissions at chain level (i.e. from cradle to farm-gate) and on labor income at farm level using an integrated approach. We combined a whole-farm optimization model with a mechanistic model for enteric methane and life cycle assessment (LCA). Feeding strategies under study included dietary supplementation of extruded linseed, dietary supplementation of nitrate, and reducing the maturity stage of grass herbage and grass silage (for further details, see Van Middelaar et al., 2014a). In case of breeding, we focused on the impact of one genetic standard deviation improvement in milk yield and longevity (for further details, see Van Middelaar et al., 2014b). By evaluating the impact of one unit change in individual traits, the relative value of each trait to reduce GHG emissions along the chain can be determined.

2. Methods

2.1. Dairy farm linear programming model

A dairy farm linear programming (LP) model based on Berentsen and Giesen (1995) was used to simulate a Dutch dairy farm before and after implementing the strategies. The farm production plan was optimized based on the objective to maximize labor income of the farm family. The LP model is a static year model and includes all relevant activities and constraints that are common to Dutch dairy farms, such as on-farm roughage production, purchase of feed, and animal production, including the rearing of young stock. Prices of purchased and sold products were based on KWIN-V (2008).

The central element of the LP model is an average dairy cow from the Holstein Friesian breed, with a given milk production and longevity, calving in February, and conditions representing the dairy cattle of the farm. Feed requirements (energy and protein) and intake capacity of this average cow were determined using the bio-economic model of Groen (1988). The same model was used to determine herd composition and yearly replacement rate, based on the average longevity of the cow. The replacement rate determines the number of young stock that needs to be kept on the farm for yearly replacement of the dairy cows.

The model distinguishes a summer and a winter period regarding feeding. Available land can be used as grassland or as corn land. Dietary options include grass from grazing, grass silage, corn silage, and three types of concentrates that differ in protein levels (i.e. standard, medium and high). All dietary options were available in winter and summer, except for fresh grass (only in summer). Table 1 shows the feed characteristics of the feeds that are standard available in the model. Based on feed restrictions, the LP model matches feed requirements of the cow with on-farm feed production and purchased feed. Constraints of the model include fixed resources of the farm (e.g. land area, family labor), links between activities (e.g. fertilizer requirements of grass- and arable land with available nutrients from manure and purchased fertilizers), and environmental policies (e.g. limits to the application of nitrogen (N) and phosphate (P_2O_5) fertilization). For a more detailed description of the LP model see Van Middelaar et al. (2013).

2.2. Calculating greenhouse gas emissions

We used LCA to calculate emissions of carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O) from the different stages along the production chain, up to the moment that milk leaves the farm gate. Processes included are the extraction of raw materials to produce farm inputs, the manufacturing and distribution of these inputs, and all processes on the dairy farm. Stages related to transport and processing of milk were assumed to be unaffected by the strategies, and, therefore, not included in the analysis.

Emissions from the production of synthetic fertilizer, pesticides, tap water, and energy sources (gas, diesel, and electricity) were based on Eco-invent (2007), and from the production of concentrates and milk replacer on Vellinga et al. (2013). Emissions from production of concentrates include emissions from the production of inputs (e.g. fertilizers, pesticides, machinery, and energy), direct and indirect N_2O emissions from cultivation, CO_2 emissions from liming and urea fertilization, emissions from drying and processing, and emissions from transport in between stages, up to the farm gate.

Emissions of CH_4 from on-farm processes relate to enteric fermentation and to manure management. Emission of enteric CH_4 from dairy cows was calculated using a mechanistic model originating from Dijkstra et al. (1992). Production of CH_4 is estimated from the hydrogen (H_2) balance. Sources of H_2 include H_2 from production of acetate and butyrate, and from microbial growth with amino acid as N-source. Sinks of H_2 include H_2 used for production of propionate and valerate, for microbial growth with ammonia as N-source, and for biohydrogenation of lipids. The surplus H_2 is assumed to be completely converted into CH_4. To calculate the effect of dietary supplementation of extruded linseed and nitrate on enteric CH_4 production, additional calculations were required (see section 2.3). In case of breeding, results of the mechanistic model were transformed into empirical relations between dry matter (DM) intake of feed ingredients and CH_4 emission factors per ingredient (Vellinga et al., 2013). For young stock, enteric CH_4 emission was based on IPCC Tier 2 methods and default values, i.e. the average gross energy content of feed is assumed to be 18.45 MJ/kg DM, and 6.5% of the gross energy intake is converted to CH_4 (IPCC, 2006). Emissions of CH_4 from manure management were based on national inventory reports, i.e. 0.746 kg CH_4 per ton manure produced in stables, and 0.110 kg CH_4 per ton manure produced during grazing (De Mol and Hilhorst, 2003).

Emissions of CO_2 from on-farm processes related to the combustion of diesel and gas were based on Eco-invent (2007). Emissions of N_2O from on-farm processes include both direct and indirect N_2O from manure management and from N application to the field, including N from manure, synthetic fertilizers, and crop residues. Indirect N_2O emissions result from N that is removed from the farm via leaching of nitrate and volatilization of ammonia and nitrogen oxide (IPCC, 2006). Emissions of N_2O from crop residues were based on IPCC (2006). Other N_2O emissions were based on national inventory reports (see Van Middelaar et al., 2013).

Different GHGs were summed up based on their equivalence factor in terms of CO_2 equivalents (CO_2e) (100-year time horizon): 1 for CO_2, 25 for CH_4, and 298 for N_2O (IPCC, 2007). Emissions were calculated per ton fat-and-protein corrected milk (FPCM), i.e. milk corrected to a fat percentage of 4.0% and a protein content of 3.3%. After summing up emissions, they were allocated to the different outputs of the farm (i.e. milk and meat) based on the relative economic value of these outputs (i.e. economic allocation).

2.3. Feeding strategies

We evaluated the impact of feeding strategies for a current Dutch dairy farm on sandy soil. This farm has 44.9 ha of land, housing facility for 76 dairy cows with young stock, and a milk quota of 603 tons per year. Milk production per cow was assumed to be constant at 7968 kg/year (4.39% fat and 3.52% protein). Data were based on the Farm Accountancy Data Network of the Agricultural Economics Research Institute from the Netherlands (FADN, 2012). The maximum fresh grass intake in summer was assumed to be 12 kg DM/cow per day, because limited grazing was applied. Safety margins for requirements of true protein digested in the small intestine and for rumen degradable protein balance were set at 100 g/cow per day. In addition, the option to feed dietary urea was included. The maximum amount of urea was limited by including a restriction on the amount of non-protein-nitrogen (NPN) equal to the amount of NPN in the diet supplemented with nitrate (see below). The reference situation (REF1), which includes no predefined feeding strategy, was determined by maximizing labor income for this current Dutch dairy farm. Subsequently, one of the three feeding strategies was introduced. Labor income of the farm was maximized again to determine diets and farm plan after implementing each strategy.

Feeding strategy LINS. Extruded linseed was added as a commercially available linseed product described by Dang Van et al. (2008), containing 56.0% crushed linseed, 21.0% wheat, 15.0% sunflower cake, 4.5% field beans, 2.0% butylated hydroxytoluene, 1.0% linseed oil, and 0.5% salt. Table 2 shows feed characteristics of this product. One kg product/cow per day was prescribed in the diet in summer and 2 kg/cow per day in winter (the product contains 0.9 kg DM/kg product). The effect of adding fatty acids in the form of extruded linseed on enteric CH_4 production was based on (Eq. 1) by Grainger and Beauchemin (2011):

$$y = - 0.102\ x \qquad \text{Eq. 1}$$

where, y is the reduction in enteric CH_4 (g/kg DM intake); and x is the amount of dietary fat added (g/kg DM).

Feeding strategy NITR. A nitrate source ($5Ca(NO_3)2{\cdot}NH_4NO_3{\cdot}10H_2O$; 75 % NO_3 in DM) was added at 1% of dietary DM. Table 2 shows feed characteristics of this nitrate source. The effect of nitrate on enteric CH_4 production was based on Van Zijderveld (2011). Stoichiometrically, a reduction in CH_4 of 0.258 g/g nitrate is expected. In vivo, efficiency of CH_4 reduction decreases with increased levels of nitrate intake according to Eq. 2.

$$y = - 0.17\ x + 1.13 \qquad \text{Eq. 2}$$

where, y is the actual reduction in enteric CH_4 expressed as a fraction of the reduction potential according to stoichiometry; and x is the amount of nitrate expressed in g/kg metabolic weight ($kg^{0.75}$) per day. The metabolic body weight of the cow is assumed to be 129 kg.

Feeding strategy GMS. Reducing the maturity stage of grass herbage and grass silage results in a lower DM yield/ha per year, but increases grass quality in terms of energy and protein content per kg DM. Total yield in MJ net energy for lactation (NE_L)/ha per year was assumed to remain unchanged. In the reference situation, grazing was applied at 1700 kg DM/ha, and harvesting at 3500 kg DM/ha. After implementing the strategy, grazing was applied at 1400 kg DM/ha, and harvesting at 3000 kg DM/ha. Table 2 shows feed characteristics of less mature grass and grass silage (based on CVB, 2011). Costs per grass cut were assumed to be the same as in the reference situation. Due to a lower DM yield per grass cut, the number of cuts per year increased.

Table 2. Feed characteristics of feeds available after implementing the feeding strategies, expressed per kg dry matter (DM).

Feed product	**NE_L [1] (MJ/kg DM)**	**DVE [2] (g/kg DM)**	**OEB [3] (g/kg DM)**	**N [4] (g/kg DM)**	**Fill value [5] (kg/kg DM)**	**NDF [6] (g/kg DM)**	**Crude fat (g/kg DM)**

[6] Neutral detergent fiber.

2.4. Breeding strategies

The LP model was adapted to future production circumstances to allow exploration of economic and environmental consequences of selective breeding. We evaluated the impact of breeding strategies for a representative Dutch dairy farm on sandy soil for the year 2020, and with a cow that has the same characteristics as an average Holstein Friesian cow in 2013 (Table 3). The future farm has 85 ha, which is the estimated size of an average Dutch dairy farm in 2020 (Rabobank, 2009). In 2015, the milk quota system will be abolished in the EU, and, therefore, no milk quota was assumed. The number of cows on the farm is an outcome of the LP model, and restricted by a constraint that prescribes that all manure produced on the farm needs to be applied on the farm. Grass and corn yield per hectare were increased based on historical data analysis (Berentsen et al., 1996; Rijk et al., 2013). For the environmental policies, no changes in limits to the application of N are expected, whereas limits to the application of P_2O_5 are reduced according to the new standards for 2020 (Vierde Nederlands Actieprogramma Nitraatrichtlijn, 2009). Furthermore, prices of milk components and purchased feed products were adapted based on price prediction for 2020 (KWIN-V, 2013). Based on the assumption that farmers become more efficient in the future, safety margins for true protein digested in the small intestine and for rumen degradable protein balance were set to zero. The reference situation for evaluating breeding strategies (REF2) was determined by maximizing labor income for this future Dutch dairy farm.

To determine the impact of one genetic standard deviation improvement in milk yield or longevity, each trait was increased with one genetic standard deviation, while keeping the other traits constant. The genetic standard deviation for milk yield of the Holstein Friesian breed in the Netherlands is 687 kg/cow per year (standard deviation applies to milk yield of a mature cow), and for longevity it is 270 days (CRV, 2012). Using the model of Groen (1988), the effect of this change on average production, feed requirements, herd composition and replacement rate was determined. Increasing milk yield increased feed requirements (Table 3). Increasing longevity changed herd composition (i.e. more cows in later lactations), and decreased replacement rate and number of young stock. Due to an increase in the number of cows in later lactations, milk yield of the average cow increased and fat content of the milk decreased, while feed requirement of dairy cows increased (Table 3). The new data on milk yield, feed requirements, and replacement rate were incorporated in the LP model, and labor income of the farm was maximized again to determine diets and farm plan after implementing each strategy.

Table 3. Production traits and feed requirements per cow, and yearly replacement rate (repl. rate) of the dairy herd for the reference scenario and after increasing milk yield and longevity with one genetic standard deviation.

	Production traits				**Feed requirements**			**Repl. rate**
	Milk yield kg/yr	Fat %	Protein %	Longevity # days	Energy GJ NE_L[1]/yr	Protein kg DVE[2]/yr	Intake capacity kg/yr	%

3. Results

3.1. Feeding strategies

Table 4 shows the diets of the dairy cows and farm plan for the reference situation of the current farm (REF1) and the situations after implementing the feeding strategies. In REF1, the maximum amount of fresh grass is fed in summer, because this is the cheapest way of feeding. Corn silage is added up to 6.59 kg DM/cow per day in combination with standard protein concentrates and dietary urea. As a result, minimum requirements for energy and rumen degradable protein are met within the limiting intake capacity. In winter, 2.86 kg DM grass silage/cow per day is fed, which is the amount of grass left for ensiling after grazing, in combination with 10.98 kg DM corn silage/cow per day. High protein concentrates and urea were added to meet requirements for energy, rumen degradable protein, and true protein digested in the small intestine. 70% of the farm land was used as grassland and 30% as corn land. Labor income of the farm family was €42,605 per year. GHG emissions added up to 840 kg CO_2e/t FPCM. The most important contributor was enteric CH_4 (52%), followed by emissions from manure (14%), on-farm feed production (13%), purchased feed products (10%), and fertilizers (8%).

Feeding strategy LINS increased the fat content of the summer diet from 35 g/kg DM (REF1) to 44 g/kg DM. As a result, total DM intake reduced. The amount of corn silage decreased and standard concentrates and urea were removed from the diet. In winter, dietary fat content increased from 32 g/kg DM in REF1 to 56 g/kg DM (LINS). As a result, the amount of corn silage decreased by almost 3 kg DM/cow per day, and urea was removed from the diet. The amount of high protein concentrates remained to fulfill requirements for true protein digested in the small intestine. Labor income reduced to €26,564 per year. This reduction is caused almost completely by the relatively high costs of the extruded linseed product compared to the costs of corn silage and concentrates. In total, GHG emissions decreased by 9 kg CO_2e/t FPCM. Emissions of enteric CH_4 from dairy cows decreased by 42 kg CO_2e/t FPCM. Due to a decrease in the amount of purchased corn silage, concentrates, and urea, emissions related to the production of these products decreased by 29 kg CO_2e/t FPCM in total. Emissions from the production of the extruded linseed product added up to 63 kg CO_2e/t FPCM.

Feeding strategy NITR resulted in a dietary NPN level of 37 g/cow per day in summer, and 31 g/cow per day in winter, being the maximum amount of dietary NPN allowed. As a result, urea was removed from the diet. No other dietary changes occurred. Due to an increase in dietary N content, the amount of N in manure increased.

Table 4. Diets and farm plan for the current dairy farm (REF1) and after implementing one of the three feeding strategies.

		REF1	**LINS**	**NITR**	**GMS**

Concentrates high protein		2.40	2.36	2.40	2.37
Urea		0.06	-	-	0.06
Extr. linseed product		-	1.80	-	-
Nitrate		-	-	0.16	-
Diet is restricted by [1]		E,R,T	E,T	E,T	E,R,T
Farm plan					
Dairy cows	n	76	76	76	76
Milk production	ton FPCM/farm/year	603	603	603	603
Young stock	unit [2]	25	25	25	25
Grassland 225 kg N/ha	ha	31.4	31.4	31.4	31.4
Corn land	ha	13.5	13.5	13.5	13.5
Synthetic fertilizer	kg N/ha	117	118	111	116
	kg P_2O_5/ha	8	7	7	10
Purchased corn silage	t DM	96	48	96	98
Purchased concentrates	t DM	55	43	55	53
Urea	t DM	1	-	-	1
Extr. linseed product	t DM	-	38	-	-
Nitrate	t DM	-	-	5	-
Labor income	€	42,605	26,564	37,142	42,142
GHG emissions	kg CO_2e/ton FPCM	840	831	808	829

[1] The diet can be restricted by: E = energy requirements; R = rumen degradable protein balance; T = true protein digested in the small intestine; I = intake capacity. [2] One unit includes 1 animal < 12 months and 0.96 animal > 12 months.

As a result, the amount of synthetic fertilizer decreased. No other changes in farm production plan occurred. Labor income reduced to €37,142 per year. This reduction is caused by the higher costs of dietary nitrate compared with urea. In total, GHG emission decreased by 32 kg CO_2e/t FPCM. Emission of enteric CH_4 from dairy cows decreased by 33 kg CO_2e/t FPCM. Producing nitrate instead of urea increased emissions by 3 kg CO_2e/t FPCM. Changes in other emissions were minor and relate to an increase in the N content of manure.

Feeding strategy GMS did not affect the amount of grass in kg DM/cow per day in the summer diet. Due to a higher energy content and a higher rumen degradable protein content per kg grass, however, the amount of concentrates and urea slightly decreased and that of corn silage slightly increased. Because total DM yield per ha grassland decreased, the amount of grass silage in the winter diet decreased. Corn silage slightly increased, while the amount of concentrates and urea remained unchanged. Due to a higher N and a lower P content in the diet, the amount of N in manure increased, while the amount of P decreased. This is reflected by a change in purchased fertilizers. Labor income reduced to €42,142 per year. This reduction is caused mainly by an increase in costs related to grassland management, resulting from an increase in the number of grass cuts per ha per year. In total, GHG emissions decreased by 11 kg CO_2e/t FPCM. GMS reduced emissions of enteric CH_4 from dairy cows by 10 kg CO_2e/t FPCM. Changes in other emissions were minor and relate to changes in the diet and an increase in the N content of manure.

3.2. Breeding strategies

Table 5 shows the diets of the dairy cows and farm plan for the reference situation of the future farm (REF2) and the situations after increasing milk yield and longevity. For the reference situation the following results apply. In summer the maximum amount of fresh grass is fed. Subsequently, corn silage in combination with a small amount of medium protein concentrates is added to meet requirements for energy and rumen degradable protein balance. In winter, the diet contains 2.7 kg DM grass silage per cow per day, based on the amount of grass remained after grazing. Again, corn silage in combination with medium protein concentrates is added. The reference situation has 168 dairy cows, 59.5 ha of grassland and 25.5 ha of corn land. The number of cows is based on the amount of manure that can be applied on the farm according to environmental legislation. In the reference situation, application standards on the amount of P_2O_5 were restricting. The area of grassland is exactly 70%, which is the minimum requirement for farms to comply with the derogation regulation that allows the application of 250 kg N/ha per year from animal manure, instead of 170 kg N/ha per year. Labor income is €115,050/year. GHG emissions added up to 796 kg CO_2e/t FPCM. The most important contributor was CH_4 from enteric fermentation (50%). Other important contributors were emissions from manure and from production of concentrates (both 13%).

Increasing milk yield by one genetic standard deviation resulted in an increase in the number of cows and an increase in the area of grassland at the expense of corn land. Changes in diets resulted from an increase in requirements for energy and protein, and from an increase in the area of grassland. Grassland increased because of the increase in the number of cows and P_2O_5 application standards being restricting (more P_2O_5 from animal manure can be applied on grassland than on corn land). In the reference situation, the costs of an increase in grassland at the expense of corn land were higher than the revenues of keeping more cows. After increasing milk yield, the revenues per cow increased, and outweighed the costs of an increase in the area of grassland at the expense of corn land. After increasing milk yield, the number of cows and grassland increased until application standards for N from animal manure became restricting. Total milk production at farm level increased to 1691 t FPCM/year, and labor income to €135,477. In total, GHG emissions decreased by 27 kg CO_2e/t FPCM. Increasing milk yield per cow reduced emissions per t FPCM by diluting emissions related to maintenance and young stock. In addition, emissions changed because of changes in diets and farm plan, e.g. emissions from the production of concentrates decreased, because the amount of concentrates in the diets decreased.

Increasing longevity by one genetic standard deviation reduced the replacement rate of the dairy herd (from 27.0% in REF2 to 22.5 % after increasing longevity). Similar to milk yield, this resulted in a situation where corn land was changed into grassland to increase to amount of P_2O_5 that can be applied on the field, and hence the number of dairy cows. Because of the reduced replacement rate, less young stock was kept, reducing manure production of the herd. As a result, the number of dairy cows increased to 182. Again, the application standard for N from animal manure limited a further increase of dairy cows. Total milk production at farm level increased to 1677 t FPCM/year, and labor income to €128,765. In total, GHG emissions decreased by 23 kg CO_2e/t FPCM.

Table 5. Diets and farm plan for the future dairy farm (REF2) and after implementing one of the two breeding strategies.

		REF2	Milk yield	Longevity
Diet dairy cows – summer period (kg DM/cow per day)				
Grass herbage		12.0	12.0	12.0
Corn silage		8.4	8.9	8.4
Concentrates medium protein		0.7	1.3	0.7
Diet is restricted by [1]		E,R	E,R	E,R
Diet dairy cows – winter period (kg DM/cow per day)				
Grass silage		2.7	5.0	4.2
Corn silage		8.0	8.9	8.4
Concentrates medium protein		6.5	4.6	5.0
Diet is restricted by [1]		E,R	E,R	E,R
Farm plan				
Dairy cows	n	168	171	182
Milk production	ton FPCM/farm/year	1543	1691	1677
Young stock	unit [2]	51	52	46
Grassland 225 kg N/ha	ha	59.5	67.9	67.4
Corn land	ha	25.5	17.1	17.6
Synthetic fertilizer	kg N/ha	107	113	112
	kg P_2O_5/ha	-	-	-
Purchased corn silage	t DM	207	396	381
Purchased concentrates	t DM	247	207	213
Manure application is restricted by [3]		P	aN, P	aN, P
Labor income	€	115,050	135,477	128,765
GHG emissions	kg CO_2e/ton FPCM	796	770	774

[1] The diet can be restricted by: E = energy requirements; R = rumen degradable protein balance; T = true protein digested in the small intestine; I = intake capacity. [2] One unit includes 1 animal < 12 months and 0.96 animal > 12 months. [3] The intensity of the farm is restricted by the possibility to apply manure. Manure application can be restricted by: tN = total mineral N; aN = N from animal manure; P = P_2O_5.

Due to a lower replacement rate, emissions related to young stock (mainly enteric CH_4) decreased by 12 kg CO_2e/t FPCM. Due to a change in the diets of dairy cows towards more roughage and less concentrates, emissions from production of grass and corn silage increased by 10 kg CO_2e/t FPCM (including on- and off farm production), whereas emissions from production of concentrates decreased by 20 kg CO_2e/t FPCM.

4. Discussion

Each feeding strategy reduced GHG emissions along the milk-production chain, but also reduced labor income. A negative impact on labor income reduces the likelihood of adoption by farmers, because profitability is often the main driver in decision making. While supplementing diets with nitrate resulted in the greatest reduction, a reduction in maturity of grass and grass silage resulted in the smallest reduction in labor income. Combining the impact on labor income with the impact on GHG emissions showed that this latter strategy is most cost-effective, and, therefore, offers most potential to be implemented on commercial farms.

Both breeding strategies reduced GHG emissions along the milk production chain while increasing labor income. The reduction in GHG emissions per ton FPCM were greater for milk yield than for longevity. The increase in labor income was also greater for milk yield. In this study, however, correlation between traits were not considered. Including correlations might change the balance between milk yield and longevity in favor of longevity, because production traits such as milk yield are negatively correlated with fertility and health traits, whereas longevity is positively correlated with these traits (Pritchard et al., 2013).

Breeding strategies affect GHG emissions in the long term. To evaluate the impact of an increase in milk yield and longevity, therefore, the model farm was adapted to future production circumstances without a milk quota. Differences in labor income between REF1 (current farm) and REF2 (future farm) are explained mainly by an increase in farm size, greater forage production per ha, and change in prices in case of REF2. Because only prices of important in- and outputs were changed, and because price predictions contain uncertainty, the impact of breeding strategies on labor income should be judged on their relative impact. Opposite to feeding strategies, breeding strategies resulted in an increase in income. Costs related to breeding strategies are covered by breeding organizations resulting in prices farmers have to pay for semen. There is no reason to assume that these prices will change depending on the strategy.

Emissions per ton FPCM in REF1 (current farm) are low compared with results in literature (De Vries and De Boer, 2010). This is mainly caused by the relatively high amounts of maize silage and low amounts of concentrates in the diets of dairy cows, partly because urea was used. In addition, unlike most other studies we used a model farm and calculated feed intake, which may differ from the actual intake and may increase the efficiency of the farm. Differences in emissions between REF1 and REF2 are explained by the higher productivity and efficiency in case of REF2, representing the technical and institutional setting of 2020 in combination with precision feeding (i.e. skipping safety margins for feeding protein). These results imply that future dairy farms can reduce their environmental impact in terms of GHG emission per ton FPCM when aiming for an increase in efficiency.

Results of the breeding strategies represent the impact of one unit change in milk yield and longevity. In practice, genetic selection is based on many traits simultaneously, and realized selection responses depend on the selection intensity for the trait of interest. Determining the impact of a multi-trait selection strategy requires knowledge of genetic parameters (i.e. heritability, genetic correlation) and the values of individual traits in the breeding goal. Results presented in this study, therefore, provide a first step towards a better understanding of the potential of breeding to reduce GHG emissions from dairy production. Due to differences between feeding and breeding strategies under study, results of the strategies cannot be compared directly.

This study focused on the environmental impact of strategies related to GHG emissions. Dairy production, however, has an impact on the environment in other ways, such as eutrophication, acidification, and depletion of fossil energy and phosphorus sources. Including other environmental impact categories might change results.

5. Conclusion

Each feeding strategy evaluated in this study reduced GHG emissions per ton FPCM, but also reduced labor income of the farm family. Supplementation of nitrate resulted in the largest reduction in GHG emissions, but reducing the maturity stage of grass and grass silage resulted in lower costs, and a better cost-effectiveness. One genetic standard deviation improvement of milk yield and longevity resulted in a reduction in GHG emissions, while increasing labor income. The reduction in GHG emissions as well as the increase in labor income were more pronounced for milk yield than for longevity. Identification of strategies to reduce GHG emissions is a first step towards reducing the impact of dairy production in practice. Results indicate that a combination of different strategies is required to substantially reduce GHG emissions from dairy production.

Can the environmental impact of livestock feed be reduced by using waste-fed housefly larvae?

ABSTRACT

The livestock sector is searching for alternative protein sources, because of the expected increase in demand for animal products. Insects are such a protein source. Use of insects may reduce environmental impact as they have potential to turn organic waste into high quality insect-based feed products. The aim of this study was to explore the environmental impact of using common housefly larvae fed on organic waste as livestock feed. Data were obtained from a testing site, that is designing a rearing place of 20 tons of larvae meal per day. Results showed that larvae meal has a GWP of 770 g CO_2-eq, energy use of 9,329 MJ and land use of 32 m^2 per kg dry matter meal. Compared with soybean meal, larvae meal results in lower land use and a higher GWP due to its high energy use. To conclude, larvae production has potential to make livestock diets more sustainable.

Keywords: insects, house fly, larvae, LCA, environment

1. Introduction

A growing and more prosperous world population is demanding for more animal proteins, especially in developing countries (Godfray et al. 2010; Eisler et al. 2014). Livestock production, however, already and will continue to poses a severe pressure on the environment via their emissions to air, water and soil (Tilman et al. 2001; Steinfeld et al. 2006). Moreover, livestock also increasingly competes for scarce resources, such as land, water, and fossil energy (Steinfeld et al. 2006; Godfray et al. 2010). The current sector, for example, uses about 70% of the agricultural land (Steinfeld et al. 2006), mainly for pasture and production of feed crops. Land is scarce and expansion of the area for livestock production leads to deforestation in the tropics, i.e. 80% of new croplands are replacing forest, resulting in losses of ecosystem services, biodiversity and increased carbon emissions (Foley et al. 2007; Gibbs et al. 2010; Foley et al. 2011). Similarly, about 15% of the anthropogenic emissions of greenhouse gases result from livestock production (Gerber et al. 2013), mostly resulting from production and utilization of feed (De Vries and De Boer 2010).

So, there is an urgent need for efficient production of feed for livestock. Using insects as a protein source in livestock feed potentially enables such efficient production, i.e. by more efficient use of natural resources and low emissions to air, water and soil. According to a recent publication of the FAO insects as feed can emerge as an especially relevant issue in the twenty-first century (Van Huis et al. 2013).

Insects possess favorable characteristics: 1) They are highly nutritious and have value as a protein source for livestock (Veldkamp et al. 2012). Insect-based feed products, therefore, can replace conventional feed ingredients with a high environmental impact, like fishmeal and soybean meal (SBM). 2) Insects have a low feed conversion ratio and can be consumed as a whole (no residual materials i.e. no bones or feathers). 3) Insects may offer the possibility to reduce the environmental impact of livestock production. In contrast with feed cultivation, the production of insects is not necessarily land intensive (Van Huis et al. 2013). A further environmental benefit of the use of insects lays in their capability to turn organic waste streams, such as manure, household waste or formal food products, into high quality insect-based feed products (Veldkamp et al. 2012; Van Huis et al. 2013). By feeding waste-fed insects, livestock can be fed less food products that are directly edible by humans, thus reducing the competition for land. As an example, around 70% of the cereal grains used in developed countries is fed to livestock (Eisler et al. 2014). With a rather inefficient feed conversion ratio of livestock – for chicken 1.6, for pigs 2.5 and cattle 5.1 per kg dry matter feed/kg product (Šebek and Temme 2009) – more people could be supported from the same amount of land if they did not consume meat from livestock fed with cereals (Godfray et al. 2010).

Feeding waste-fed insects to livestock, therefore, might be an effective strategy to transform inedible waste streams for livestock and humans into high quality food products, such as meat, milk, and eggs. Already in 1970, Calvert et al. showed that housefly larvae (*Musca domestica L.*) can be used for biodegradation of chicken manure, while Ocio et al. (1979) showed that larvae can grow on municipal organic waste. As tons of manure and food waste are produced in western countries –according to the FAO one third of the food is never consumed (Gustavsson et al. 2011)- feeding insects organic waste streams seems a promising solution for the environment.

To our knowledge no study quantified the reduction of the environmental impact of livestock production by including waste-fed insects in livestock feed. The aim of this study, therefore, was to explore if the environmental impact of livestock production can be reduced by using larvae of the common housefly fed on organic waste streams as livestock feed. Environmental impacts included were land and energy use, and emission of greenhouse gases. Data were obtained from a commercially-exploited testing site that designs a rearing place for 20 tons of larvae meal per day. The larvae were fed with a substrate of poultry manure and food waste.

2. Methods

Life cycle assessment (LCA) is an internationally accepted and standardized holistic method (ISO14040 1997; ISO14041 1998; ISO14042 2000; ISO14043 2000) to evaluate the environmental impact during the entire production chain (Guinée et al. 2002; Bauman and Tillman 2004). An attributional LCA was performed to assess the environmental impact, as we aimed, to analyze the environmental impact of larvae meal in a status quo situation.

2.1. Goal and scope definition

Figure 1 illustrates the production chain of the larvae meal. The system consists of four stages: egg production, larvae production, substrate/feed production for larvae and processing of larvae in order to produce larvae meal. In the egg production stage, pupae are brought into a cage and will eclose into flies within 2 days. Feed of the flies consists of sugar, milk powder and egg powder. Flies are kept at a temperature of 25 degrees Celsius. Female flies start to lay eggs after 7 days in an oviposition substrate, consisting of milk powder, yeast, fiber, vegetable oil and vitamins. Drinking water is provided by a nozzle system and water is used for cleaning. The output of the egg production consists of eggs with the oviposition-substrate. The larvae production stages starts with mixing eggs with the oviposition-substrate with larvae-substrate. Subsequently, larvae are kept at a temperature of 27 degrees Celsius and are full grown after 5 days. The larvae-substrate consists of 195 ton food waste, 65 ton laying hen manure and 1 ton premix. Per 4 kilograms of substrate, one kilogram of larvae is produced. After harvesting the larvae, the cage is cleaned with water. Harvesting of the larvae is performed by shutting off the ventilation, which makes the larvae crawl to the surface of the substrate when oxygen levels drop. Per day 65 ton of live larvae are produced resulting in 20 ton of larvae meal with a dry matter (DM) content of 88%. Besides the larvae meal, 159 ton larvae manure is produced. The larvae manure is not a waste product as it can have different application e.g. as fertilizer. The environmental impact related to the larvae manure was not included in this study. Larvae meal was compared with fishmeal and SBM as both products are protein rich. The functional unit to calculate the impact of larvae meal is one kilogram DM of larvae meal.

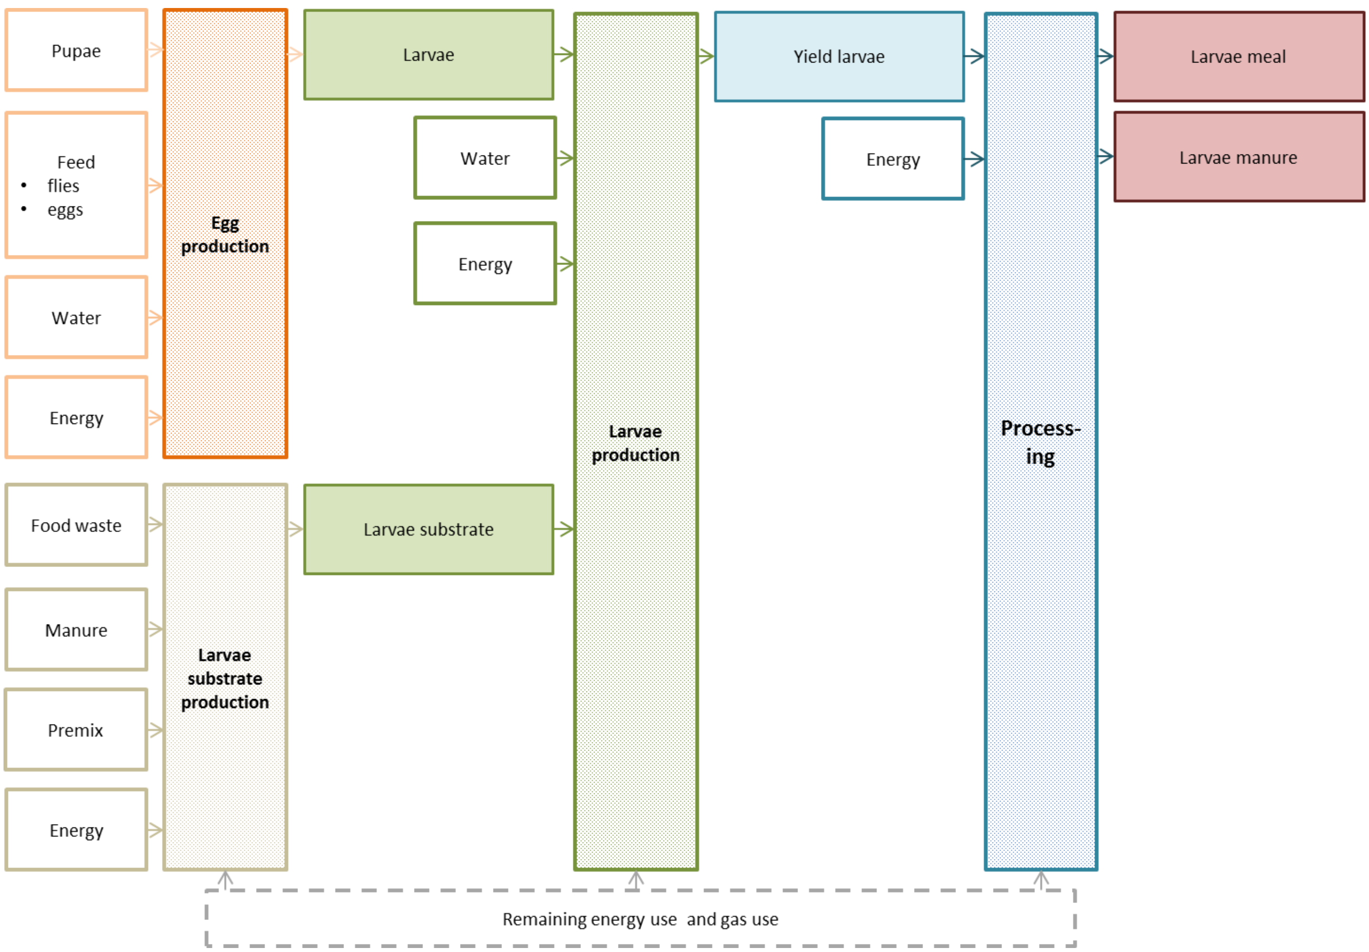

Figure 1. Stages in the production chain of larvae meal

2.2. Data collection

The model, based on experimental studies, is developed by four companies in the Netherlands (an animal nutrition company, Denkavit, two waste processing companies, AEB and SITA and an insect rearing company, Jagran). All data were provided by those four companies and a summary of the data is presented in table 1.

2.3. Measuring environmental impact

The impact categories greenhouse gas (GHG) emissions, energy use (EU) and land use (LU) were assessed. Emission of GHGs, EU and LU were assessed because the livestock sector contributes significantly to both climate change and LU worldwide (Steinfeld et al. 2006) and earlier results of Oonincx and De Boer (2012) demonstrated that insect production is related to high energy use. The following GHGs were included: carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). These GHGs were summed up based on their equivalence weighing factors in terms of CO_2 (100 years' time horizon): i.e. 1 for CO_2, 25 for CH_4, and 298 for N_2O (Forster et al. 2007). Land use was expressed in m^2 per year per kg dm of larvae meal and energy use was expressed in MJ per kg dm of larvae meal. For both, parameters of GHGs, EU and LU and quantitative input data a sensitivity analyses was performed. In case of multifunctional processes, economic allocation was used. Economic allocation is the partitioning of the environmental impact between co-products based on the relative economic value of the outputs (Guinée et al. 2002).

A summary of the input and output data required to maintain the production of larvae meal together with the related impact factors is provided in table 1. The GWP, EU and LU related to the feed for the flies and egg substrate were based on Vellinga et al. (2013) for the production of feed ingredients and on EcoinventCentre

(2007) for the production of tap water. Environmental impact from production of feed ingredients included impacts from cultivation (e.g. fertilizers, pesticides, machinery, energy, emissions related to direct and indirect N_2O and CO_2 emissions from liming and urea fertilization) impacts from drying and processing, and impacts from transport up to the farm gate.

The emissions related to the substrate for the larvae were based on IPCC (2006). According to IPCC, emissions of methane from organic waste occur only after several months. As food waste was used for 4 days only during the larvae production process, we assumed that emissions from organic waste were negligible. During the handling and storage of laying hen manure CH_4 and direct and indirect N_2O were emitted. As there were no specific data available of the use of manure for insect rearing, we assumed emissions for using manure were equal to emissions emitted on a laying hen farm. For CH_4 a tier 2 approach was used based on country specific data of Coenen et al. (2013) and IPCC default values (an organic matter content of 0.35 kg per kg manure, maximum CH_4 producing potential of 0.34 m^3 CH_4 per kg organic matter and a methane conversion factor of 0.015). For direct N_2O emissions a tier 2 approach was used based on country specific data of Coenen et al. (2013) (0.8 kg N excretion per laying hen per year, 18.9 kg manure per laying hen per year and a default emission factor of 0.01). For indirect N_2O emissions a tier 1 approach was used based on IPCC default values (volatilisation 40% and an emission factor of 0.01). The GWP, EU and LU for transportation of food waste and manure over an average of 65 km per day were included, based on Eco-invent (2007). The GWP, EU and LU related to the production of electricity and gas were based on Eco-invent (2007). Electricity was assumed to be substituted with marginal Dutch electricity, i.e. 28% coal-based, 67% natural gas-based, and 5% wind-based electricity (EcoinventCentre 2007). The GWP, EU and LU related to SBM and fishmeal were based on Vellinga et al.(2013).

Table 1. Input data and related global warming potential (GWP), energy use (EU) and land use (LU) data for the environmental impact of producing one ton dry matter larvae meal.

Ingredients	**Unit**	**Amount** /ton (DM)	**GWP** (g CO_2)	**EU** (MJ)	**LU** (m^2)
Feed flies	kg	1	3,808	12.2	1.34
Substrate eggs	kg	17	1,351	3.9	0.34
Food waste	kg	11,079	11	0.2	0.00
Manure	kg	3,693	42	0.2	0.00
Premix	kg	57	1,362	3.9	0.34
Water	kg	10,309	0	0.0	0.00
Electricity	kWh	378	753	11.8	0.01
Gas	kWh	183	586	11.2	0.00

3. Results

Producing larvae meal resulted in a GWP of 770 kg CO_2-eq, an EU of 9,329 MJ and a LU of 32 m^2 per ton DM larvae meal. Figure 2 shows the GWP, EU and LU for different production phase including a sensitivity range of 30%. The egg production phase contain processes like feed and water use. The larvae production phase contains processes like water and substrate use. The electricity for the building contained the complete electricity use and gas for the building contained the complete gas use. The gas for drying the larvae is in this business model obtained from residual heat from a waste incineration plant in which the larvae production is situated. The largest part of the GWP was caused by the feed for the larvae (44%), whereas an additional 37% resulted from the use of electricity and 14% form the use of gas. Electricity and gas use, however, explained the majority of the EU (70%), whereas production of vitamins and minerals in larvae feed explained the majority of the LU.

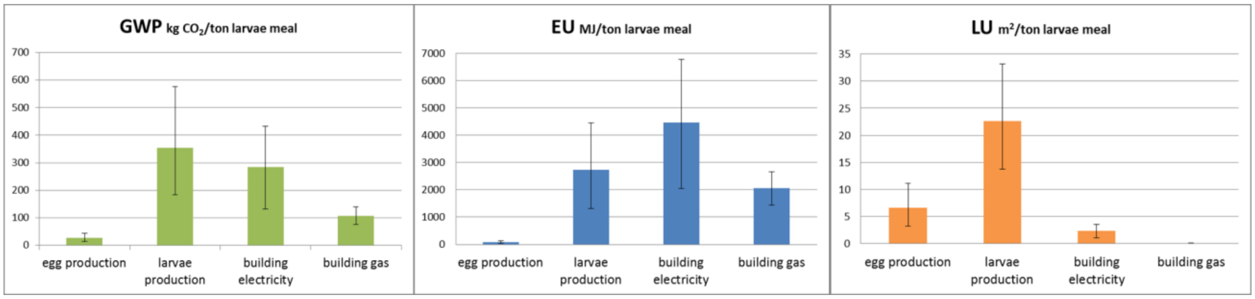

Figure 2. Global warming potential (GWP), energy use (EU) and land use (LU) of each phase of larvae meal per ton dry matter larvae meal, including a sensitivity range of 30%

To compare larvae meal with other protein rich ingredients a comparison of the nutrient content is of importance. Table 2 shows the nutrient content of larvae meal (based on analysis of the commercially-exploited testing site), fishmeal and SBM (CVB 2010).

Table 2. Nutrient content (%) of larvae meal, fishmeal and soybean meal (SBM)

	Larvae meal	SBM	Fishmeal
Dry matter	88.0	87.5	92.7
Crude protein	47.9	46.0	56.7
Fat	24.2	18.4	15.8
Lysine	32.6	28.5	43.1
Methionine	11.3	6.4	15.9

Figure 3 shows a comparison for the average GWP, EU and LU with other protein rich feed ingredients. The production of larvae meal and fishmeal results in high EU affecting the GWP but are not land intensive like SBM.

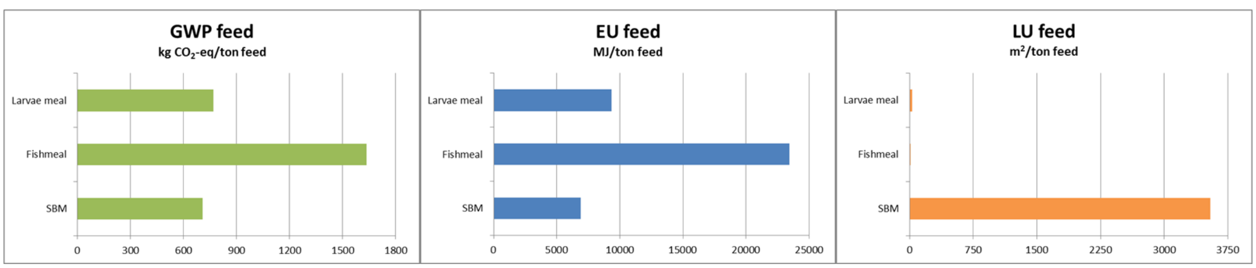

Figure 3. Comparison of global warming potential (GWP), energy use (EU) and land use (LU) of larvae meal, fishmeal and soybean meal (SBM) based on ton dry matter feed

4. Discussion

The results of this conference paper show the direct environmental impact of larvae meal production. Production of larvae meal, however, also resulted in indirect environmental consequences. The human food waste which was used to grow insects can be used for different application e.g. composting or production of biogas. The indirect environmental consequences of replacing another potential application of waste used for insects, therefore, should be considered as well. Just as the possible applications of the larvae manure. The larvae manure can, for example, be used as fertilizer or for biogas production. Further research on the indirect environmental impact is, therefore, required.

The range of GWP, EU and LU is based on a sensitivity analysis in which the values of GWP, EU and LU and quantitative input data were decreased and increased with 30%. Varying the values of emissions was required as some processes are uncertain. The most uncertain factor were the emissions related to the larvae substrate. Calculation of emissions were based on IPCC guidelines for manure and composting of food waste. We assumed that emissions of food waste were negligible as according to IPCC emissions of composting only occur after several months (IPCC 2006). Even though food waste is used for only 4 days, the circumstances for composting were favorable due to high temperatures and constant ploughing by the larvae. Un underestimation is, therefore, possible. Furthermore, IPCC calculations for manure were based on emissions related to the complete laying hen sector and not only for the storage of manure and, therefore, possibly resulting in an overestimation. To minimize the uncertainty experimental studies are required.

The nutrient content of larvae meal was determined on basis of only two samples. However, a literature review of Veldkamp et al. (2012) shows similar outcomes: larvae contain 43-68% protein and 4-32% fat on a dry matter basis. The protein content of insects is within the fishmeal and SBM range and its fat content is higher (Veldkamp et al. 2012).However, in vivo animal studies are required to determine the palatability, digestibility and other relevant characteristics of the larvae meal before a reliable comparison with fishmeal and SBM can be made.

In this study, we found that electricity use per kg DM of larvae meal was 4.46 MJ an gas use was 2.05 MJ. For mealworm production, a high electricity and gas use was also found. Oonincx and De Boer (2012) found an electricity use of 15.8 MJ and a gas use of 26.0 MJ per kg of DM mealworms. These values are thus higher than that of the production of housefly larvae, which is caused by a longer production cycle of mealworms (10 weeks instead of 5).

The production of larvae uses high amounts of energy due to the required ambient temperature. One should, however, take into account that the required energy use is an estimation and the bio-efficiency of the industrial process to acquire larvae meal is still advancing. However, the high cost price and institutional barriers (EU-legislation, health concerns etc.) are issues that should be overcome before an insect-based business model can be exploited (Veldkamp et al. 2012; Van Huis et al. 2013).

5. Conclusion

Energy use was the main contributor to the direct environmental impact of larvae meal production, however, the industrial process to acquire larvae meal is still advancing. Compared with fishmeal, larvae meal resulted in a lower GWP and EU and a similar LU. Compared with SBM larvae meal resulted in a higher GWP and EU but a lower LU. Two of the main production factors, land and fossil energy, are scarce. However, fossil energy can be replaced by more sustainable sources, i.e. solar- and wind energy, that reduces the GWP, while there is no practical solution for the scarcity of land. Therefore, we conclude that in the future larvae production has the potential to contribute as a more environmentally sustainable livestock feed.

ABSTRACT

European pilchard (*Sardina pilchardus*) is a commonly purchased species in Portugal and Spain, since it constitutes a cheap and healthy source of protein. Therefore, numerous final products are commercialized based on this same raw product. The current study presents a cross-product environmental analysis using Life Cycle Assessment (LCA) for three different final consumer-purchased products based on European pilchard landings in Galicia (NW Spain): canned pilchards, fresh pilchards and European hake caught in the Northern Stock using pilchard bait. Furthermore, the entire life cycle of the products were considered, including a series of different cooking methods for each final product. The midpoint and endpoint results obtained showed important differences in the final environmental impacts between the products, with the different cooking methods also appearing to be a crucial source of uncertainty. The results are analyzed regarding relevant limitations, uncertainties and consumer and policy implications through the use of Mixing Triangles.

Keywords: canning industry, consumption patterns, LCA, Mixing Triangle, seafood

1. Introduction

Iberian countries (i.e., Portugal and Spain) are among the few countries in the world in which protein supply for human consumption associated with the intake of seafood products represents over 20% of the daily protein intake of animal origin (FAO 2012). More specifically, European pilchard (*Sardina pilchardus*) constitutes an attractive seafood product in Spanish and Portuguese households. For instance, the annual per capita consumption of pilchard in Spain is currently around 2.1 kg, only behind tuna and hake products in terms of seafood products (Martín-Cerdeño 2010). Pilchards are usually consumed fresh in the summer months (June to early October) due to their higher levels of fat in this period, improving their taste and aroma (Zlatanos and Laskaridis 2007). During the rest of the year, however, most of the landed pilchard is used mainly for the canning industry or as bait in demersal fisheries. In 2009 a total of nearly 30,000 metric tons of pilchards were canned in Spanish territory, of which approximately 80% was canned in Galicia, a region in NW Spain known for its seafood industry (ANFACO 2011).

Independently of the current overexploitation of the European pilchard stock off the coast of Portugal and NW Spain or the natural fluctuations that this species presents from one year to another, the environmental impacts linked to the operation of the fishing fleet that captures pilchard has historically been ignored. However, the landing, processing and consumption of seafood products has shown to be a relevant source of greenhouse gas (GHG) emissions, due to the intensive energy use in the fishing and canning sectors (Hospido et al. 2006; Vázquez-Rowe et al. 2013). Therefore, an increasingly used methodology to monitor in an integrated manner a range of environmental impacts linked to anthropogenic activities, including fishing, is Life Cycle Assessment – LCA (ISO 2006a). In fact, this method has been used in several recent publications to understand the main environmental dimensions that are affected by fishing activities and their derived supply chains (Vázquez-Rowe et al. 2012).

The main aim of the current study was to understand the environmental impacts using an LCA perspective associated with the entire life-cycle of a selection of three seafood products available for Spanish consumers in supermarkets and other retailing stores derived from the landing of European pilchard. The latter raw material was monitored based on landings performed by Galician purse seiners. However, beyond these particular landings, a cross-product analysis was performed based on an equal amount of protein supply at the plate of the consumer, with the aim of analyzing the variable environmental impacts linked to different processing and/or consumption routes for one single raw product.

The described goals intend to provide support for decision-making at a company level throughout the supply chain, as well as a starting point for the evaluation of integrated policies for the reduction of environmental impacts in the food sector. Finally, the results will also guide consumers in terms of responsible consumption of seafood products (González et al. 2011).

2. Methods

2.1. Goal and scope definition

The main function of the production system is that of nourishing human communities with a specific amount of protein content (an essential part of human diets) embedded in seafood final products (Pimentel and Pimentel 2003). However, in this specific study a comparison is provided between three different final products at the retailing center for the consumers to purchase, but deriving from one single raw product: European pilchard. Hence, the functional unit (FU) selected was fixed as the amount of protein available (17.26 g) in *Scenario A*, that is, a can of pilchards in olive oil (85.0 g) produced by a Galician canning factory. For the alternative scenarios, the same amount of protein available for the consumer was considered. Therefore, in *Scenario B* a total of 137 g of fresh round pilchard were assumed ready for intake. Similarly, in *Scenario C* the consumers' final intake is 183 g of European hake landed by Galician long liners. However, in the latter scenario it should be noted that this hake is captured using pilchard as bait (75.2 g per FU), which justifies its comparability with the previous scenarios.

2.2. System description

Figure 1 presents a schematic representation of the different subsystems included in the life-cycle of each scenario. Subsystem I comprises the fishing activities to capture and land pilchard and, therefore, is common to all scenarios together with Subsystem II, which includes the auction and port activities. In contrast, Subsystem III only applies to Scenarios *A* and *C*, since *Scenario B* does not include a processing stage (the pilchard is consumed fresh). For the former, Subsystem III comprises the entire processing of the canned pilchard, including the reception and storage of the raw pilchard, cutting and canning of the cleaned pilchard, cooking and the addition of more ingredients (i.e. olive oil and salt), sterilization, packaging and, finally, the distribution of the processed product to the regional distribution center. For *Scenario C*, however, this subsystem is associated with the processing, freezing and distribution of pilchard in the form of bait to supply the Galician long liners, as well as the fishing stage, auction and port activities for the hake landings. Subsystem IV comprises the wholesaling and retailing of the different products, which are thereafter consumed in Galician households (Subsystem V). Moreover, Subsystem V also includes the end-of-life (EOL) activities of the different materials used throughout the supply chain that are disposed of by the consumer (e.g., tins, packaging, organic residues…). Finally, Subsystem VI deals with the human excretion phase based on the assumptions available in Muñoz et al. (2008).

2.3. Data acquisition

Data for the European pilchard fishery were retrieved from a previous study developed by Vázquez-Rowe et al. (2010) that analyzed the Galician purse seining fleet from an LCA approach. Landing and auction activities were inventoried based on data disclosed by the port of Vigo (Autoridad Portuaria de Vigo, personal communication, September 2010). For the processing stage, data for the canning factory were obtained from a canning factory located in *A Coruña* province. This factory destines 95% of its production efforts to deliver canned pilchard. For the baiting data, however, data were delivered by a bating SME located in *Lugo* province. In addition, European hake landings were obtained from a study undergone by Vázquez-Rowe et al. (2011) that analyzed hake landings by Spanish vessels in the North Atlantic. Finally, the remaining inventory data were retrieved from a wide range of bibliographical sources, including the ecoinvent® database, from which background data for most inventory items were modelled (Frischknecht et al. 2007).

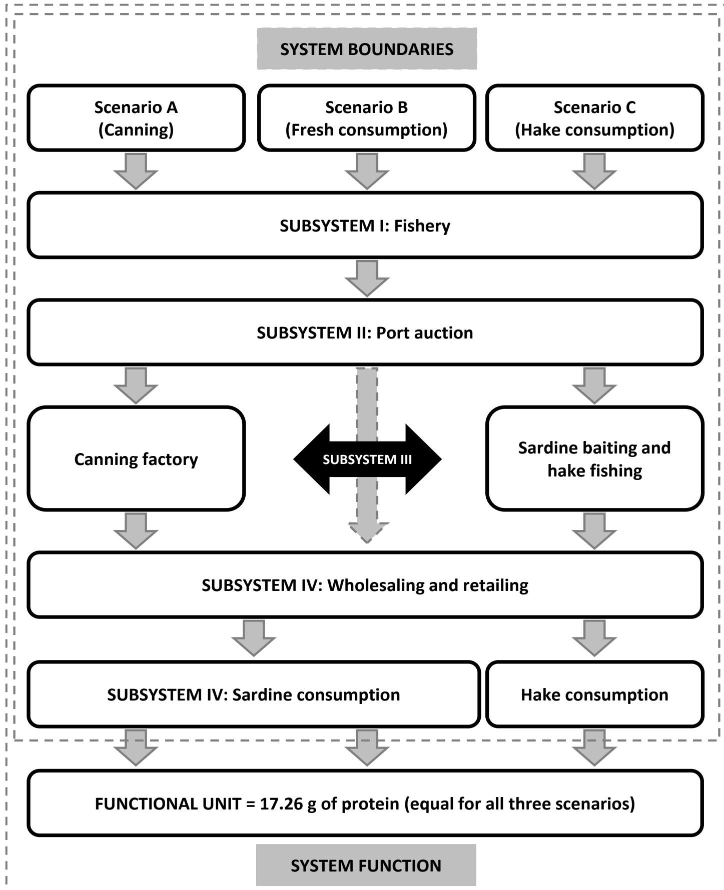

Figure 1. Schematic representation of the analyzed production systems.

2.4. Life Cycle Inventory

The Life Cycle Inventory (LCI) consists of the organization and structuring of the data collected to perform the LCA (ISO 2006b). Table 1 presents a summarized LCI for the three subsystems.

2.5. Allocation and other assumptions

Two different allocation approaches were considered throughout the supply chains analyzed. On the one hand, allocation was identified as been necessary in Subsystem I, since pilchard is captured in a multispecies fishery together with Atlantic mackerel or horse mackerel (Vázquez-Rowe et al. 2010). As recommended by ISO 14044 and the PAS 2050 appendix for seafood products, mass allocation was selected with the aim of accounting for the physical relationship between co-products (ISO 2006b; BSI 2012). On the other hand, in *Scenario A* an important intermediary residue is generated in the canning factory: the portion of the life weight of pilchards that is not used in the cans (141 g per FU). For this particular co-product scenario, three different allocation approaches were used in the three alternative situations considered for *Scenario A*: i) economic allocation based on economic revenues in the canning plant; ii) economic allocation considering economic savings in the factory; iii) energy allocation, which takes into consideration the final amount of protein that the residues provide to humans diets when used for reduction and aquaculture feeding.

2.6. Life Cycle Impact Assessment

Results computation was performed using the SimaPro software, version 7.3 (Goedkoop et al. 2010). The selected assessment method to calculate the final midpoint and endpoint results was ReCiPe (Goedkoop et al. 2009). For the endpoint results the hierarchist approach was selected.

3. Results

The total endpoint single score environmental impacts identified in *Scenario A* ranged from 0.52 to 0.58 Pt depending on which of the three residue allocation perspectives was selected, representing a maximum variability of only 11%. The canning stage (Subsystem III) accounted for 91% of the total endpoint impacts, while the fishery (4%) and the remaining subsystems (6%) only accounted for a minor part of the overall impacts. *Scenario B*, in contrast, was identified as the scenario with lowest environmental impacts per FU, 90%-95% lower than those found for *Scenario A* and 70%-83% lower than those for *Scenario C*. Nevertheless, important differences were detected depending on the way in which the fresh pilchards had been cooked in the consumer stage. More specifically, the overall environmental impacts of preparing pilchards on a barbeque (i.e., grilled) were quantified at 2.93E-2 Pt, 45% lower than those linked to the consumption of fried pilchards. In this scenario the main contributor to the overall environmental impact was the fishery stage (45%), followed by the consumption subsystem (24%) and wholesaling and retailing (15%) whenever the pilchards are grilled. However, if the pilchards are fried the consumption stage becomes the main contributor (57%), followed by the fishery stage (25%). Finally, the impacts related to *Scenario C* add up to 1.80E-1 Pt if the hake is fried or 1.75E-1 if the hake is boiled. Impacts in this scenario are dominated by the fuel use intensity of the long lining fleet in Subsystem III and, to a lesser extent, to the fuel combustion in the purse seining fleet and in terrestrial transport.

The impact categories that dominate the majority of the processes analyzed were fossil depletion, climate change and particulate matter formation, demonstrating the high reliance on fossil fuels of the processes analyzed, independently of the scenario. Midpoint results for the three scenarios are shown in Table 2.

Table 2. Total environmental impacts per scenario reported per functional unit (ReCiPe midpoint).

4. Discussion

Environmental impacts in *Scenario A* are strongly influenced by the operations occurring in the canning stage (Subsystem III). The combustion of fuel-oil, the use of packaging materials or the impacts related to the life-cycle of olive oil are all important contributors in this stage. However, the production and use of tin for canning is the main source of environmental impacts, especially in terms of climate change and fossil depletion. Tin impacts, that were modelled according to the ecoinvent® database, are known for the high degree of uncertainty (Classen et al. 2007). Having said this, in the current study these uncertainties were minimized by including recent recycling rates for tin in Spain. Therefore, it is quite obvious, as pointed out in previous studies (Hospido et al. 2006), that a change in the container for canned pilchard could be a convenient improvement action, as long as this measure does not imply a burden in sales due to consumer preferences (Calvo 2013).

The use of olive oil in the cans also presented high environmental impacts, although in this case the impacts were fairly evenly distributed between different stages of production (fertilizers, pesticides, refining, etc…). Hence, integrated minimization of impacts schemes will be necessary in the olive oil producing sector to reduce impacts in this particular operation (Iraldo et al. 2014). Finally, the fuelling of the fishing vessels, especially in Scenario C, in which the long liners constitute an important source of environmental impacts, was also identified as a main carrier of environmental burdens. Consequently, appropriate fuel optimization schemes or changes in the energy carrier of the vessels should be analyzed (Bengtsson et al. 2012).

Comparison for the different supply chains monitored in this study was performed with care, since there are some methodological issues that must be taken into consideration. For instance, there are a series of characteristics, such as the shelf life of the products, or the food waste they generate throughout the chains that can vary enormously. However, the lack of data and the assumption that the supply chains were centered in Galicia, a coastal region in which the arrival of fresh fish is done on a daily basis (unlike other landlocked areas in which the shelf life of fresh seafood is reduced considerably) manages to minimize the effect of this issue. Figure 2 shows the direct endpoint single score environmental impacts for each of the processes analyzed, showing a clear dominance of *Scenario A* (all three alternatives) in terms of overall environmental burdens. Nevertheless, it should be noted that the methodological assumptions regarding allocation in the canning phase imply considerable final impacts, although not sufficient to reduce the impact of canned pilchard to the level of Scenarios *B* or *C*. Consequently, it appears that the consumption of the three main ways in which the pilchard raw material is finally consumed by the general public presents three completely different patterns in terms of environmental burdens: i) *Scenario A* presents a high energy use in the processing stage, due to the use of different packaging material -namely tin- as well as the use of electricity and logistics; ii) *Scenario B* presents a very low environmental impact, which is in line with the fresh consumption of other small-pelagic fish (Ramos et al. 2011; Avadí et al. 2014); and iii) *Scenario C* presents a high energy intensiveness, which implies that the final environmental profile of consuming hake is among the highest in the literature (Vázquez-Rowe et al. 2012; Avadí and Fréon 2013).

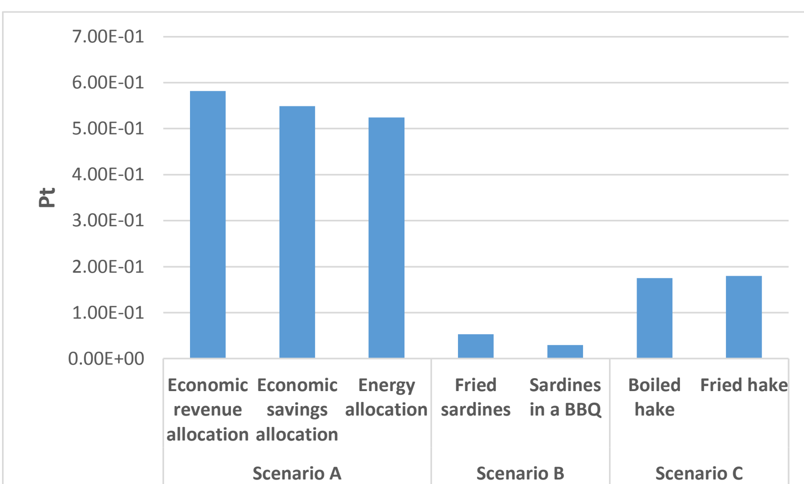

Figure 2. Endpoint single score environmental impact results for the selected scenarios (assessment method: ReCiPe endpoint H/H).

While the results when analyzed in subsystems do not show major surprises in terms of environmental impacts as compared to previous studies available in the literature, to the best of our knowledge the current study is the first attempt to follow the entire life-cycle of seafood products, including consumption, EOL of wastes and human excretion providing an extended view of a variety of different supply chains based on pilchard extraction. Interestingly, the cooking, consumption and EOL stage of the different products in households did not appear to be a major factor affecting the comparability of the three scenarios. However, whenever each scenario is analyzed depending on cooking options, the preparation of fried fresh hake or pilchard showed increased environmental impacts than when other cooking options were considered, such as grilling or boiling, demonstrating that consumer behavior can also have an important impact on the final profile of the products (Vázquez-Rowe et al. 2013b).

Having said this, it is important to highlight that the comparison between cooking methods was done with a fixed weighting of damage categories. Hence, the ReCiPe hierarchist single score values reported in this study imply a 40% weighting of ecosystem damage categories (land use and toxicity categories, together with acidification and climate change), 30% for human health categories (which include climate change (partially, ozone depletion or human toxicity) and 30% for resources (mineral and fossil depletion). However, the use of the MIXTRI 2.0 model, developed by Doka (2011) was selected in order to analyze how different weighting possibilities may lead to variable final results (Hofstetter et al. 1999). In fact, given the high use of energy in the fisheries and transportation stages of the systems analyzed, as well as the use of important amounts of tin in the canned pilchard processing phase, it is arguable that the resources damage category should be weighted higher. Hence, Figure 3, using an uncertainty interval of 35% due to the numerous assumptions considered and described in section 2, represents the Mixing Triangles for Scenarios *B* and *C*. In the first place, the results for *Scenario A* show dominance for the energy allocation perspective. While this is barely surprising due to the allocation assumptions included in each perspective, implying that lower values of inputs and outputs are allocated to most of the processing stage in the energy perspective, the results do confirm the importance of methodological assumptions. However, these results were not represented in Figure 3 since they do not represent different consumption pattern options. Secondly, for fresh consumption of pilchard, the triangle showed complete dominance of grilled pilchard despite the high uncertainty range considered. Finally, for *Scenario C* the results showed that the relative dominance of boiled hake is highly constrained by the different sources of uncertainty underlying the calculations. While the results presented in the Mixing Triangles do not provide any further findings, they do demonstrate the strong dominance in environmental impacts for certain consumption patterns of one single raw product and consumer behavior trends. Consequently, beyond the relevant findings in terms of improvement actions that can be undergone in the different production systems, these results could be potentially used to drive consumer awareness policies by policy-makers with the aim of improving the environmental sustainability of human diets.

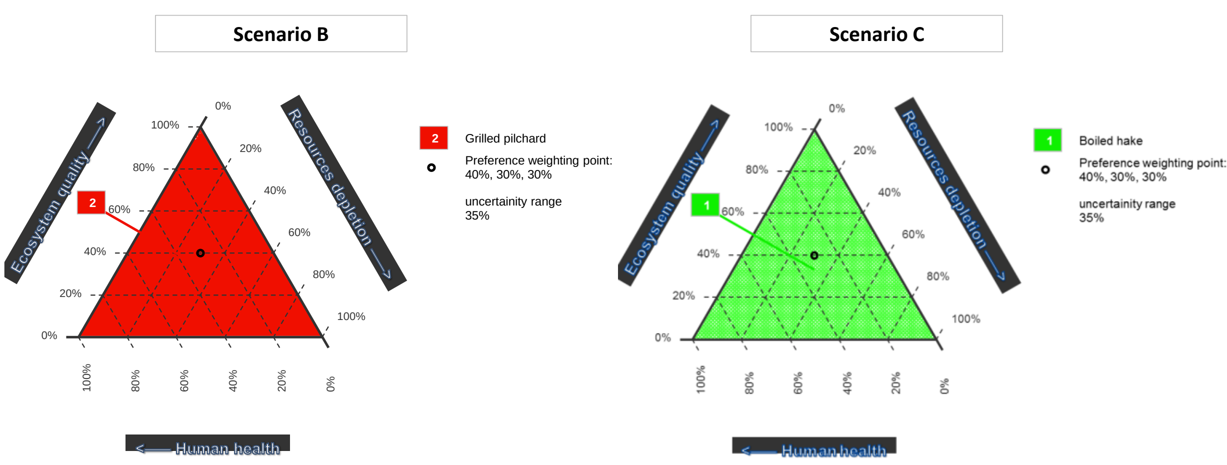

Figure 3. Weighting triangle matrix for different spreading techniques in Scenarios *B* and *C*.

5. Conclusion

The results presented in this study suggest that consumer choices in terms of how to intake a specific raw material can have important consequences on environmental impacts. For instance, the consumption of fresh round pilchard implied environmental impacts up to 95% lower than if the pilchard is consumed in cans. In addition, as pointed out in a previous study by Vázquez-Rowe et al. (2013b), cooking methods can also determine to a great extent the amount of environmental impact produced by the analyzed system.

Therefore, we argue that the analysis of the entire life-cycle of seafood products can provide important additional information for policy-makers, retailers, processors and consumers regarding sustainable seafood consumption patterns. In other words, while the extraction of a specific raw material can drive the main environmental profile of a final product, the on-land stages can also have an important role when it comes to mitigating or augmenting the final footprint of these products.

Nevertheless, future research should focus on analyzing these patterns at a broader scale -including the complex wholesaling and retailing networks that occur in the seafood sector- as a way to steer upcoming seafood and general food policies, as well as increasing awareness among consumers regarding the important role that their decision-making can have on the final environmental impact of seafood products.

ABSTRACT

Land use changes (LUCs) are an important source of environmental changes in production systems, especially in the agricultural sector, where LUCs have been found to be a relevant factor to take into consideration when analyzing greenhouse gas (GHG) emissions. The viticulture subsector, as part of a broader agricultural sector, is not alien to the problematic of GHG emissions and climate change. Spain, as one of the main producers of wine worldwide, but also due to the important legislative and productive changes that have occurred ever since it joined the European Union, plays an important role in the analysis of how LUCs linked to the viticulture sector have effects on the environment. Therefore, in the current study we examined the LUCs that have occurred in the Ribeiro appellation in NW Spain between 1989 and 2009. For this, GIS was used to map the gradual dynamic changes on an annual basis of the areas used for wine production. Thereafter, the different land uses that substituted or were substituted by vineyards were identified in order to calculate the carbon storage and carbon emission dynamics based on the IPCC guidelines. Finally, operational activities linked to viticulture, including changes in technology over time, were added to the model in order to obtain a broad picture of entire impact of viticulture in terms of GHG emissions. The results present an interesting pattern, with GHG emissions linked to LUCs steadily decreasing in the timeframe analyzed. Similarly, the improvement of machinery, the reduction on fossil dependency in the Spanish electricity mix and the stricter use of specific standards for the use of plant protection agents also contributed to a gradual decrease in GHG emissions per functional unit (i.e. 1 ha of cultivated vineyards). These results are aimed at providing the appellation and other appellations throughout with environmentally relevant information regarding how different factors influencing their change through time can be analyzed to give support in policy making and decision making at a business level.

Keywords: appellation, dynamic LCA, land use changes, Life Cycle Assessment, viticulture.

1. Introduction

Wine production in Spain and other Mediterranean countries constitutes an important source of income in many rural areas. In fact, Spain is the country in the world with the highest surface area destined to wine production, even though the final gross productivity is still higher in Italy and France. In addition, the increasing interest in wine tasting worldwide, together with the limitations in wine-growing enforced by the Common Agricultural Policy of the European Union, have produced important changes in the sector since the early 1990s. In the first place, an increasing number of wine producing regions have clustered in appellations, in order to increase the visibility of the wine produced abroad, as well as to create a series of standards of production. This has led to higher level of technological improvements in the appellations, as compared to subsistence practices used until the mid-1980s. Secondly, most rural areas in Spain have suffered important demographic losses in the past 30 years, due to a wide range of factors, which include urbanization and the impact of the new European agricultural policies. Finally, changes in the wine consumption market, which is now targeted to a more educated wine taster, in which the wine product is no longer a companion of a meal, but a quality product in itself, have also led wine-growers to change the markets they serve and the way in which wine products are presented.

All these factors that have been briefly described have derived in important changes in the landscape of numerous appellations across Spain, with a gradual decrease in surface area destined to wine making, but with more intensive practices and with a higher level of appellation control in terms of operational practices (e.g. use of plant protection agents or application of fertilizers) on the individual wine-growers. In addition, these changes in landscape have also created changes in two important spheres. On the one hand, on the land use changes (LUCs), an issue that has been identified by the IPCC as an important generator or inhibitor of greenhouse gas (GHG) emissions, depending on the direction of the LUC. Hence, the substitution of agricultural land by forestry is most likely to create conditions for carbon storage, not only from an aerial perspective in the vegetation, but also due to the enhancement of the storage capacity of the soil (Williams et al. 2011). On the other hand, technological improvements and changes in the use of materials in the viticulture sector have also occurred in the past two decades. For instance, the trellis, which was traditionally constructed with wood, has been gradually substituted by other materials through time, such as granite slabs, and more recently, slate slabs or galvanized iron.

Based on these on-going trends in the sector, the main aim of this study is to understand from a timeline approach how these changes are affecting the environmental profile of wine produced in a selected appellation in NW Spain: *Ribiero*, located in the autonomous community of Galicia. The selected method for this analysis was Life Cycle Assessment (LCA), an internationally standardized assessment method that provides, based on detailed inventories with a life-cycle approach, an integrated analysis of different environmental dimensions, such as climate change, toxicity or use of resources among others (ISO 2006a). Therefore, LCA is used to monitor the changes in the environmental profile of *Ribeiro* wine from a timeline perspective from 1989 to 2009, with the aid of GIS mapping and the IPCC guidelines, in order to understand the evolution of its environmental burdens and to analyze the implications it may have in future policy making and decision making at a business level.

2. Methods

2.1. Goal and scope of the study

The main goal of this study was to understand the environmental profile of wine production in the *Ribeiro* appellation in the period 1989-2009. The selected functional unit (FU) for this case study was fixed as 5380 ha of land. This choice of FU is based on the fact that this was the entire land surface that was destined to wine production in the period 1989-2010. In other words, all land used for viticulture in this period was included within the system boundaries, regardless of the fact that either this land may have changed land use during this period, or that at the beginning of the period (1989) the land had a different use other than viticulture. This choice of a land FU is based on the lack of data regarding the yield on a temporal basis. Moreover, even if it were available, it would be subject to interannual changes due to natural fluctuations in yield. Therefore, the FU that was finally used serves as an adequate proxy to determine the changes in environmental impact in the appellation in the past two decades.

The system boundaries of the study included, as aforementioned, the entire surface destined to viticulture in the appellation, regardless of any LUC that may have occurred in the timeline under analysis. Based on this geographical boundary, that includes a total of 5380 ha, the biogenic carbon interactions on-going on an annual basis were monitored based on the IPCC guidelines for monitoring carbon release and/or storage due to LUCs. In addition, the entire life-cycle of viticulture activities, such as the production and use of fertilizers and plant protection agents, the use of trellis, machinery and operational activities in the vineyards, as well as the final harvesting activities up to the gate of the vinification plant, were included within the boundaries.

2.2. Data acquisition and IPCC guidelines

Data were obtained from a wide range of sources. In the first place, data on LUCs changes in the appellation were obtained from land use maps purchased from the Spanish Ministry for the Environment. These maps were only available for the period spanning from 1989 to 2009 and, therefore, guided the final time delimitation (see Table 1). Secondly, based on these LUCs, the IPCC guidelines for LUCs were taken into consideration to monitor which land use dynamics had a positive impact on carbon storage, or whether these changes were actually contributing to carbon emissions, as depicted in Table 2 (IPCC 2006). In addition, data for operational activities of vineyards in the appellation were retrieved from previous LCA studies analyzing the appellation (Vázquez-Rowe et al. 2012; 2013; Villanueva-Rey et al. 2013). Finally, data on trellis appeared to suffer major changes in the past two decades. Therefore, the appellation authorities provided guidance regarding changes in trellis materials in vineyards over time (DO Ribeiro, 2014, personal communication).

2.3. Life Cycle Inventory

The Life Cycle Inventory (LCI), as explained briefly in the previous section included LCI data for the appellation used in prior studies (Vázquez-Rowe et al. 2012; 2013; Villanueva-Rey et al. 2013). However, it was important to adapt the operational activities to the entire extent of the period analyzed in two different steps. On the one hand, contacts were made with stakeholders in the appellation in order to understand the operational changes, including machinery, use of fertilizers and plant protection agents. Moreover, specific data were disclosed by the appellation authorities linked to historical data on trellis and use of pesticides. On the other hand, once these data were structured correctly, and inserted in the software selected (i.e., SimaPro v8.0), background processes supporting these data were adapted to the different years of assessment. For this, the electricity mix for Spain was modelled for all years of analysis and inserted into the software, in order to link each production process (i.e., production of fertilizers, pesticides, etc.) to the most appropriate electric profile (see Table 3). In addition, similar processes were done regarding machinery and the use of fossil fuels.

Table 3. Electricity mix profile for Spain in selected year of assessment. Data reported per 1 kWh.

2.4. Allocation assumptions

The function of the analyzed system was not linked directly to a specific final product, such as harvested grapes or wine bottles. Moreover, it is important to consider that numerous additional products, co-products or residues are formed throughout the winemaking process. However, given the surface-based perspective and the limitation of the system boundaries to the viticulture stage of wine production, the derived environmental impacts were not disaggregated between different material flows. Hence, allocation between co-products was not necessary.

2.5. Life Cycle Impact Assessment

ReCiPe is the assessment method selected for the computation of the environmental impacts. The rationale behind this selection is due to the vast range of environmental impacts that it considers and the possibility of providing a single score weighted endpoint average for the results, which allows tackling priority impact categories based on the values obtained.

3. Results

While the results for this study are still under computation, and will be presented in full at the LCA of Foods 2014 Conference, at this point in the analysis is was possible to anticipate to a certain extent some of the main drivers of environmental impact in the appellation under study. On the one hand, as can be observed in Figure 1, the biogenic GHG emissions for the appellation were computed based on the IPCC guidelines for the entire assessment period. The results show a steady tendency toward a higher potential of carbon storage in the appellation as surface land destined to viticulture decreases. In fact, by year 2008 the carbon storage potential of the land was found to be superior to the biogenic GHG emissions occurring in the area studied.

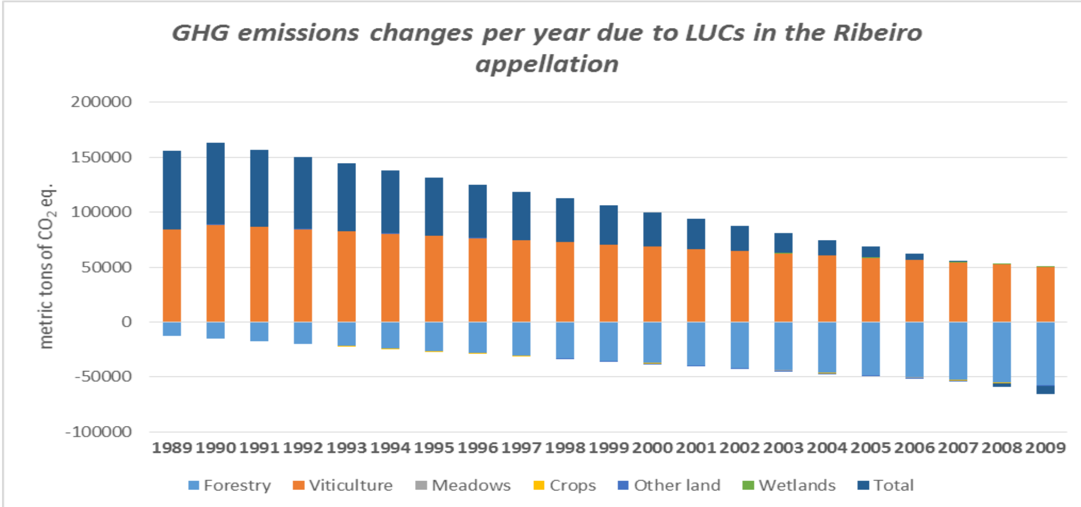

Figure 1. Biogenic greenhouse gas emissions (metric tons of CO2eq) and storage potential of the *Ribeiro* appellation in the period 1989-2010 (Results referred to the FU).

A second issue of interest, was the analysis of the electric mix evolution in Spain in the timeframe analyzed (see Figure 2). As can be seen below, the GHG emissions associated with the production of electricity in Spain ranged from 0.5-0.6 kg CO_2eq per 1 kWh between 1989 and 2005, depending mainly on the proportion of coal used for electricity production, as well as on the hydroelectric power available. However, in 2005, led by the increase in installed power of some renewable energies, namely wind power, but also photovoltaic to a lesser extent, and to an important reduction in the use of coal, the GHG emissions associated with the production of 1 kWh of electricity were down to 0.3-0.45 kg CO_2eq for the period 2009-2011.

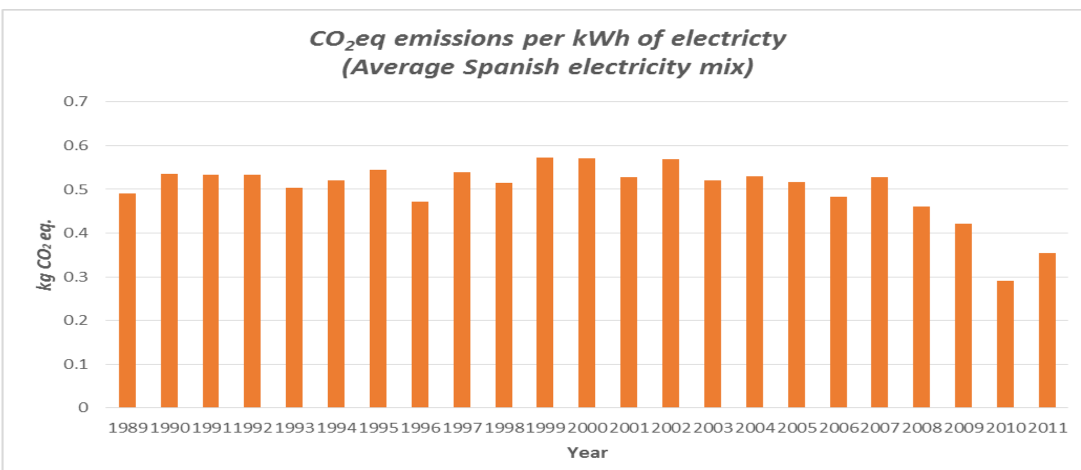

Figure 2. Greenhouse gas (GHG) emissions per kWh produced in the Spanish electricity mix (1989-2011). Data referred to 1 kWh produced, including pumping and international exchanges.

4. Discussion and conclusions

The partial results presented in this paper demonstrate substantial increases in carbon storage in the *Ribeiro* appellation in the past two decades due to LUCs. This is attributable to the lower surface area destined to winemaking, a phenomenon that can be linked to the demographic crisis in the area, but also to a more specialized and technological production system, in which the average producer cultivates more viticulture land than in the late 80s. While these results can seem positive, it is also important to bear in mind that most of the land that has been abandoned in the past 20 years has not received adequate management, but has been absorbed without any human monitoring by the surrounding habitat conditions. Therefore, risks linked to forest fires, as well as a lack of understanding of the optimized carbon storage potential of abandoned land, are two issues that remain essentially unexplored.

In this preliminary analysis of the results, and based on the results gathered in Figure 2, it may appear that the anthropogenic GHG emissions regarding electric production in Spain would also contribute to enhance the trend shown by biogenic emissions. However, this interpretation can be highly biased due to the increase in technological use in viticulture activities. Therefore, while the total GHG emissions per kWh have decrease in this period, especially linked to the higher proportion of renewable energy in the mix (mainly wind power) in recent years, viticulture practices are also using more energy intensive materials in trellis (e.g. concrete or granite slabs, rather than *Acacia dealbata*) or fertilizers (more widespread use of inorganic fertilizers in recent years).

While this results are still partial and preliminary, they do present some promising tendencies for the environmental profile of the appellation. However, numerous issues remain open from an LCI and LCIA perspective. In the first place, the uncertainties in the LCI appear to increase as we go back in the year of assessment, linked to the increasing difficulty to retrieve data. Secondly, the preliminary results advances in this paper have also focused on GHG emissions, ignoring other impact categories used in ReCiPe. While this decision is justified in the fact that both energy and land use are of extreme importance in the assessment of climate change, future updates of this work will have to analyze in depth the trade-offs between impact categories linked to the dynamic changes occurring in the appellation.

Finally, while the results presented already allow certain interpretations from a policy-making approach, the expected final outputs of the study will permit a broad discussion on how different policy decisions can steer the dynamic environmental impact changes in the near future.

ABSTRACT

Research on the sustainability of capture fisheries has focused more on environmental and economic sustainability than on social sustainability. To assess social sustainability, relevant and important social sustainability issues (SSIs) need to be identified. The objective of this study was to identify relevant and important SSIs for cod and haddock fisheries in the northeast Atlantic based on two stakeholder surveys. The first survey resulted in the identification of 27 relevant SSIs that were ranked in order of importance in the second survey. Results show that worker safety, product freshness and companies' salary levels are the most important SSIs. Results on the relevance and importance of SSIs enable the industry and policy-makers to direct improvement efforts towards the more important SSIs.

Keywords: social issues, stakeholders, capture fisheries, working conditions, fish welfare

1. Introduction

Sustainability of food production was firmly put on the research agenda with the release in 1987 of the Brundtland report on sustainable development entitled 'Our Common Future' (Brundtland 1987). Sustainable development was defined in this report as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." This definition captures notions of human needs (economic sustainability), equity concerns (social sustainability) and the carrying capacity of our planet (environmental sustainability).

Research on social sustainability has mainly concentrated on the inclusion of the social dimension in LCA (Benoît-Norris et al. 2011, Dreyer et al. 2006, Hunkeler 2006, Kruse et al. 2009, Norris 2006, Weidema 2006). To this end, indicators have been proposed (e.g. UNEP/SETAC 2010a, b, c, d, e) that address various social sustainability issues (SSIs) (i.e. aspects of social sustainability that are important to consider in an assessment) that are considered to be universal. The importance of SSIs, however, depends on the cultural, political, social and economic context of the case considered (Benoît-Norris et al. 2011, Glaser & Diele 2004).

A social sustainability assessment, therefore, should start with a description of the case considered (Mollenhorst & De Boer 2004, Van Calker et al. 2005). This study concerns a group of cod and haddock fishing companies in the northeast Atlantic. These Norwegian and Icelandic fishing companies employ trawlers, longliners, auto-liners, and Danish seiners in coastal and offshore fisheries to produce fresh and frozen fillets. The second step in social sustainability assessment is the identification of relevant and important social sustainability issues (Mollenhorst & De Boer 2004, Van Calker et al. 2005). Since the importance of SSIs depends on the context of the case considered, stakeholder input should be used (Caffey et al. 2000, Meul et al. 2008, Mollenhorst & De Boer 2004, Van Calker et al. 2005). Stakeholders are those individuals or organizations that can affect or are affected by the activities of the cod and haddock fishing companies in the northeast Atlantic (based on Freeman 1984).

The objective of this study is to identify relevant SSIs for cod and haddock fisheries in the northeast Atlantic and to determine the importance of these SSIs based on stakeholder input. Since social sustainability concerns a diversity of stakeholders with different interests, a heterogeneous group of stakeholders was consulted in order to get a representative set of SSIs (Caffey et al. 2000, Meul et al. 2008, Mollenhorst & De Boer 2004, Van Calker et al. 2005).

2. Methods

Stakeholders were invited to take part in two consecutive surveys on SSIs. These stakeholders were identified from a detailed value chain characterization and distributed across seven distinct stakeholder groups, namely: fishing companies, fishing company employees, suppliers and processors, sales organisations, consumers (represented by consumer organizations), policy-makers, and fish welfare organizations. Each stakeholder group encompasses multiple stakeholders who share similar interests.

The first survey served to compile a long list of relevant SSIs for cod and haddock fisheries in the northeast Atlantic. To this end, respondents were asked to 1) indicate whether SSIs on an initial list of possible SSIs based on literature (Table 1) were relevant, and 2) add new SSIs in case of deficiencies. SSIs on this initial list concern working conditions, terms of employment, employees' job fulfilment, companies' contribution to the local community, food safety and product quality. When at least one respondent indicated that an SSI on the initial list of SSIs was relevant, then this SSI was added to the long list. If any stakeholder mentioned a new SSI, it was added to the long list as long as the SSI was clear, concerned social sustainability and did not overlap with any of the SSIs on the initial list.

Table 1. Initial list of social sustainability issues with the relevant references to literature

SSI	Reference
Employees' working schedule	(Kruse et al. 2009, UNEP/SETAC 2010e)
Arrangements for employees' overtime	(UNEP/SETAC 2010e)
Companies' salary levels	(Benoît-Norris et al. 2011, Caffey et al. 2000, Kruse et al. 2009, Meul et al. 2008, UNEP/SETAC 2010e)
Companies' timely payment of salaries	(UNEP/SETAC 2010e)
Pension fund contributions of companies for their employees	(Kruse et al. 2009, UNEP/SETAC 2010e)
Employees' income security during sickness	(UNEP/SETAC 2010e)
Worker safety	(Caffey et al. 2000, UNEP/SETAC 2010e)
Healthy working environment (ergonomics)	(Mollenhorst & De Boer 2004, UNEP/SETAC 2010e)
Provisions aboard for the crew (for example, sports and internet facilities on vessels that go out to sea for longer periods of time)	(Kruse et al. 2009)
Employees' job satisfaction	(Bavinck & Monnereau 2007)
Employees' professional pride	(Meul et al. 2008)
Freedom of association and collective bargaining	(UNEP/SETAC 2010e)
Equal opportunities for immigrant workers	(UNEP/SETAC 2010e)
Community involvement of cod and haddock fishing companies	(UNEP/SETAC 2010b)
Local ownership of cod and haddock fishing companies	(Caffey et al. 2000)
Local employment from cod and haddock fisheries	(UNEP/SETAC 2010b)
Seasonality of employment	(Kruse et al. 2009)
Product freshness	(Roininen et al. 2006)
External damages to the fish (e.g. cuts)	(based on Mollenhorst & De Boer 2004)
Internal damages in the fish (e.g. bleedings)	(based on Mollenhorst & De Boer 2004)
Microbiological food contamination (from, for example, bacteria and parasites)	(Codex Alimentarius Commission 2009)
Chemical food contamination (from, for example, cleaning materials or pesticides)	(Codex Alimentarius Commission 2009)
Physical food contamination (from, for example, gear or equipment)	(Codex Alimentarius Commission 2009)

The second survey served to determine the importance of each SSI on the long list of relevant SSIs that resulted from the first survey. Respondents were asked to put the five most important SSIs from the long list in order of importance.

The analysis of the second survey focused on responses per stakeholder group in order to correct for unequal numbers of responses between stakeholder groups. For each respondent, five SSIs were scored 1 to 5 points, where 1 point was assigned to the SSI that the respondent ranked lowest and 5 points were assigned to the SSI that the respondent ranked highest. These individual scores were then used to calculate the average score for SSI i and stakeholder group k as follows:

$$\overline{S}_{ik} = \frac{\sum_{l=1}^{l} S_{ilk}}{n_{lk}}, \qquad \text{Eq. 1}$$

where S_{ilk} is the score for SSI i of respondent l in stakeholder group k and n_{lk} is the number of respondents l in stakeholder group k. Then, the overall score for SSI i was calculated as follows:

$$\overline{S}_i = \frac{\sum_{k=1}^{k} \overline{S}_{ik}}{n_k}, \qquad \text{Eq. 2}$$

where $\bar{S}_{ik}$ is the average score for SSI *i* and stakeholder group *k*, and n_k is the total number of stakeholder groups *k*.

3. Results

In total, 41 copies of the first survey were returned from April to August 2013 via mail, e-mail and online. Table 2 reports the number of responses per stakeholder group for the first survey and shows that responses from employees in fishing companies represent the largest share of responses.

In the first survey, each SSI on the initial list of SSIs was selected by at least 5 and at most 33 respondents. This indicated that all SSIs on the initial list had to be included in the long list of SSIs for the second survey. In addition, six new SSIs suggested by respondents were added to the long list, namely: fish welfare during capture, humane slaughter of fish, opportunities for life-long learning, on-the-job training, employees' travel time from home to work and back, and time at home. The new SSI 'fish welfare during capture' implicitly included the former SSIs 'internal and external damages to fish', which were thus excluded from the long list of SSIs. As such, the first survey resulted in a long list of 27 relevant SSIs that was used as input for the second survey.

Table 2. Targeted sample and number of responses for survey 1 and survey 2 per stakeholder group and per stakeholder

Stakeholder group	**Stakeholders**	**Targeted sample (n)[a]**	**Responses survey 1 (n)**	**Responses survey 2 (n)**
Fishing companies	Fishing company owners	7	3	4
	Fishing company associations	1	1	2
Fishing company employees	Fishing companies' employees	81	12	20
	Labor unions	7	1	0
Suppliers and processors	Suppliers to the vessels	0	0	1
	Processing company owners	4	3	4
	Processing companies' employees	335	1	6
	Processing company associations	1	2	2
Sales organizations	Retailers	12	1	1
	Merchants	3	6	1
	Organizations promoting the sector	2	1	0
Consumers	Consumer organizations	1	0	0
Policy-makers	Local municipalities	4	0	1
	Government fisheries department	2	4	1
	Public administration	0	0	1
	Public institutions	0	0	1
	Government unspecified	0	0	1
	Certifiers of stock sustainability	3	1	0
Education	Organizations that provide education to employees in fishing companies	Not applicable	Not applicable	4
Fish welfare organizations	Fish welfare organization	1	1	1
Other interest groups	Other interest groups not specified further	0	4	0

[a] Targeted sample refers to the number of organizations or the number of individuals.

In total, 66 copies of the second survey were returned from October to December 2013 via e-mail and online. Seven surveys were excluded because they were incomplete and no stakeholder affiliation was entered. Eight surveys were excluded because stakeholder affiliation was either unclear or irrelevant. Table 2 reports the number of responses per stakeholder group for the second survey and shows that responses from employees in fishing companies represent the largest share of responses.

The analysis of the second survey focused on the importance of the SSIs on the long list, based on overall scores per SSI. Overall scores for the SSIs ranged from 0 to 1.99, with an average of 0.6. The three most important SSIs are worker safety, product freshness and companies' salary levels, as indicated by the highest overall scores for these SSIs (1.99, 1.46 and 1.34, respectively). The three least important SSIs are seasonality of employment and arrangements for employees' overtime, which were not ranked by any respondent, and equal opportunities for immigrant workers (with an overall score of 0.02).

4. Discussion

The first survey resulted in the identification of 27 relevant SSIs for cod and haddock fisheries in the northeast Atlantic. These 27 SSIs include six SSIs that were not considered before in studies on social sustainability (Bavinck & Monnereau 2007, Benoît-Norris et al. 2011, Caffey et al. 2000, Codex Alimentarius Commission 2009, Kruse et al. 2009, Meul et al. 2008, Mollenhorst & De Boer 2004, Roininen et al. 2006, UNEP/SETAC 2010b, e). The newly identified SSIs address aspects of employees' training and education opportunities, employees' time off from work and fish welfare. The second survey resulted in a ranking of the 27 relevant SSIs in order of importance. This ranking of SSIs shows that the most important SSIs for cod and haddock fisheries in the northeast Atlantic are worker safety, product freshness and companies' salary levels. Worker safety (Kruse et al. 2009, Utne 2007) and companies' salary levels (Kruse et al. 2009) were identified as important SSIs in studies on social sustainability of capture fisheries before, but product freshness was not.

Results on the relevance and importance of SSIs for cod and haddock fisheries in the northeast Atlantic were based on relatively low numbers of responses to the first and the second survey (41 and 51 responses, respectively). Larger numbers of responses to the surveys would have been preferable, but consulting a diversity of stakeholders was prioritized. There were no responses, however, from consumers, one of the seven stakeholders groups distinguished. Therefore, consumer perspectives on social sustainability issues should be addressed in future research.

Responses to the surveys were unevenly distributed across stakeholder groups; the largest number of responses per stakeholder group was 20, whereas the smallest number of responses per stakeholder group was one. Not correcting for this uneven distribution of responses across stakeholder groups would have resulted in a disproportionately large influence of certain stakeholder groups at the expense of other stakeholder groups. Therefore, average scores (indicating relative importance of the SSIs) were first determined per stakeholder group and then averaged over all stakeholder groups.

It is interesting to explore to what extent results on the importance of SSIs for cod and haddock fisheries in the northeast Atlantic are applicable beyond the context of this case. In this study, several different types of fishing techniques were considered (i.e. trawling, seining, auto-lining and long-lining in coastal and offshore waters) within one region. This means that the context of cod and haddock fisheries in the northeast Atlantic is mainly determined by its regional setting. Therefore, similar results on the importance of SSIs can be expected for other capture fisheries (e.g. herring or mackerel fisheries) in the northeast Atlantic and its subareas, and for capture fisheries in similar regions (e.g. the northwest Atlantic).

5. Conclusion

This study resulted in the identification of 27 relevant SSIs for cod and haddock fisheries in the northeast Atlantic. These 27 SSIs include six newly identified SSIs that address aspects of employees' training and education opportunities, employees' time off from work and fish welfare. The most important SSIs are worker safety, product freshness and companies' salary levels. Results presented in this study on the relevance and importance of SSIs for cod and haddock fisheries in the northeast Atlantic inform stakeholders, and especially the industry and policy-makers, about the relevant social sustainability themes and their valuation by different stakeholders. This enables the industry and policy-makers to direct improvement efforts towards the more important SSIs.

ABSTRACT

Assessing and improving the sustainability of dairy production systems requires an accurate quantification of greenhouse gas (GHG) emissions and major nutrient (N, C, P) flows associated with milk production at the animal, farm and field-scale. Life cycle inventory databases are, however, often based on rough estimates of GHG emissions and nutrient flows, and cannot account for spatially-explicit variation in these flows. Emission estimates can be improved when underlying processes influencing GHG emissions and nutrient balances are explicitly considered. We aim to improve life cycle inventory databases for milk production in the US by integrating process-based models into LCA data acquisition. We therefore perform a quantitative comparison of five process-based models to determine major nutrient flows and GHG emissions of milk production at the animal, farm and field-scale.

Keywords: milk production, nutrient flows, greenhouse gas (GHG) emissions, process-based models

1. Introduction

The livestock production sector is a key contributor to a range of critical environmental problems, at local, regional and global scales (Steiner et al. 2006, Pelletier and Tyedmers, 2010, Bouwman et al. 2013). Ruminant livestock systems contribute substantially to global warming through greenhouse gas (GHG) emissions. The global dairy sector is presently responsible for 2.7% of total, global greenhouse gas emissions (FAO, 2010). In the US, the agricultural sector is responsible for 8.1% of total GHG emissions (EPA, 2014). After fossil fuel, enteric and manure methane (CH_4) emissions are the second and third most important sources of GHG from the dairy supply chain in the US (Thoma et al. 2013). In addition, crop-livestock production systems are the largest cause of human alteration of the global nitrogen (N) and phosphorus (P) cycles (Bouwman et al. 2013). Total N and P in animal manure exceed global N and P fertilizer use (Bouwman et al. 2013) and livestock manure is a major source of anthropogenic ammonia (NH_3) emission in the U.S. (NRC, 2003) and globally (Steiner et al. 2006).

Assessing and improving the sustainability of dairy production systems thus requires an accurate quantification of greenhouse gas (GHG) emissions and major nutrient (N, C, P) flows associated with milk production at the animal, farm and field-scale. In large, nonhomogeneous countries like the US, milk production practices and climate conditions vary widely, which can result in large, farm-specific variations in GHG and nutrient emissions (Henderson et al. 2013). Life cycle inventory databases are, however, often based on rough estimates of GHG emissions and nutrient flows, and cannot account for spatially-explicit variation in these flows. Emission estimates can be improved when underlying processes influencing GHG emissions and nutrient balances are explicitly considered (e.g. Schils et al. 2004, Li et al. 2012). We aim to improve life cycle inventory databases for milk production by integrating process-based models into LCA data acquisition. We therefore perform a quantitative comparison of five process-based models to determine major nutrient flows and GHG emissions of milk production at the animal, farm and field-scale. We compare these models in terms of GHG and NH_3 emissions to air, as well as nitrate (NO_3^-) and phosphate (PO_4^{3-}) emissions to ground water, and allocate these emissions to the different dairy production components, including five feed crops, animal (enteric) emissions, and manure management. This model comparison study is part of a larger project that aims to reduce the life cycle environmental impact of dairy production systems in the USA (www.sustainabledairy.org). Here, we present the results of the first round of model comparison, which focussed on GHG and NH_3 emissions to air.

2. Methods

2.1. Model description

In the model comparison, we included five process-based models: CNCPS6.1, DAYCENT, ManureDNDC, APEX and IFSM3.4 (Table 1). These models operate on different scales, each having their own unique features. The *Cornell Net Carbohydrate and Protein System (CNCPSv6.1*) model is an animal scale model that predicts changes in N_2O, CH_4, and NH_3 emissions for a wide range of feed, environmental and ration characteristics (Tylutki et al. 2008). The model provides enteric emissions and nutrient balances per cow.

Table 1. Included process-based models

DNDC-manure	Farm	www.dndc.sr.unh.edu/
APEX	Field to watershed	www.epicapex.tamu.edu/
IFSM	Farm	www.ars.usda.gov/

DAYCENT is a daily-time step, plant-centric soil biogeochemical model (Del Grosso et al. 2001, 2002, 2005). Model outputs include daily fluxes of various N-gas species (e.g., N_2O, NO_x, N_2), daily CO_2 flux from heterotrophic soil respiration, soil organic C and N, net primary productivity (NPP), daily water and nitrate (NO_3) leaching, and other ecosystem parameters. *Manure-DNDC* provides a detailed description of the on-farm biochemical cycle of N and P as well as the use of water for each individual crop (alfalfa, corn, grass, soybean and wheat). The model can be used for predicting crop growth, soil temperature and moisture regimes, soil carbon dynamics, nitrogen leaching, and emissions of trace gases including nitrous oxide (N_2O), nitric oxide (NO), dinitrogen (N_2), ammonia (NH_3), methane (CH_4) and carbon dioxide (CO_2). A specific feature of DNDC is the biogeochemical process model for quantifying greenhouse gas and ammonia emissions from livestock manure systems (Li et al. 2012). *APEX* (Williams et al. 2012) is a comprehensive daily-time step model able to link field to watershed-scale, simulating detailed agricultural management and quantifying productivity as well as impacts on a suite of environmental processes (hydrology, erosion, net ecosystem exchange, soil carbon dynamics, nitrogen balance, etc.) (Gassman et al., 2010). The model can be configured to simulate pertinent management strategies, such as rotational grazing, movement of animals between paddocks, and application of manure removed from livestock feedlots or waste storage ponds. *The Integrated Farm System Model (IFSM)* provides a process level simulation of farm production systems and predicts the performance, economics, and environmental impacts of alternative production practices (Rotz et al., 2012). IFSM provides field scale emissions for individual crops, use of machinery, enteric emission, manure management and other flows from the barn.

2.2 Model comparison – whole farm approach

For model comparison, the whole-farm model approach was used, which is an established powerful methodology to develop GHG mitigation strategies for farming systems (e.g., Schils et al. 2005, Schils et al. 2007, del Prado et al. 2013). The whole-farm approach reveals trade-offs between emissions of the different GHGs and other pollutants, and ensures that interactions between nutrient cycles are taken into account (Schils et al. 2005). All models were run for a dairy farm in New York state, using the same input data. Emissions of NH_3 and important greenhouse gases, e.g. CH_4 and N_2O, were collected for each model. As not all models include the same processes, emissions were allocated to three main farm processes, e.g. barn, manure handling, and field, to facilitate a meaningful comparison of the models. Barn emissions were further segregated into “enteric emissions from livestock” and “other barn emissions”, such as ground emissions. “Field” emissions include all emissions associated with crops and soil, such as soil N_2O emissions.

Total global warming impacts were quantified for each farm process by multiplying the emissions of CH_4 and N_2O with the substance-specific global warming potential (GWP100, IPCC 2007, 1 for CO_2, 25 kg_{CO2eq}/kg_{CH4} and 298 kg_{CO2eq}/kg_{N2O}). These substance-specific global warming impacts can be aggregated to obtain the total global warming impact (in CO_2 equivalents). At this stage, biogenic CO_2 emissions were excluded from the quantification of global warming impacts, assuming that the total biogenic CO_2 input balances the biogenic CO_2 output.

2.3 Pilot farm

Input data collected for the NY state farm, include detailed feed scenarios, use of machinery on the farm, a description of feed crop cultivation practices and a description of the manure management system. A summary of the main farm characteristics is provided in Table 2.

Table 2. Summary of farm characteristics

Dairy cows (number)	**Annual average production (lbs/head)**	**Housing**	**Manure management**	**Crop types**	**On-farm feed production**
1100 lactating 165 dry cows 425 older heifers 500 young heifers	26364	Free stall	Slurry with natural crust	485.6 ha corn 344 ha alfalfa 48.6 ha soybean 80.9 ha small grain 60.7 ha grazing	85%

3. Results

3.1 GHG emissions

First results show that predicted enteric CH_4 emissions dominate GHG impacts at the individual farm level (Fig. 1). Enteric CH_4 emissions, are similar for ManureDNDC v3, IFSM3.4 and CNCPS6.1 and range from $2.0\cdot10^5$ $kgCH_4$/yr to $2.4\cdot10^5$ $kgCH_4$/yr, leading to a dominant GHG contribution between $5.0\cdot10^6$ and $5.9\cdot10^6$ $kgCO_{2equ}$/yr. For the other farm processes, predictions of GHG emissions differ more between models. ManureDNDC and IFSM3.4 differ in their prediction of manure emissions (both CH_4 and N_2O) and barn N_2O emissions. IFSM3.4 predicts a relatively large contribution, i.e. ~20%, of manure CH_4 to total GHG impacts, whereas the contribution of manure CH_4 to total GHG impacts is only 3% in manureDNDC predictions. Alternatively, manureDNDC predicts a relatively large contribution of barn N_2O emissions to total GHG impacts (15%), whereas these emissions are not included in IFSM3.4. Particularly striking is the difference in predictions of field N_2O emissions. The DayCent prediction of $1.5\cdot10^4$ kgN_2O emitted per year is substantially higher than the predictions of ManureDNDC, IFSM3.4, which are $1.2\cdot10^3$ kgN_2O/yr and $1.7\cdot10^3$ kgN_2O/yr, respectively. APEX predicts an emission of $1.9\cdot10^3$ kgN_2O/yr (excluding fallow land), and an emission of $4.2\cdot10^3$ kgN_2O/yr if most of the manure is assumed to be applied on a fallow land. On a per crop basis, other differences between model field N_2O predictions appear (Fig. 2). Both APEX and DAYCENT predict a high contribution of alfalfa to total N_2O emissions, whereas alfalfa contributes only slightly to the total N_2O emissions from the field in manureDNDC predictions. ManureDNDC predicts a dominant contribution of corn (46%) to total N_2O emission. This is consistent with DAYCENT predictions, where corn, next to alfalfa, dominates total N_2O field emissions.

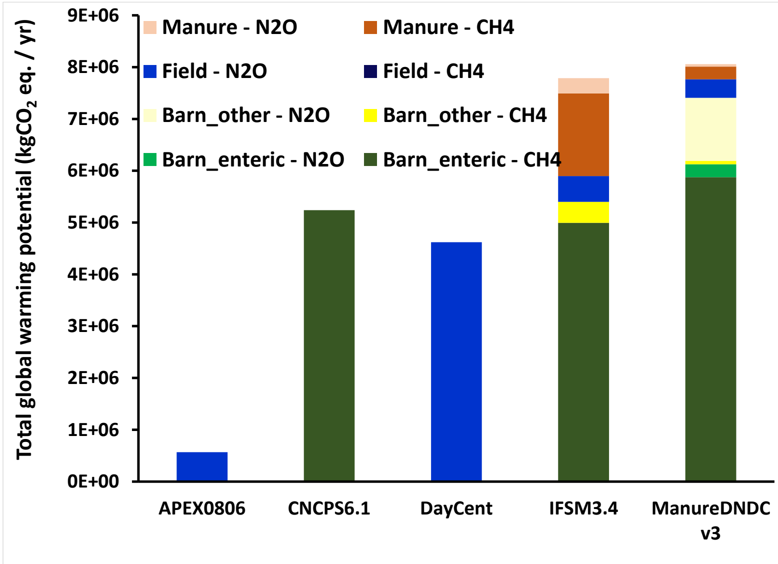

Figure 1. Comparison of total annual global warming impact calculated by five process models for field barn and manure management systems of the pilot NY farm

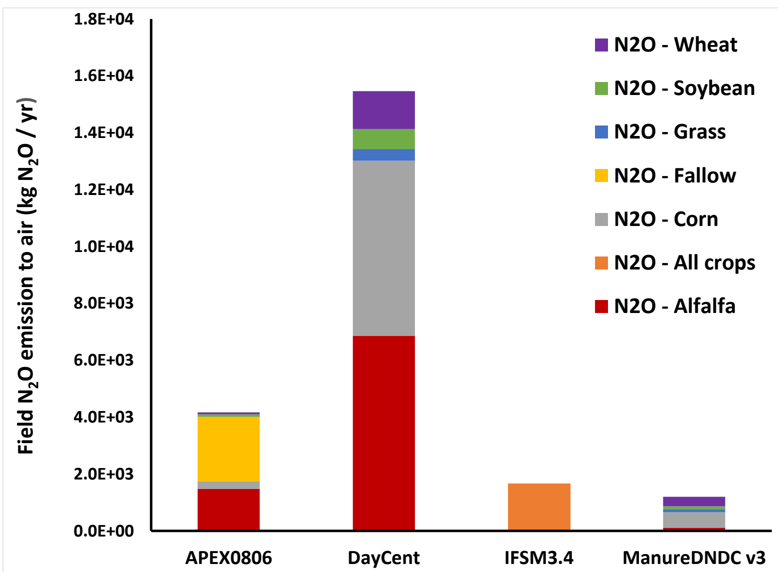

Figure 2. Crop-specific nitrous oxide (N_2O) emission to air for crop production calculated by four process models

3.2 Ammonia emission

This first model comparison show that predictions of ammonia emissions to air are mostly similar across models (Fig. 3). Predictions of barn NH_3 emissions are very close for ManureDNDC and CNCPS6.1, i.e. $4.3 \cdot 10^4$ kgNH_3/yr and $4.5 \cdot 10^4$ kgNH_3/yr, respectively. These emissions are a factor of 1.6 higher than the barn NH_3 emissions predicted by IFSM3.4. Field NH_3 emissions are highly comparable between ManureDNDC, IFSM3.4 and APEX, ranging from $1.4 \cdot 10^4$ kgNH_3/yr to $1.9 \cdot 10^4$ kgNH_3/yr. Manure NH_3 is highly comparable as well. Manure NH_3 emission estimations differ by a factor 1.1 between IFSM and ManureDNDC. CNCPS6.1 predicts only livestock emissions.

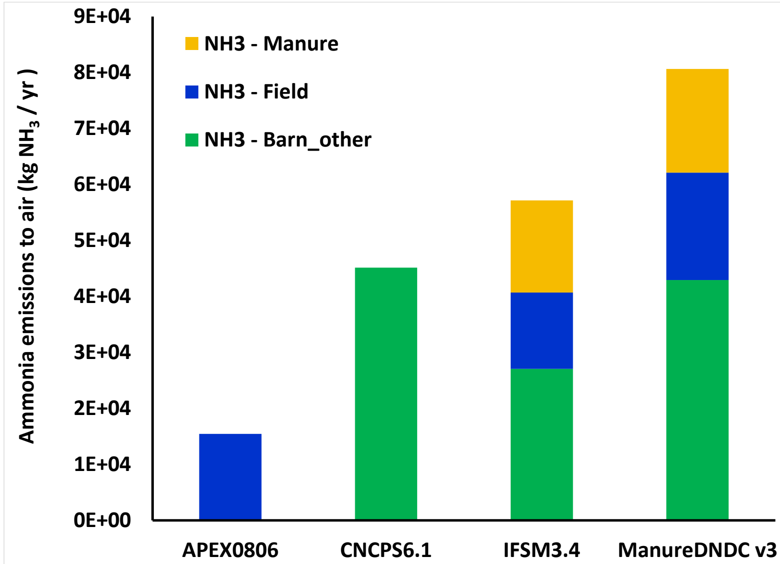

Figure 3. Ammonia emissions to air

4. Discussion

Results of the first round of model comparison show that enteric CH_4 emissions are dominating the total global warming impact at the individual farm level. This finding is consistent with results from other studies. Thoma et al. (2013) showed that enteric CH_4 emission contribute 25% of total C footprint of the dairy supply chain. In addition, DelPrado et al (2013) found that enteric CH_4 and crop land N_2O are the main contributors to whole-farm greenhouse gas impacts for grassland ruminant-based farms system in Europe, although large site- and farm-specific variations were observed.

The different models vary primarily in their prediction of N_2O emissions related to barn and field. One of the reasons for these differences can be that not all models were run with exactly the same input data. A closer inspection of model input data revealed that model input data differ in terms of meteorological data and soil type. Current research efforts focus on further harmonization of input data. A further analysis of model differences will be carried out after the second modelling round with the harmonized input data set. Model validation will then be carried out on another pilot farm for which more detailed experimental data are available. Finally, for improving the process modelling of N_2O flows, the monitoring tasks of the larger project will provide empirical measurements of field barn and manure emissions.

5. Conclusion

A first comparison of five process-based models shows that enteric CH_4 emissions are dominating the total global warming impact at the individual farm level. It is thus necessary to accurately predict and measure these enteric CH_4 emissions. Field CH_4 emissions play only a minor role in the total global warming impact of the individual farm. There may be less urgency to monitor variations in field CH_4 emissions. Model predictions mainly differ in terms of field N_2O emissions, which may partly result from differences in input variables. Current research focusses on further harmonization of the input data for the pilot farm, which will be used for the second model round. In this second round, we will extend the model comparison to nitrate (NO_3^-) and phosphate (PO_4^{3-}) emissions to groundwater. In addition, we will establish and compare whole-farm nutrient (C, N, P) balances. Once models are evaluated and harmonized, integrating process-based models into LCA data acquisition, as proposed here, can provide a more accurate, spatially-explicit approach to derive farm-specific nutrient flows and GHG emissions, which is essential to improve sustainability assessments of (US) dairy production systems.

Consideration of the product quality in the life cycle assessment: case of a meat product treated by high pressure

Gina Villamonte, Marie de Lamballerie, Vanessa Jury

ABSTRACT

New technologies play an important role on sustainable food production and to ensure food security for the next decades (Sonesson 2010). High-pressure processing is a promising emerging technology which was considered environmentally friendly in terms of energy consumption (Toepfl et al. 2006). The technology improves food quality that was not included in previous LCA studies. In this case study, the food safety as a quality characteristic was included in the comparison of the environmental impact between a high-pressure treated ham and the traditional one. At the consumption stage, the food safety was considered as the potential damage to human health by *Listeria monocytogenes*. As an additional step of meat processing, the contribution of high-pressure processing to the life cycle of cooked ham was negligible. However, improving food safety could partly compensate for the environmental impact due to the extended shelf life of meat products.

Keywords: Meat product, high pressure processing, Life Cycle Assessment

1. Introduction

Sustainable food processing is a critical element for the future generations to ensure food safety and to preserve food quality with efficient use of resources (Floros et al. 2010). The impact of high pressure processing on food production has been recently explored (Davis et al. 2009; Pardo and Zufía 2011). Previous studies have focused on high pressure processing without considering new characteristics of high-pressure treated products.

Commercialized high-pressure treated products are mainly vegetable products (33%), meat products (30%), seafood and fish (15%) and beverages (12%) (Mújica-Paz et al. 2011). Within those food categories, meat products were reported to have the greatest environmental impact (Tukker et al. 2006). Moreover, there is little knowledge about the environmental impact of high pressure processing on meat products.

Nutritional quality has been considered in sustainable approach of life cycle assessment as functional unit (Shau and Fet 2008). However, other quality features should not be neglected in efforts to evaluate the environmental impact of products. Food safety is a food attribute which is associated to health risk (Röhr et al. 2005). Novel preservation technologies improve food safety and potentially decrease the human risk associated to foodborne illness (Hugas et al. 2002). Likewise, the food recall for microbiological criteria is an important wastage that could be avoided by emerging technologies.

Listeria monocytogenes is a pathogen of public health concern, responsible of listeriosis. For the characteristics of production and consumption, ready-to-eat foods are considered to be a vehicle of listeriosis foodborne (Zhang et al. 2012). High-pressure processing is an alternative to control *Listeria monocytogenes* without using growth inhibitors and post packaging pasteurization. For this reason, we develop an approach to consider the food safety in the comparison of the high pressure treated product with the traditional one. The objective of the study was to evaluate the environmental impact of a sliced ham treated by high pressure and to compare it with the untreated product, considering the quality of products.

2. Methods

2.1. Goal definition, system description and data collection

The life cycle assessment was performed to compare the environmental impact between the sliced cooked ham treated by high pressure and the conventional product. The functional unit is 1 kg of sliced cooked ham consumed. The economic value of the traditional product and the high-pressure treated one was also used to compare their environmental impact. The prices of the products were recorded in countries where the technology is currently employed on commercialized sliced cooked ham.

From a cradle-to-crave perspective, the system consists of 4 subsystems: meat production, cooked ham production, distribution and consumption. Figure 1 shows the studied system and the high-pressure processing as an additional step of cooked ham production. The data were collected from a meat producer (slaughtering and cooked ham production) in France and a high-pressure equipment manufacturer. The data for the meat production in France were obtained from Agribalyse database 1.1. Capital goods, cleaning products and packaging material for transportation were not included. Mass allocation was performed for multi-products system. The high-pressure treatment of the packaged sliced cooked ham is 600 MPa for 3 minutes at room temperature in order to eliminate post processing contamination of *L. monocytogenes*.

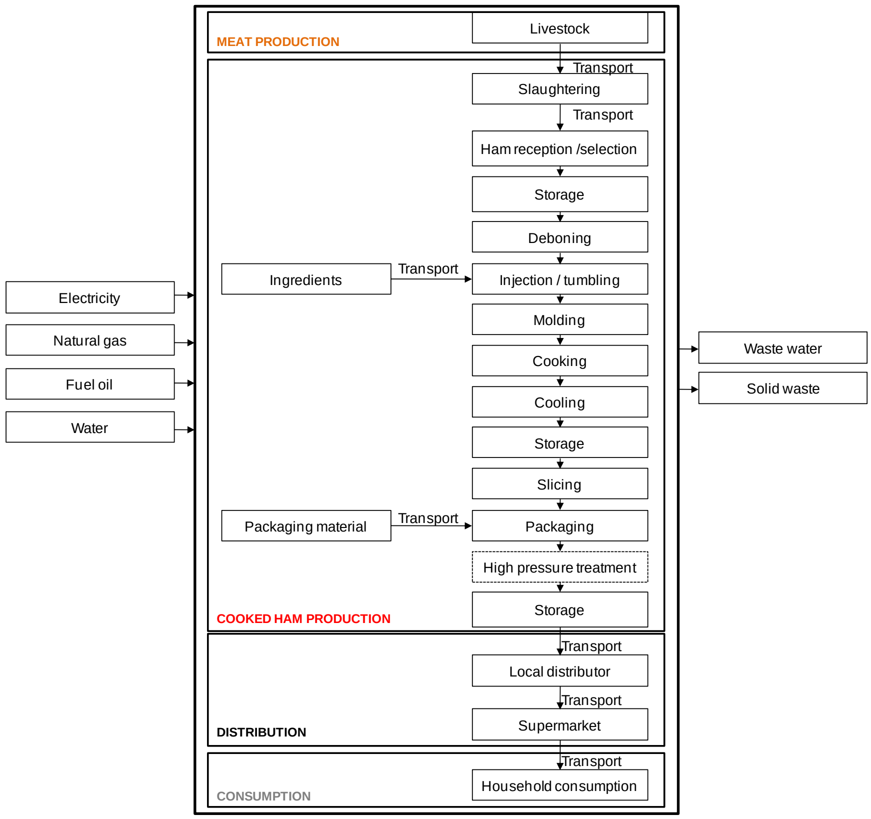

Figure 1. Flow diagram of the life cycle of sliced cooked ham

2.2. Food safety: Health effects due to the exposure to *L. monocytogenes*

Food safety is a food attribute, presented as damage to human health. Food quality in the ready-to-eat meat product is evaluated in terms of the disease burden caused by *L. monocytogenes*. The model refers to the change of Disability Adjusted Life Years (DALY) upon exposure to the pathogen. The comparison between the meat products provides the potential benefit of using high-pressure processing as a listericidal treatment. We proposed to consider this aspect on the human health damage category.

The impact of using high-pressure processing to control *L. monocytogenes* was evaluated by using the risk assessment of *L. monocytogenes* in ready-to-eat food (WHO/FAO, 2004) and the BRAFO tiered approach (Hoekstra et al. 2012). The framework consists of three parts which are: the exposure assessment, the dose-response and the risk characterization.

The exposition factor is the quantitative evaluation of the ingestion probability of *L. monocytogenes*. The prevalence and contamination level of *L. monocytogenes* on ready-to-eat meat products from the report of the European Food Safety Authority (2013) were assumed. The distribution of *L. monocytogenes* in the ready-to-eat meat product was obtained from the serving size (g) and the distribution of the contamination level (European Food Safety Authority 2013).The serving size (g) was calculated from the annual consumption of cooked ham in France. The serving size was assumed to be the same to women and men. The dose is estimated by using the Equation 1.

$$\text{Dose(cfu)} = \text{Average serving(g)} \times \text{Contamination level(cfu/g)} \qquad \text{Eq. 1}$$

The probability of illness ($P_{illness}$) at a specific dose (16 g/day) is obtained from the distribution of *L. monocytogenes* on the ready-to-eat meat (Dose) and the probability of *L. monocytogenes* of causing an infection to a susceptible population (r: 5.85 x 10^{-12}) (WHO/FAO 2004), as presented by the exponential dose-response relation (Eq. 2).

$$P_{\text{illness}} = 1 - e^{-rDose} \qquad \text{Eq. 2}$$

The probability of listeriosis due to the annual consumption of packaged sliced ham in France at the prevalence and contamination level reported is 5.1 x 10^{-8}. The probability to develop a specific manifestation was estimated by using equation 3. The factor (F) is the proportion of cases of listeriosis which develop the specific manifestation and it was obtained from government publications and literature data (Institut de veille sanitaire 2012, Lecuit and Leclercq 2013).

$$P_{meningitis/\,septicemia/\,neo-natal listeriosis} = P_{\text{illness}} \times F_{meningitis/\,septicemia/\,neo-natal listeriosis} \qquad \text{Eq. 3}$$

Listeria monocytogenes is responsible for two forms of listeriosis: non-invasive and invasive listeriosis. The invasive listeriosis is the most severe manifestation form and it may induce meningitis, septicaemia and neonatal infection. In this study, the invasive listeriosis was only considered. The severity of listeriosis was estimated in terms of the indicator of the human health impact category (Disability-adjusted life years, DALY). Similar approach was used to evaluate the impact of foodborne disease on public health in Greece and Netherlands (Gkogka et al. 2011, Havelaar et al. 2012).

Listeriosis, in the invasive form, was evaluated in the susceptible population (older adults and pregnant women). The DALY estimation was according to "BRAFO tiered approach" (Hoekstra et al. 2012) for quantal health effects. The expression (Eq. 4) considers the health recovering, the decease and the sequelae of individuals, which was calculated for each manifestation of listeriosis (meningitis, septicemia and neo-natal listeriosis).

$$\text{DALY}_{a,s} = P_{effect}\,(P_{rec} \cdot \text{YLD}_{rec} \cdot w + P_{die}(\text{YLD}_{die} \cdot w + \text{LE}_{a,s} - \text{CA} - \text{YLD}_{die}) + (1 - P_{die} - P_{rec}).(\text{LE}_{a,s} - \text{CA}).\,w) \qquad \text{Eq.4}$$

The DALY $_{a,s}$ is the disability-adjusted life years for a specific age (a) and sex (s). The P_{effect} is the probability of illness by listeriosis. The P_{rec} is the probability of health recovering (Aouaj et al. 2002, Dzupova et al. 2013, Goulet et al. 2012). The P_{die} is the probability to die due to the illness (Varon 2009, Goulet et al. 2012). The YLD_{die} and the YLD_{rec} is the illness duration for the individuals who die and recovers health, respectively (Gerner et al. 2005, Fernandez et al. 2011, Kemmeren et al. 2006). The w is disability weight of the disease (Melse et al. 1998, Melse et al. 2000). The CA is the actual age of diseased individual. The LE is the life expectancy for the individual with an age CA. The Table 1 summaries the parameters used for each manifestation. For neo-natal listeriosis, parameters values ($P_{rec,}$ YLD_{rec}, YLD_{die}, P_{die} and *w*) were assumed since it represents the neonatal death and the abortion due to this manifestation. The data for the concerned population in France were obtained from the INSEE (National Institute of Statistics and Economic Studies). The annual DALY is estimated and summed for each individual of the susceptible population.

Table 1. Values of parameters used for DALY calculation

Diseases	**F**	**P_{rec}**	**YLD_{rec}**	**P_{die}**	**YLD_{die}**	***w***
Meningitis	0,28	0,565	0,500	0,22	0,080	0,310
Septicemia	0,65	0,791	0,020	0,209	0,080	0,930
Neo-natal listeriosis	0,315	0	0	1	0	1

The baseline scenario is the current characteristics of distribution and prevalence of *L. monocytogenes* on ready-to-eat meat products (European Food Safety Authority 2013). The worst scenario is based on a challenge test in a cooked ham at the limit of pathogen inactivation by high pressure processing (Myers et al. 2013). It was assumed a lower prevalence of contaminated products (0.001%) for the worst scenario and the potential human health damage due to listeriosis was evaluated for 14 days of storage time at the retail store.

2.3. Life cycle impact assessment

The life cycle assessment was conducted by using the SimaPro 8.0.2 software. Two methodologies of impact evaluation were employed: problem-oriented method (CML IA v 3.0 and Cumulative energy demand v 1.08) and damage-oriented method (Eco-indicator 99 v 2.09). The environmental impact categories selected in the analysis were non-renewable energy, global warming potential, acidification, eutrophication, and photochemical oxidation. The impact categories for the human health damage were also included.

2.4. Sensitivity analysis

A sensitivity analysis was performed to evaluate the impact of input variables on the human health damage due to listeriosis. Likewise, the impact of capital goods and the extended shelf life of products were considered.

3. Results

3.1. Environmental impact of meat products

Figure 2 shows the contribution of each stage of the life cycle of the meat product untreated (traditional product) and treated by high pressure processing (HP product). The results of the stage contribution to environmental impact categories are expressed in mass of products (vertical axis). The environmental impact of products is quite similar in this case, while no changes of post-processing stage were described. Meat production is the main contributor for the life cycle of the meat products. For the traditional product, 45.3% of non-renewable energy use, 73.1% of global warming potential, 92.4% of acidification, 87.7% of eutrophication and 89.4% of photochemical oxidation were due to meat production. It is in accordance to the composition of final products which contains about 90% of pork meat. Besides, cooked ham production was responsible for 27.5% of the non-renewable energy use and 15.6% of the global warming potential. The contribution of cooked ham production was 5.7%, 9.9% and 6.4% for acidification, eutrophication and photochemical oxidation, respectively. High pressure processing as an additional operation to meat processing represents an increase of 0.7% of non-renewable energy demand. The contribution of high pressure processing was equal or less than 0.1% increase on the results for global warming potential, acidification, eutrophication and photochemical oxidation. The distribution and the consumption phase accounted for 15% and 12% to non-renewable energy use. For global warming potential, the contribution of distribution and consumption was 9% and 2% while for acidification, eutrophication and photochemical oxidation contributed equal or less than 2%.

Food quality is related to human perception and how the product fulfills their expected requirements (Röhr et al. 2005). Considering food quality implies to include its multiple aspects. The results are also presented in terms of the economic value since it reveals the emotional value of a product (Shau and Fet 2008). The economic value of products (price of packaged sliced cooked ham in Europe) is used to compare the environmental impact between the traditional and the treated product as presented in Figure 2. The environmental burden of different impact categories decreased about 16% on the treated cooked ham in comparison to the traditional one.

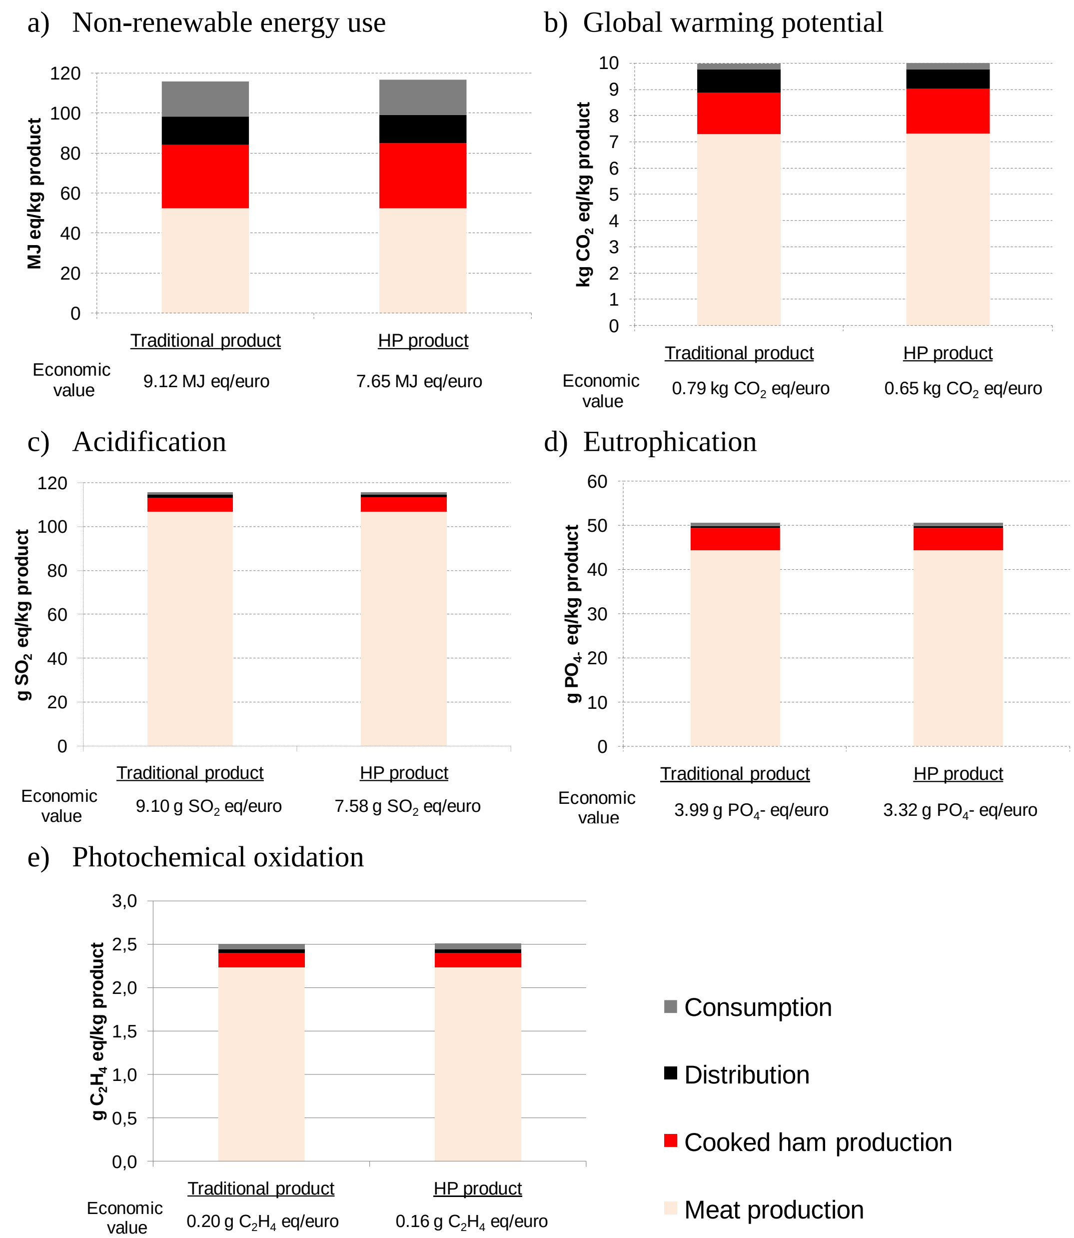

Figure 2. Contribution of stages to the environmental impact categories for the life cycle of the sliced cooked ham per functional unit: bar graphs present results per kg of product and below the figure, the results are presented per euro spent for product.

3.2. Food safety: Health effects due to the exposure to *L. monocytogenes*

The total annual health impact of the exposure to *L. monocytogenes* by the meat product for the susceptible population in France is 2.84 DALY [2.24 – 3.63]. The risk of listeriosis among the older adult population contributed about 66% to the total impact.

The table 2 reports the results of impact categories for human health per 1 kg of product. The baseline considered the actual impact of listeriosis on the susceptible population in France. High pressure processing is able to inactive *L. monoctogenes* up to 10^4 cfu/g (Bajovic et al. 2012, Myers et al. 2013). Considering the actual characteristics of prevalence and contamination of *L. monocytogenes* on the ready-to-eat meat products, high pressure is an efficient listericidal treatment if it is used as final step of meat processing.

In relation to the damage impact categories, the actual exposition to the pathogen presents a more relevant impact for human health than the consequences associated to ozone layer depletion for the life cycle of the meat product. Human health damage is mainly caused by carcinogens, climate change, respiration inorganics and radiation. Minor changes were observed in the endpoint impact categories of the treated product.

For the worst scenario, the potential damage due to listeriosis increases with the pathogen growth at storage conditions. It becomes more relevant than health risk due to exposition to organic particles after 12 days. No growth of *L. monocytogenes* in treated products reduces the potential human health damage due to sliced cooked ham.

Table 2. Results of impact categories of human health damage category for the life cycle of the sliced cooked ham per functional unit

Impact category	**per 1 kg of product**	**Baseline**		**Worst scenario - traditional product**				**HP product**
		Traditional product	**HP product**	**0**	**7 days**	**12 days**	**14 days**	**14 days**

3.3. Sensitivity analysis

The sensibility analysis showed the influence of product contamination, consumer behavior and characteristics of the concerned population on the results of human health damage due to the microbiological risk; which were evaluated individually. The variations of the prevalence of *L. monocytogenes* on meat products from the actual level (2.07%) increased the human health damage results; about 48.6% for increasing 1% the prevalence level of contamination. The changes on the consumer consumption also influence the human health damage results and it was proportional to the magnitude of serving size change; about 6.3 % for increasing 1 g the actual serving size.

Considering the projection of population growth from government publications, to 2050, the population in France would increase 6.7% and the older adult (60 years and more) population would represent 31.9% of the estimated population. The human health damage results for the projected population increased 36.6% the indicator value. The increase of older adult population was the main contributor of the indicator variation.

On the other hand, the differences of the environmental load between the traditional product and the treated product increase less than 1% if capital goods are included in the analysis.

The extended shelf life of the treated meat product can increase the storage time at the supermarket. If we consider two-fold the baseline of the storage time, the use of non-renewable energy increases 10% and less than 1% for other impact categories in comparison to the traditional product.

4. Discussion

4.1. Contribution analysis

The meat production has the greatest contribution to the life cycle of meat products. Cooked ham production is the second contributor to environmental impact. The contribution of this stage refers to energy consumption and refrigerant leakages. High pressure processing has a little influence on the environmental profile of the sliced cooked ham if there are no modifications of the behavior at the distribution and consumption stages. Main differences between meat products concern to the storage time that can be prolonged in treated products. The treated meat products with extended shelf life increase the use of non-renewable energy without important change of global warming potential due to electricity mix in France.

4.2. Food quality in the life cycle assessment

The treated meats products commercialized are value-added products (Bajovic et al. 2012). The average price of treated sliced cooked ham and untreated ones recorded in Europe was considered in the analysis. The difference between prices was observed in data collection. Consumers with knowledge of high pressure processing are able to pay an additional cost for the features of the high-pressure treated product (Hick et al. 2009). High pressure processing provides added value to meat products by improving food safety since it allows not only the inactivation of pathogenic microorganisms, but also the reduction of use or the removal of food preservatives.

The comparison of the value performance with regards to the environmental impact is defined as eco-efficiency (Schau and Fet 2008). For treated products, each monetary unit as benefit represents less environmental load. In consequence, the use of high pressure processing on cooked ham production improves the eco-efficiency of the meat product. In fact, the comparison between the traditional and the treated product is greatly influenced by the choice of functional unit.

Food safety is also presented as the human health impact of the disease associated to *L. monocytogenes*. Including other dimensions of sustainability at the endpoint level could lead the identification of the main concerns to human health. Although uncertainties of endpoint methods are large, the comparison of impacts at the endpoint level shows that carcinogens, climate change, effects of respiration inorganics, radiation are the most important contributors to damage to human health. However, the human health effect due to listeriosis is relevant in comparison to effects to human health by ozone layer depletion.

For the worst scenario, the human health effects due to listeriosis raised importantly in two weeks; followed by the radiation impact category which is associated to radiation exposition by the power production of nuclear plants. High pressure processing can prevent the years of life lost due to the disease at the baseline (2.84 DALY) and for the worst scenario (14 days: 62.22 DALY). It is important to note that the results of human health effects of listeriosis correspond to specific geographic conditions, consumer characteristics and for a susceptible population (older adults and pregnant women). The benefit of preservation technologies are not only limited to the actual state of food safety of meat products; but also in the prevention of higher human health damage due to food-borne diseases. Efforts are necessary to decrease the principal contributors to the environmental impact and therefore, the damage to the human health. Reduction of meat content in meat products is complicated without affecting its nutritional value. Finally, novel technologies play a role in minimizing losses by improving food quality.

5. Conclusion

Novel technologies have a great responsibility to improve sustainability on food processing. In this case, increasing food processing steps to improve food quality does not necessary cause a notable increase of environmental load of processed food. The eco-efficiency of the meat product can be enhanced by using high pressure processing. In fact, the food quality can be improved without important contribution to the environmental impact of the meat product. Furthermore, the direct impact of food safety on one of protection areas of LCA, human health, was described. The benefits of high pressure processing on food safety could compensate in part the use of non-renewable resources due to the extended shelf life of products. Other quality features should be included in life cycle assessment for improving comparison between products.

Co-digestion of dairy cow manure and food waste creates a more efficient biogas cycle

ABSTRACT

The AgSTAR project of the U.S. EPA analyzed the possibility of installing anaerobic digesters with energy generation and nutrient capture in all confined dairy operations in the US with 500+ cows, with a total potential capacity of more than 2,000 digesters nationwide. This study uses environmental life cycle assessment to identify the potential benefits of disposing locally accessible commercial food waste with manure at those digesters (via co-fermentation) in comparison to other disposal options. Anaerobic digesters show an advantage compared to compost or landfill for all impact indicators examined: human health, climate change, ecosystem quality and water withdrawal. For greenhouse gases, the installation of digesters could potentially reduce 20-25 million metric tons (MMT) CO_2e of fugitive methane emissions from manure compared to current manure management practices, 10 MMT CO_2e of fugitive methane emissions from landfilled food waste, and another 10 MMT of CO_2e from avoided electricity, fertilizer production and peat moss production by harvesting energy, nutrients, and fibers from digesters, respectively.

Keywords: Dairy, food waste, anaerobic digestion, compost, landfill, manure

1. Introduction

It is estimated that 13 percent of greenhouse gases in the United States are associated with growing, manufacturing, transporting, and disposing of food (US EPA 2009). This sector is therefore among the high priorities for achieving climate reduction goals. As part of the next phase of the 2013 Climate Action Plan, announced in March 2014, the US government has placed a heavy focus on cutting methane emissions to help meet a national goal of reducing U.S. greenhouse gas emissions by 17 percent below 2005 levels by 2020. Two key sources of methane reductions cited in the strategy are the reduction of landfill waste and a plan to manage biogases. The latter component mentions implementation of manure digesters on dairy farms as one key component.

Economic analysis has previously shown a large potential benefit for implementation of digesters on US dairy farms (Informa 2013), emphasizing in particular the potential economic benefits that might be gained through taking advantage of the excess capacity of these digesters to produce fuel from other organic matter, such as collected food waste. In addition, the financial potential to market the co-product of digesters as a landscaping material (replacement to peat moss) is also explored. In total, the potential economic benefits of implementing these systems on dairy farms are estimated to be in the range of $3 billion.

Complementary to the economic analysis, the objective of this research was to use environmental life cycle assessment to validate and to examine the effectiveness of the strategy of diverting food waste to co-digestion with dairy manure as a solution for reducing greenhouse gas emissions and other environmental impacts. The system analyzed forms an example of how a circular economy concept is possible within the food production chain, with wastes from food production re-entering the food production system in a way that supports the solution environmental problems at earlier stages of production. The system also provides linkages to other industrial systems, resulting in a potential for a type of Eco-industrial Park centered around an agricultural system. The quantification of the benefits of this system is based on a life cycle assessment (LCA) approach).

2. Methods

2.1. Scenarios under study

Worldwide, the dominant methods of waste disposal are landfills and open dumps. According to U.S. EPA 2012 MSW Characterization Reports (US EPA 2012a), food waste is the largest category of municipal solid waste (MSW) sent to landfills in the United States, accounting for approximately 21% of the waste stream. In

2012, over 30 million tons of food waste is sent to landfill in the US. Of the less than 5% of food waste currently being diverted from landfills, most of it is being composted to produce fertilizer. In this study, the following three systems are analyzed:

a. Landfilling (baseline)
b. Composting
c. Co-digestion of food waste with dairy manure.

In addition to these scenarios for the management of food waste, the benefit is also assessed of using the fiber derived from digesters as a replacement for peat moss in landscaping applications. The present scope does not include consideration of the impact in producing any of the treatment infrastructures for the various options.

2.2. Landfilling

Figure 1 illustrates the methane emissions from landfills based on data provided by US EPA (2012 b). Approximately, 38% of methane is directly emitted to atmosphere, 33% of methane is either flared or oxidized, and 29% of methane is recovered for energy, of which most (74%) is harnessed for electricity generation, 24% is used for heating, and 2% is used for alternative transport fuel (US EPA 2012c) LMOP database).

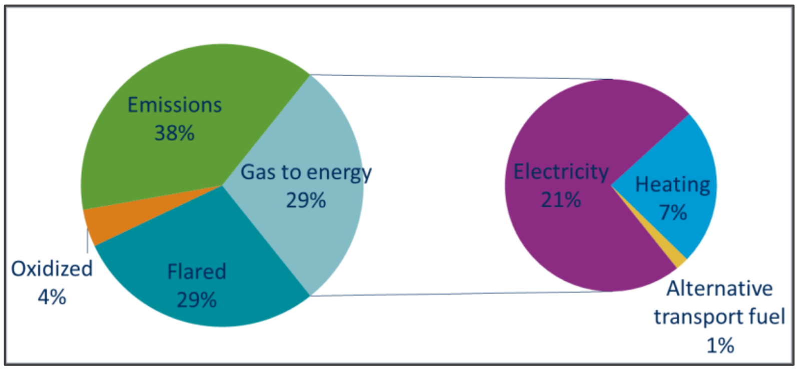

Figure 1. Fate of CH_4 generated by U.S. landfills in 2009

The environmental impact of landfilling food waste was modeled based on an LCA approach using the ecoinvent v2.2 database (processes "disposal, biowaste, 60% water to municipal landfill/CH U") with adaptations made to account for 84% degradation of the materials within a 100 year timespan, following the estimates made in the US EPA (2006) solid waste report. The direct methane emission factor is calculated to be 0.085 kg methane per kg of wet food waste mix treated. The avoided electricity generation, heating and transport fuel were also modeling with the ecoinvent 2.2 database with adaptation from US LCI database and GREET Model.

2.3. Composting

There are several types of composting technologies, including Backyard or Onsite Composting, Aerated (Turned) Windrow Composting, Aerated Static Pile Composting and In-Vessel Composting. ISWM-TINOS (2010) and Morris et al (2011) review recent LCA publications related to composting for more than 30 different sample sizes, results are found with large variability, especially for energy requirement and fugitive emissions. For energy requirement, Rob van Haaren, et al (2010) reported an estimate of 30kWh/ton of wet food waste mix, which is in line with the average energy requirements reported by Diaz et al. (1986, cited in US EPA 2000 report) that estimates 34.4 kWh is required per ton of waste in an MSW composting facility. For fugitive CH_4 and N_2O emissions, default factors from biological treatment for Tier 1 method given by IPCC (2006) were used that is 4 g CH_4/kg waste treated and 0.3 g N_2O/kg waste treated on a wet weight basis. In this study, life cycle inventory data is based on the Rob van Haaren, et al (2010) study for windrow composting technology with fugitive CH_4 and N_2O emission adjusted with data mentioned above.

2.4. Anaerobic digestion

The AgSTAR project (US EPA 2011) analyzed the possibility of installing anaerobic digesters in confined dairy operations of 500 cows or larger, which, at the time of their analysis, amounted to 2,647 dairy operations nationwide. The anaerobic digestion scenario here considers the primary electricity output and co-product (N, P, fiber) produced by disposing of food waste in dairy farm digesters that are also managing manure. The characterization of this system made here relies heavily on the Informa (2013) report National Market Value of Anaerobic Digester Products. This representation attempts to reflect a realistic implementation of the use of digesters for disposal of all accessible food waste within the U.S. on an annual basis. It is assumed that the food waste used in digesters will primarily be commercial food waste and food processing wastes, rather than residential food waste; also the food waste generated on farm (pre-harvest food waste) is not included. Table 1 below lists the potential products for a manure and food waste co-digestion system. Table 2 gives CH_4 emission factors of different feedstock inputs used for anaerobic digesters.

Table 1.Potential Production and Value of Products and Co-Products for co-digestion of manure and food waste in 2,647 Dairy Anaerobic Digesters.

Inputs and assumptions[a]	**Manure+ Food waste**	**Manure**	**Food waste**	**Unit**	**Avoided burden**
Number of cows	3,974,143	3,974,143		Number	
Manure	108,792,165	108,792,165		US tons/year	
Food waste	19,849,474		19,849,474	US tons/year	
Output					
Electricity production	11,701,222	6,375,637	5,325,585	MWh/year	Electricity production, US average
Recovered Nitrogen	331,163	176,337	154,826	US tons/year	Nitrogen production, US average
Recovered Phosphorus	108,782	57,174	51,608	US tons/year	Phosphorus production, US average
Nutrient enriched Fiber	30,111,422	30,111,422		US tons/year	Horticultural peat moss

[a] Data comes from Informa (2013) report.

Table 2.Methane emission factors for different composition of inputs for anaerobic digesters

Type of input	**Quantity**	**Unit**
Manure only (wet)	0.0101	kg CH_4/kg treated
Manure and food waste (wet)	0.0140	kg CH_4/kg treated
Food waste mix only (wet)	0.0353	kg CH_4/kg treated

The methane calculation follows the calculations done in the Ag STAR study (US EPA 2011). The calculation is based on volatile solids (VS) excretion by cattle. This calculation includes a weighted average methane conversion factor based on the manure management systems used on these dairies. EPA provided those estimates by state, but they effectively reduce the methane used in the calculation of the GHG credits by a factor ranging from 35% to 76%, with a national average of 58%.

2.5. Modelling impact of operating digesters and avoided burdens

2.5.1. Impact of operating digester systems and avoided burden from energy and nutrient products

The impact of operating digester systems are modelled based on the ecoinvent v2.2 dataset “electricity, at cogen with biogas engine, allocation exergy/kWh/CH” with adaptations to reflect the biogas generation from food waste.

Methane emissions from dairy manure are assumed to be 100% emitted to air if they are not managed by anaerobic digesters. The avoided burdens associated with energy and nutrient production are modeled with ecoinvent v2.2 datasets as described in Table 1.

2.5.2. Avoided burden from replacing peat moss with digester-derived fibers

There are three main uses for anaerobic digested fiber from dairies. Digested fiber is used for animal bedding, land application to provide plant nutrients, and as a peat moss replacement (Informa 2013). Here, we assume all digester fibers produced are used as peat moss replacement. The Informa report made state-by-state assumptions regarding the fiber that would be available as a peat moss replacement, estimating that of the 18,843,757 cubic yards of fiber produced by plug flow digesters, 16 million cubic yards could be used as peat moss replacement.

Table 3 provides the volume consumed for different types of horticultural peat moss consumption in US in 2011 based on USGS statistics. In total, nearly 6.8 million cubic yards of peat moss is consumed annually in US for horticulture. Most of this volume is imported from Canada. The fiber that goes to peat moss replacement will be 52.8% of the total digester fiber produced. In this study, the maximum benefits are estimated based on future scenario assuming the peat moss market will reach 16 million cubic yards.

Table 3. Different type of peat moss consumed in US in 2011 (USGS statistics)

Type of peat moss consumed in US 2011	**Quantity[a] (cubic yards)**
Canada Sphagnum moss	6,503,569
US Sphagnum moss	289,057
Other import	190,881
Peat moss total	6,792,626

[a] Source: USGS statistics http://minerals.usgs.gov/minerals/pubs/commodity/peat/

The peat life cycle includes harvest, packaging, transport, use, disposal, as well as the in-situ decomposition from the harvest site. For environmental impact of horticultural peat moss production and use, we compared both European (Quantis 2012a) and Canadian peat moss (CIRAIG 2006) studies. Both studies show that peat decomposition during use and disposal stages contributes the majority of climate change impact across the peat moss life cycle (175-180 kg CO_2e/ m^3 of black peat moss). Contributions from other life cycle stage are relatively small or negligible in the European peat moss study. However, in-situ decomposition contributes ~60 kg CO_2e/m^3 peat moss in Canadian horticultural sphagnum peat study, which accounts for peat oxidation from the opening of the harvesting site until its restoration, considering that 50% of the sites are restored after the product cycle and 50% are rehabilitated. Detailed study on peat moss replacement can be found in Quantis (2012b) report (URL: http://www.usdairy.com/~/media/usd/public/digesterfiberstudyquantis.pdf.pdf)

2.6. Impact assessment method

The impact assessment methodology used in this study is based on IMPACT 2002+ vQ2.21, adapted by Quantis to included Water Withdrawal indicator that is the sum fresh water (drinking water, irrigation and sea water. Our results will focus on climate change, water withdrawal and three areas of protection (human health, ecosystem quality and resource depletion). Although the presentation of results focusses on these endpoints, a complete interpretation should also consider the contributing results at the midpoint level and some discussion of midpoint results is included here where relevant to the interpretation. Further details are found at http://www.quantis-intl.com/pdf/IMPACT2002_UserGuide _for_vQ2.21.pdf

3. Results and Discussions

3.1. Detailed results for climate change

Figure summarizes the estimated climate change benefit (CO_2e) of co-digestion of food waste and dairy manures that could potentially be provided by 2,647 digesters, if they were installed in large US dairy operations nationwide and produced the products used in the ways described above. Each bar shows the contribution of a different aspect of the digester + avoided burdens system to the total net impact. Beneficial contributions appear on the positive y-axis, while detrimental contributions appear on the negative y-axis. Compared to landfill of food waste and direct methane emissions from manure, the potential benefit of co-digestion of 18 Million MT of food waste with manures in 2647 dairy farm digesters in US for a year equates to avoiding release of greenhouse gases equivalent to 50 million metric tons of CO_2e.

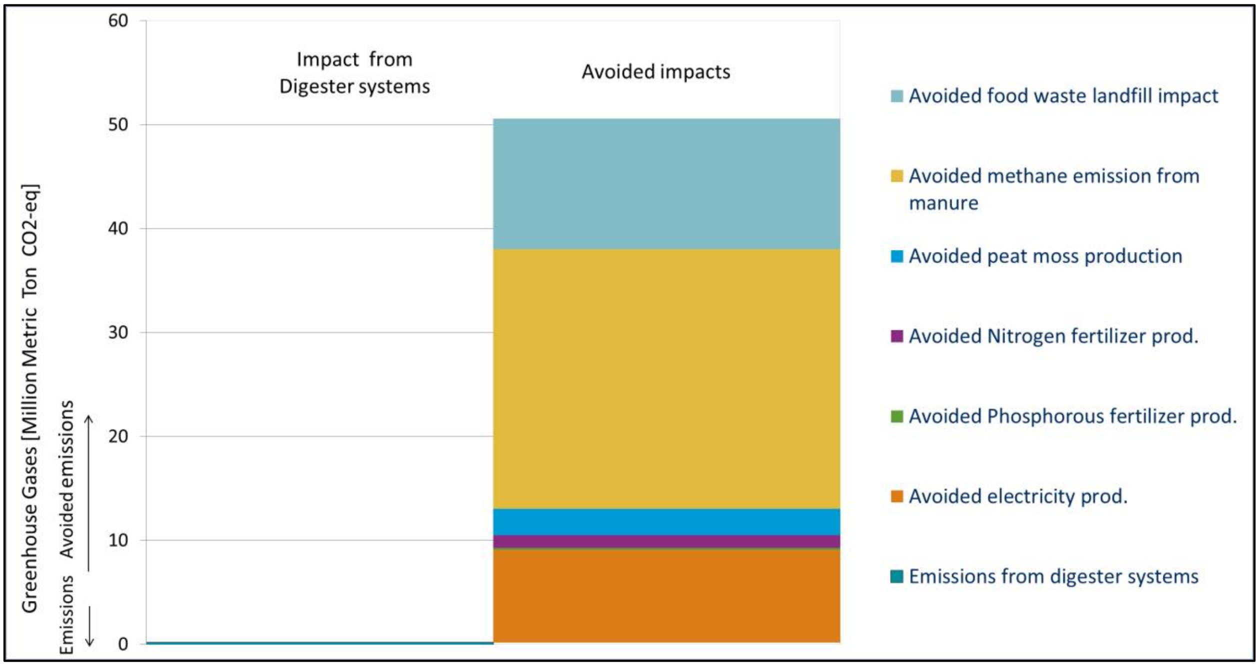

Figure 2. Contribution of different life cycle stages to climate change benefits for co-digestion of food waste with manures system vs. food waste landfill & direct methane emissions from manure (Positive value: beneficial/credits; Negative value: detrimental/impact)

For all scenarios, the avoided fugitive methane emissions from dairy manure management provide the largest climate change benefit (25 million metric ton CO_2e), by converting all biogenic methane that would otherwise be emitted into air to energy. Diversion of food waste from landfill provides the second largest climate change benefit (12 million metric ton CO_2e). US EPA (2012b) reports that 38% of landfill methane is emitted directly to air, and avoiding this release also provides substantial climate change benefit. The third largest climate change benefit (9 million metric ton CO_2e) is due to using the biogas harvested from digesters to replace electricity production.

The impacts of producing the biogas and then converting it to electricity are shown in Figure 2 as 'Emissions from digester systems'. It should be noted that landfill gas is harvested from landfills in the US at a rate of roughly 28%, and largely converted to electricity. When food waste is diverted from landfills, the beneficial use of the landfill gas is also lost. This loss of recovered landfill gas to energy has been subtracted from the food waste landfill benefits shown.

Finally, during the digestion process, nitrogen and phosphorous are recovered, and as a result the digester systems are credited with the avoided impact of average nitrogen and phosphorous fertilizer production in the US. Table Table 4 details the potential positive and negative (beneficial and detrimental) environmental impacts of food waste and manure disposal in landfills, compost and digesters, and the difference among these scenarios. Landfill and composting of food waste generates environmental impact for climate change and ecosystem quality but provides a net benefit for resources due to the harvested landfill gas for electricity and heat, which avoids the fossil fuel use associated with conventional sources for electricity and heat. Composting also shows a net impact in the category of human health effects of pollution, whereas landfilling shows a small net befit in this category. In contrast to landfilling and composting, digestion of food waste and manure causes benefits for all the impact categories examined here.

Table 4: Potential environmental profile of baseline landfill and compost relative to dairy farm co-digestion system (Positive value: beneficial/credits; Negative value: detrimental/impact)

Impact category	Unit[b]	Baseline: Landfill	Alternative: Compost	Alternative: Digester	Compost vs. landfill	Digester vs. Compost	Digester vs. Landfill
Climate Change[a]	MMT CO_2 e	-13	-3.4	37	9.1	41	50
Human Health	DALY	0.22	-4.3	7.2	-4.5	11	7
Ecosystem	Million PDF.m^2.yr	-140	-700	1400	560	2100	1500
Resources	Million MJ Primary	11	1.7	190	-9.7	190	180
Water Withdrawal	Million m^3	17	7.1	340	-10	330	320

a.Climate change result for digester systems also includes 21 MMT CO_2e. benefits from avoided methane emission from dairy manure management. By excluding this benefit, digester is still preferable to other options
b. Abbreviations: MMT= million metric tons

The results indicate that digester disposal is preferable to landfill and compost for all environmental impact categories when biogas is used for electricity generation.

3.2. Summary of results for endpoint impact categories

Figure 3 provides impact results for indicators in addition to climate change for all options under evaluation. The comparative advantage of anaerobic digesters also holds for all endpoint environmental impact categories examined.

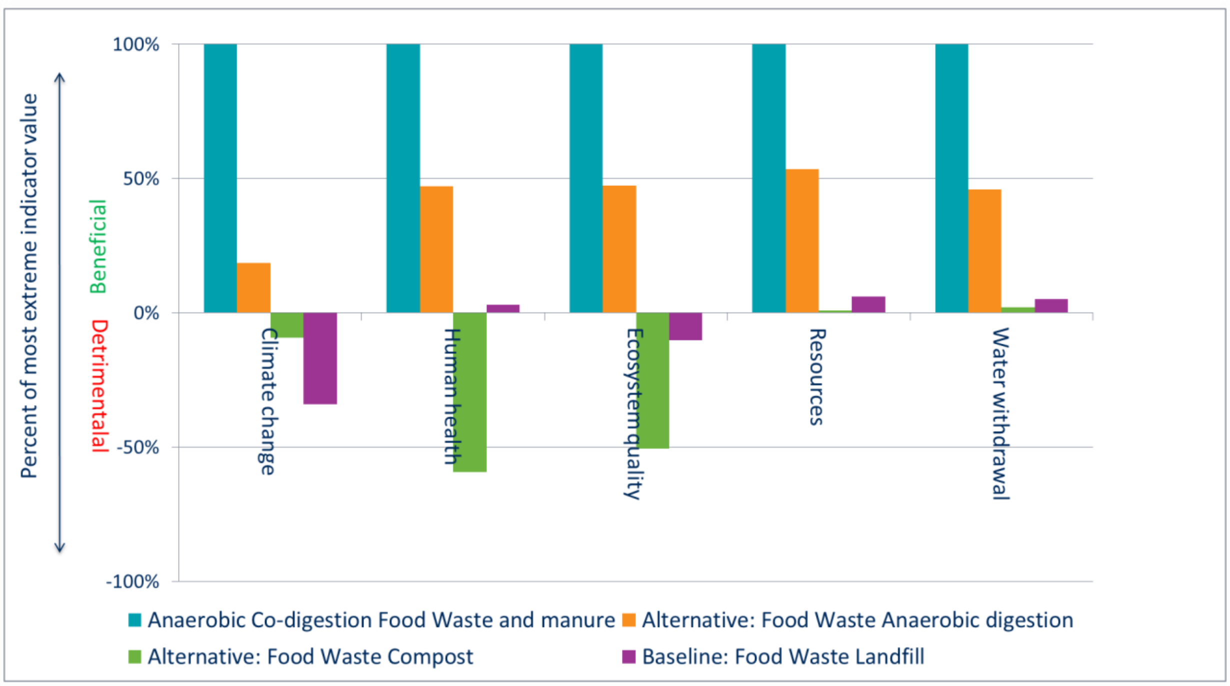

Figure 3. Multi-indicator environmental evaluation of routes of disposing food waste (and/or manure) (IMPACT 2002+ VQ2.2)

4. Conclusion

The findings indicate that for each impact category examined (including climate change, human health, ecosystems and resources), co-digestion of food waste with dairy manure is preferable to landfill disposal and composting for most environmental indicators. In terms of climate impacts particularly, diversion of this food waste from landfill to digesters could avoid the release of greenhouse gases equivalent to between 50 million metric tons of CO_2e. This equates to taking 10 million cars off of the road for a year or to reducing U.S. annual methane emissions by 7%.

Dairy farm digesters are proven to be not only a financially cost-effective but also environmentally favorable business model to provide opportunities for dairies, food processors and retailers. The digesters can play an important role to cultivate the circular industrial economy for food and agriculture industry and also an effective strategy to support achieving greenhouses gas reduction goals in this U.S.

ABSTRACT

The UNEP International Resource Panel has the objective to evaluate the current and projected use of natural resources and as well as to identify opportunities for improvements, using a food systems approach. These opportunities will probably not only include more technical and process oriented opportunities as typically identified with a LCA-approach, but will also include opportunities as the consumption side as reducing food losses and dietary changes. The concept of 'food system' includes all processes and infrastructure involved in feeding a population in a certain region; the global food system is composed of many, partly connected, local and regional food systems. The notion that food systems actors as food processing companies and retailers not only influence the how and where food is being produced, but also people's eating habits and diets, is gaining momentum. Other than in the food chain concept, which perceives the different actors in a more neutral way, the food system concept acknowledges that the actors influence each other, within a certain political, technological, environmental, cultural and institutional setting. Food systems have environmental, socioeconomic and health outcomes, which can, for example in case of undesired outcomes, lead to changes in the context. Given the large differences in regional food systems, a number of global regions (as sub-Saharan Africa, South-East Asia and Europe) are studied in more detail, partly by means of expert workshops.

Keywords: food system, sustainability, resource efficiency

1. Introduction

To most people in the world, current food systems deliver ample and safe food on a day-to-day basis, which can be regarded as a great achievement. This is possible thanks to a large number of actors as farmers, fishermen, processors, retailers and restaurant, as well as to the distribution sector. These actors together make a the food system in a certain region: the concept includes all processes and infrastructure involved in feeding a population in a certain region. The global food system is composed of many, partly connected, local and regional food systems. Governments support the functioning of food systems, for example by regulation on food safety and by investments in the knowledge infrastructure. However, still more than 842 million people are undernourished (FAO 2013), while the same time many people suffer from obesity and other food-related diseases mainly due to unhealthy eating habits. At the same time, food systems are a major user of natural resources, such as land, water and minerals (nutrients) (Foley et al. 2005; Molden 2007), as well as a major source of emissions (as greenhouse gases, pesticides and nutrients) (Bouwman et al. 2009; FAO 2006; Vermeulen et al. 2012). As a consequence of this, food systems are the main driver of global loss of biodiversity (PBL 2010). Due to growing population, increased welfare and urbanization, the environmental impacts are expected to increase. Due to the same drivers, vast changes in food systems are expected, such as supermarketization in developing countries (Reardon et al. 2012). Supermarketization not only affects the supply chain, but very often eating habits and product sourcing as well.

Life cycle assessments (LCA) are widely used to improve processes, support policy decisions and provide a sound basis for informed decisions. LCA can point at technical options to improve production processes and can provide objective and balanced information to compare different production techniques (for example organic versus conventional farming) and different products (for example beef versus poultry meat). Over the last several decades the scope of LCAs has been extended from more traditional subjects such as the use of energy and minerals to more complicated issues including greenhouse gas (GHG) emissions (de Vries and de Boer 2010), land use (Koellner et al. 2013; Mila i Canals et al. 2007); and even social issues as human well-being (Weidema 2006). LCAs of food products are usually quite complex for a number of reasons, but not limited to,:

(i) food production has a large number of environmental effects, including energy, land and water use, use and losses of plant nutrients (N, P and about 15 others), pesticides, GHG; (ii) the generation of co- products and by-products by agri-food production processes; (iii) the site specificity of agricultural production; (iv) the difficulty of defining the functional unit, especially when comparing different types of food, as for example calories or proteins do not cover all nutritional aspects and (v) the various social, cultural and economic aspects of agriculture and food. Thus, in spite of the many efforts to develop LCA for food systems (see e.g. Cowell 1998; Milà i Canals 2003; Brandão 2012), LCAs have been criticized for not being inclusive or complete enough, or for having a too "hard" structure biophysical focus not capable of capturing the wider socio-economic context or "soft" power relationships in value chains (Garnett 2013; Sim 2006). LCAs provide a system for systematically quantifying the relative costs of production for different products and production systems, and for analyzing the contributing factors.

To overcome a number (but certainly not all) of the issues the concept of 'food systems' might be helpful both in identifying opportunities to increase (overall) resource efficiency of food systems as well as to identify food system actors who could facilitate in taking advantage of these opportunities. This food system approach should not be seen as an alternative to LCAs, but as a complementary approach. Especially for more detailed analysis, LCAs remain very helpful, while the food system approach can place the results in a broader context.

The notion that 'food systems' not only influence how and where food is being produced, but also people's eating habits and diets, is gaining momentum in the literature (Ericksen et al., 2010; Ingram, 2011; Pinstrup-Andersen and Watson II, 2011; Vermeulen et al., 2012). In contrast to the food chain concept, which perceives different actors in a more neutral way, the food system concept acknowledges that the actors influence each other, within a certain political, technological, environmental, cultural and institutional context. The objective of the UNEP International Resource Panel (IRP) is to evaluate the current and projected use of natural resources in regional food systems and the global food system as a whole. It also intends to identify opportunities for resource efficiency improvements using a food systems approach, for example by pointing at specific opportunities for certain food system actors. As part of this initiative, the IRP is collaborating with LCA experts in order to gain insights from this well-established methodological approach and cross-fertilize each discipline.

2. Methods

As the concept of 'food systems' and their interaction with natural resources are important, first a conceptual framework was developed, to help further structuring the research questions (Figure 1). Main elements of the food system, and their interactions with natural resources, and environmental and societal impact are depicted in a conceptual framework. Food systems usually can be divided into various food system activities, ranging from provision of inputs (as fertilizers and machinery), primary production (mainly by farmers and fishermen), food trading and processing (crushing of oil seeds, sugar refinery), food industry (preparation of 'food' as eaten by consumers, from bread to ready meals), retailing and food service, consumption and finally processing of food wastes. The different steps can often not be clearly separated, and also very much depending both on the types of food as well as on the regional food system. Food chains in rural areas in developing countries are often relatively short, especially in the case of subsistence farming, where most of the food production and processing (as milling and baking) is within households. In developed countries food systems are typically much more complex. Food systems necessarily depend on certain natural resources, such as land, water and minerals in the case of agriculture, or fish stocks in the case of fisheries. Due to emissions and the use (and sometimes overuse) of resources, food systems have environmental impacts. Life cycle assessment typically addresses the natural resource use and environmental impact of one type of product from input up to the point where it is sold to the consumer and/or consumed. Food systems also include aspects as food system outcomes (effect of food security and human health, farmers' income etc.) which affect general social welfare. Finally, and maybe most importantly, food systems research postulates that the food system are shaped by food system actors (as farmers, food companies and retailers). These actors operate in a certain socio-economic context. The food system is therefore not a neutral logistical food chain as the food system actors have large interests, which basically shape food systems. From a societal point of view, the food system outcomes are most important: to which extent do food systems deliver food security, incomes and are they capable of doing so not only now, but in the future as well.

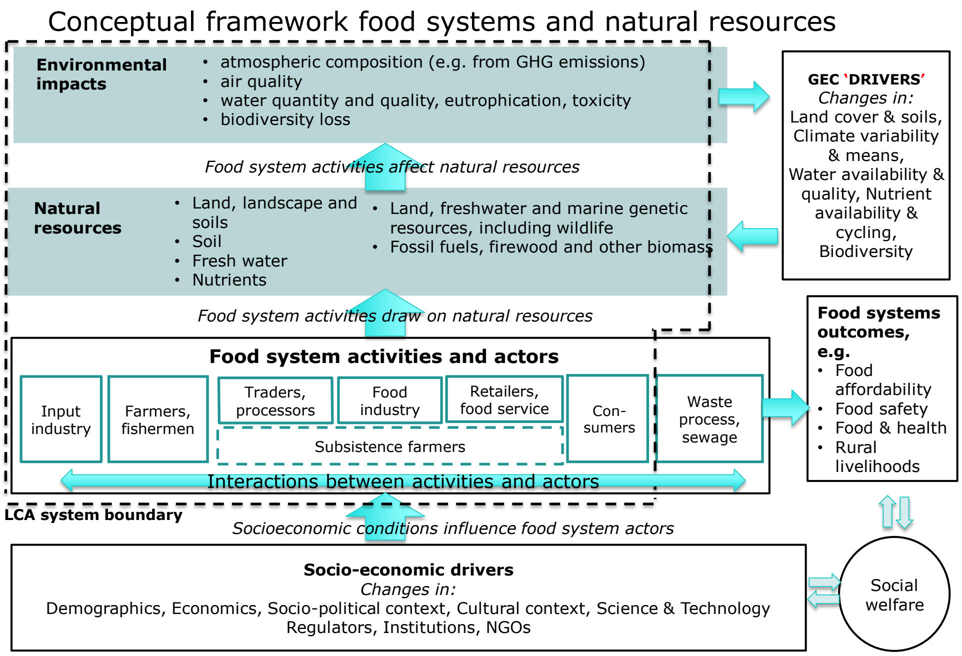

Figure 1. Conceptual framework of food systems, their interaction with natural resources and environmental impacts and food systems outcomes. Also the system boundaries of a typical food LCA study are indicated.

In order to be able to fulfill the objective, for main research question were defined: (i) What is the present and projected use of resources in the various regional food system; (ii) what are the options in biophysical terms to make this reduce this use, or to make the use more sustainable; (iii) how are current food systems functioning, in terms of institutions, technology and relationships (iv) what are the major opportunities within food systems for the various actors to improve the resource efficiency of food systems. The study was mainly based on existing literature, added by expert knowledge. Part of the input of expert knowledge was organized in the form of regional workshops.

Ad (i): The use of resources and environmental impacts were assessed for both the present as well for the future situation. For this agro-economic projection, such as the medium term FAO-OECD Outlook (OECD and FAO 2013) as well as scenario studies focusing on natural resource use have been used (Bouwman et al. 2009; Schmitz et al. 2014). The focus was on a limited number of resources: land, minerals, water, genetic resources and marine resources and environmental impacts (GHG, emission of minerals, biodiversity). Ad (ii): Also based on literature, the major options have been identified to improve the resource use efficiency or to reduce the environmental impacts. These not only include supply-side options (mainly related to production), but also demand-side options as the reduction of food wastes or dietary shifts. Ad (iii): Given the large differences in regional food systems, a number of global regions (as sub-Saharan Africa, South-East Asia and Europe) were being studied in more detail, partly by means of expert workshops. Ad (iv). Based on the previous collected information, the major opportunities for food system actors were identified. The opportunities were not only evaluated in terms of impact on resources use (for which amongst others an LCA-type information was used), but also in terms of broader societal outcomes, where aspects such as food security, health, resilience of farmers and food sovereignty were assessed.

3. Results

Results as synthesized from peer-reviewed articles and state-of-the-arts reports will be used to analyze the present and projected use of resources. Where possible, a disaggregation per region or per commodity will be made, in order have a better understanding of the drivers of resource use and environmental impacts. Examples of the latter are available for nitrogen use and losses (Leip et al. 2013) and greenhouse gas emissions (Lesschen et al. 2011).

In a second step the potential of biophysical options will be evaluated. Where possible and logic the options will be differentiated per region, as not all options are relevant for each region. Both options and the demand side as well on the supply side will be evaluated. The effect of the various options on the selected natural resources and impact will be assessed, when possible based on peer-reviewed articles or otherwise expert judgment. Examples of demand side options are the reduction of food losses (FAO, 2013; Rutten et al., 2013) and dietary shifts (Stehfest et al. 2013; Stehfest et al. 2009; Westhoek et al. 2014). A first evaluation shows that options at the demand side typically have a positive effect on the use of all resources and environmental impacts (Table 1). Supply side options might have certain trade-offs on other resources. An example is increasing crop yields by increasing fertilizer input, which could lead to higher nutrient losses if this is not done correctly (Mosier et al. 2004; Yang 2006).

Table 1. Provisional estimated effect of a number of biophysical options to increase the resource efficiency of food systems, or to reduce the environmental impacts.

	Reduction of resource use			Reduction of environmental impact			
	Land	Water	Minerals	GHG emissions	Water pollution	Bio-diversity	Examples
Demand side							
Reduce food losses and waste	+	+	+	+	+	+	Reduce post-harvest losses
Reduce consumption of livestock products	+	+	+	+	+	+	Reduce portion size, hybrid products
Supply side							
Increase crop yields	++	+?	+ / -	+	-?	+	Improved fertilization; precision farming techniques; improved seeds
Sustainable land management	++	+	+	+	+	+	Soil and water conservation practices
Improve recycling minerals, including reduction of emissions	0?	0?	++	+	++	++	Improved integration of animal manure in crop production
Increase feed efficiency livestock	++	++	++	++	+?	++	Better feeding techniques
Improve transport efficiency	0	0	0	+	0	0	Smart logistic

Consequently, the current food systems in different regions will be examined, as well as projected changes in these. Reardon and Timmer (2012) distinguish food systems in traditional versus modern, while pointing at an intermediate system too. Key findings for Sub-Saharan Africa suggest the trends of urbanization and "supermarketisation" becoming prevalent in the region, which will lead to a significant change of the more traditional food systems. Among others, these trends are leading to changes in diets, increased food wastage at the retail stage, and an increase of globally sourced food in detriment to local sources. The vast majority of energy used for cooking depends directly on local biomass, which is linked to deforestation; in addition 60-70% of this energy is lost in the cooking phase due to inefficient appliances, pointing to a significant potential improvement opportunity.

In terms of opportunities, the food systems approach highlights opportunities which might result from better cooperation between food system actors, leading for example to reduction of food wastes and losses and to a better recycling of nutrients. Other opportunities might arise when downstream actors help farmers to adopt better practices, which might lead to higher crop yields and higher farmers' income. One example is when smallholder farms would be better connected to urban markets, which could not only lead to higher incomes, but could also reduce food losses (through better storage and logistics) and facilitate the provision of inputs as fertilizers. The workshop also identified the role that large companies and global supply chains may play through investing in sustainable sourcing certification schemes. Capacity building to mainstream Good Agricultural Practices linked to these certification schemes is an essential element to enhance yields and reduce environmental impacts related to excessive nutrient losses and/or inadequate pesticide use. In addition, certification facilitates access to markets, which is usually found as a key reason behind pre- or post-harvest food losses. A last example of an opportunity of improved resource use within food system would be the case where retail and food service companies help consumers by making the healthier and environmentally logical choice for consumers. Apparently, corporate interests are not always aligned with optimal societal outcomes of food system. This might be addressed by governments if it is better known under which conditions private actors food systems can deliver better outcomes.

4. Discussion

The food systems approach facilitates consideration of the perspectives of all different actors in the food value chain, and thus the identification of improvement opportunities leading to enhanced resource efficiency, social fairness and economic benefits, in the delivery of the key outcomes. By identifying the key actors of change in specific regional systems, the most adequate opportunities may be leveraged. When considering these actions, the interests of the different key actors should be understood. These interests are often the key to understanding the way the current food system operates, and why certain societal undesired outcomes occur.

Whereas LCA already has clearly defined methods and procedures, the methodology to assess the effect of food systems and potential changes in these, mainly still has to be developed. Given the complexity of food systems, one can even doubt whether a full evaluation can ever be possible. Nevertheless, some aspects or components of food systems can be modeled, for example by using bio-physical or macro-economic models, or combination of these. Examples are the attempts to model on food prices and food security interventions as changes in trade regimes (Anderson 2010; Schmitz et al. 2012; Verburg et al. 2009), investments in agro-food systems in developing countries (IAASTD 2008) and biofuel policies (Bouët et al. 2010; Hertel et al. 2013). Some other studies have focused more on the biophysical aspects, like studies on potential changes in dietary patterns, looking especially at reducing meat consumption (Stehfest et al. 2013; Stehfest et al. 2009). Besides quantitative methods, a large number of more qualitative methods exist, based in thinking from disciplines as political science, sociology and other behavioral sciences and institutional economics. The food system approach has the potential to expand the identification of opportunities for improving the sustainable use of natural resources beyond the more food product based approach as is typically done with LCA studies. Examples of such opportunities in a more bio-physical sense are the reduction of food losses, dietary shifts towards less meat. Moreover, the food system approach offers new perspectives to address a number of issues by involving other agents of change such as food companies and retailers. This could lead to the identification by scientists of opportunities for both policy makers as for actors in the private sector policy-making, thus enhancing the science-policy interface, and maximizing the potential impact of improvement opportunities. Whereas LCA-type analyses have a well-defined methodology, the methodology for food systems analysis largely still has to be developed. This means that the two approaches should be seen as complementary.

ABSTRACT
This study analyzed impacts on global warming, energy demand and consumptive water use from meat processing of four major species, chicken, pork, sheep and beef. We investigated four different approaches for handling co-production between meat and non-meat co-products; allocation based on either i) biophysical / protein utilization (BIO); ii) economic value (ECON); system expansion (SE), and a hybrid approach utilizing both biophysical allocation and system expansion (BIO-SE). The impact from processing varied depending on species and impact category, but for all species, the choice of method used to handle co-products had a substantial impact on results. Impacts attributed to the meat product were lowest when BIO was applied, while the highest impacts were generally associated with ECON. SE results were not uniform across the species or across impact categories. Carcase and human edible yield is also discussed as an important consideration when comparing meat products at intermediate stages in the production supply chain.

Keywords: meat processing, life cycle assessment, meat chicken, pork, sheep meat, beef

1. Introduction

Numerous LCA studies have been conducted for meat production systems in the past 10 years, and many of these (e.g. Williams et al. 2006, Cederberg et al. 2009) have focused on the primary production system to the cradle-to-farm gate section of the supply chain. Meat processing, while being a relatively smaller contributor to impacts than the farming section, is a very important stage in the supply chain from the perspective of handling co-production. Livestock systems generate various important co-products, including leather, pet food, protein meals and tallow. Mass loss during meat processing also results in an increase in emissions attributable to each product irrespective of the method used for handling co-production.

A number of farm-gate livestock LCA studies (Cederberg et al. 2009; Leinonen et al. 2012; Opio et al. 2013; Williams et al. 2006) have reported results using a carcase weight (CW) or even a boneless meat functional unit, creating a mismatch between the functional unit and system boundary. This approach induces two errors; firstly it fails to include impacts associated with the meat processing stage of the supply chain and associated transport, and secondly the method attributes all impacts to the meat product, ignoring the value of the co-products entirely. This is inconsistent with other stages in the livestock system where considerable attention has been given to addressing co-production, such as approaches for handling milk and meat in dairy cattle systems (i.e. Cederberg & Stadig 2003, Flysjo et al. 2012). Processing inventories for LCA purpose have been included for chicken meat (e.g.Bengtsson and Seddon 2013), pork (Nguyen et al. 2011), sheep meat and beef (e.g.Peters et al. 2010; Ridoutt et al. 2012). However, few details were provided in these studies and co-production was often allocated on economic or mass bases. In addition, system expansion of meat processing has not been investigated in detail, and thus the significance of rendering was not fully understood. In a recent study of environmental impacts of rendering, Ramirez et al. (2011) considered animal by-products as wastes and do not include the environmental burden of their production. This ignored the fact that meat processing produces not only meat products for human consumption but also pet food and other valuable products. To the authors' knowledge, the significance of co-product handling has not been thoroughly investigated before.

In this paper, inventory data for meat processing of four species (chicken, pig, cattle, sheep) were collected from meat processing plants in Australia covering greenhouse gas (GHG) emissions, fossil energy demand and consumptive fresh water use. The impact of four methods for handling co-production (biophysical allocation based on utilized protein and energy, economical allocation, system expansion and a hybrid approach utilizing both biophysical allocation and system expansion) were presented at the point of meat processing. The results were compared with allocating all impacts to the meat product only. We suggest here a re-definition of the functional unit for meat products to include the yield of edible co-products that are an important contribution to human food supply.

2. Methods

2.1. Goal and scope

The goal of this study was to provide factors and inventory data representative of modern meat processing facilities in Australia, and to explore the impacts of co-production at the point of meat processing. The focus of the study is meat processing, but to illustrate the relevance of methods for handling co-production, the system boundary includes all stages up to the point where product is ready for transport to wholesale or retail (the meat processing plant loading dock). The functional unit is 1 kilogram of retail portions excluding packaging. The study was based on primary data collected from meat processing plants from a series of studies conducted by the authors (Wiedemann et al. 2010; Wiedemann et al. 2012). These studies also provide details of the cradle to farm-gate stage of the supply chain which have been updated to include direct land use change (dLUC) impacts in the present analysis.

The study determined GHG emissions using the IPCC AR4 global warming potentials (GWP) of 25 for methane and 298 for nitrous oxide (IPCC 2007). Energy demand was assessed using the fossil fuel energy demand indicator (Frischknecht et al. 2007) and measured in mega joules (MJ) using Lower Heating Values (LHV). Consumptive fresh water use refers to evaporative uses or uses that incorporate water into a product that is not subsequently released back into the same river catchment. In the meat processing, consumptive water includes raw water drawn from river/bores/reticulation and used in the processing plant, and subsequently treated via waste water treatment. The water subsequently used for irrigation (without going through sewage system) is not considered consumptive usage. Consumptive water use was assessed following (Bayart et al. 2010). Inventory data are reported for impacts relating to GHG emissions, energy and water while co-product handling methods were compared for GHG and energy demand only.

2.2. Processing inventory data

Inventory data were collected from a minimum of three meat processing plants for each species (Table 1, Table 2). Data from the case study processing plants were validated using a recent survey of resource use from beef and sheep meat processing plants (GHD 2011) for important inputs such as electricity, gas and water to improve the representativeness of the dataset. Inputs were reported per kilogram of Hot Standard Carcase Weight (HSCW) which is a standard descriptor in Australia. However, the inputs are inclusive of all stages of meat processing, which included chilling, boning and rendering of co-products. Importantly it should be noted that the definition of HSCW may vary between species and countries.

2.3. Product Yields

Meat processing yields different products depending on the species. Yields may be determined from primary output data, but in the absence of these data the mass of products may be determined from a series of factors. Here we report the yield of products from processing based on primary data and industry averages applicable in Australia. Yield characteristics vary between different breeds of livestock and this can have a large influence on results. As a consequence, important factors such as the dressing percentage and retail yield should be based on data reflective of the supply chain being investigated. In Table 1 we report data relative to the supply of 1000 kg of retail portions. We consider offal sold for human consumption as part of the functional unit, because this product is functionally equivalent to meat from the animal carcase with respect to nutritional characteristics. The mass of unprocessed rendering material and products from rendering are included.

Table 2 provides critical yield factors to convert live weight of animals to the amount of edible meat after meat processing for each species, including the edible fraction for the retail portions, which differs depending on the amount of bone included in the product sold at retail. This will vary depending on the degree of processing (boning), the degree of trimming for excess fat, and the inclusion or exclusion of skin in the saleable portion for chicken and pork. We specify here the edible portion, meaning the mass of product exclusive of bone and cartilage mass which are not easily digested. Importantly, the mass of meat actually consumed may be lower depending on consumer preferences and this would need to be accounted for during the consumption phase. We include the edible fraction here because it differs considerably between the species and therefore is necessary for correctly interpreting the results.

Table 1. Product mass for four meat species relative to 1000 kilograms of retail product

Product description	Product	Chicken meat	Pork	Sheep meat	Beef
Farm-gate product	Live Weight	1712	1618	2255	2375
Intermediate product	Hot Standard Carcase Weight	1216	1229	1060	1307
Wholesale product	Cold Carcase Weight	1179	1177	1017	1267
Wholesale/retail product	Retail cuts	967	906	895	887
	Edible offal	33	94	105	113
Retail portions (retail cuts + edible offal)		***1000***	***1000***	***1000***	***1000***
	Hides	0	0	169	214
	Pet food	17	84	34	30
Rendering material	Unprocessed meat, bone, offal	593	372	800	989
Rendering Products	Protein meal products	154	53	152	257
	Tallow	73	109	156	154
	Blood meal	5	5	14	14

Table 2. Meat processing yield factors for chicken meat, pork, sheep meat and beef

	Chicken meat	Pork	Sheep meat	Beef
Dressing percent	0.71	0.76	0.47	0.55
Chilling loss	0.03	0.04	0.04	0.03
Retail yield	0.82	0.77	0.88	0.70
Edible offal yield (% of LW)	0.02	0.06	0.05	0.05
Edible fraction of retail portions	0.85	0.85	0.76	0.95

2.4. Co-production

The options for handling co-production according to ISO 14044 (ISO 2006) can be divided into two broad approaches, in order of preference.

Methods to avoid allocation:

- Clear subdivision of the system, or
- System expansion (expanding the product system to include the additional functions related to the co-products to avoid allocation).

Allocation:

- Allocation on the basis of physical or biological relationship.
- Allocation on some other basis; most commonly economic (market) value.

In meat processing, sub-division has been proposed as a method of dividing impacts from meat products and rendering material (Ramirez et al. 2011) though this implies that rendering material is valueless and carries no burden from the production system. This is not valid for important co-products such as hides. Where the system can't be divided, system expansion and allocation methods are recommended. In practice, a number of studies that have included allocation in meat processing have applied economic methods (i.e. Ledgard et al. 2010; Milà i Canals et al. 2002; Opio et al. 2013).

System expansion is performed by allocating all burdens to the meat product then deducting impacts associated with the production of substitute products. This method relies on the selection of appropriate substitution products, which are typically the marginal primary products in the relevant commodity market. The ease with which substitution products can be identified varies. Animal protein meals are used in most parts of the world (with the exception of Europe) as an important feed ingredient for poultry and pigs. Animal protein meals provide a high value protein feed with a superior amino acid profile and higher levels of phosphorus than vegetable protein sources. None the less, they can and are substituted with vegetable protein sources, synthetic amino acids and alternative phosphorus sources. In the present study, we simplified the substitution process by using soybean meal and cereal grain (in this case sorghum) to create an equivalent level of energy and protein as provided by the animal protein meal. We recognize this is a simplification and could be improved by including additional synthetic amino acids to address specific deficiencies. Soymeal from Brazil and Argentina were considered the appropriate marginal protein source and the impacts from this soymeal were determined following Opio et al. (2013). We acknowledge that in some regions, animal protein meals may be used for alternative purposes such as fertilizer but animal feeding is a more important activity globally. Tallow is used for many purposes; human food, animal feed, cosmetics and biofuel to name a few. Here we substituted tallow for palm oil, which is considered the marginal oil source globally. Pet food was substituted for soymeal on a protein equivalent basis as many manufactured pet foods are heavily reliant on vegetable protein sources. This substitution overlooks one important element; animal meals provide both protein and an important meat flavor for pet food which improves the palatability of these products. Hence, the substitution is incomplete. The last major substitution product was the raw hide, which was only relevant for sheep and beef in the Australian examples. Raw hides are processed into leather and other co-products; typically at a separate facility. Because raw hides are an intermediate product, no direct equivalent exists. To add to the complexity, the final leather product operates as a primary product in premium upholstery, footwear and apparel markets. While substitutions can be found, they may be inferior in terms of market acceptance, value and in some cases durability. We applied a simplified substitution approach by determining the mass of hides that contribute to the final leather product (20%) and substituting vinyl at a ratio of 4:1 by mass (European Commission 2004) to account for the superior wear characteristics of leather (assumed to be 80 years). The greater mass of vinyl was to account for the higher durability of leather for use as upholstery or apparel. The mass of avoided product associated with meat production is provided in Table 1 while the avoided impacts per kilogram of product are provided in Table 3.

Table 3. Avoided products used in System Expansion (EcoInvent)

	GHG	**Energy**
	kg CO_2-e	MJ / kg
Leather substitute	9.7	215.9
Pet food (avoided soy) [a]	1.6	0.6
Animal protein meal (avoided soy) [a]	5.8	2.1
Tallow (avoided palm oil) [a]	1.5	4.3
Blood meal (avoided soy) [a]	9.7	2.0

[a] dLUC has been included for palm oil and soy production.

A biophysical allocation approach was applied by using the mass of utilizable protein and energy in each product (Table 4) based on Kanagaraj et al. (2006) and Meeker (2006). Meat products were assumed to have a standard proportion of protein (0.2) and fat (0.15) and were adjusted for the edible yield of product (Table 1). Hides were adjusted for the proportion of protein utilized in the leather product.

Table 4. Utilisable protein and energy in primary and co-products from meat processing

	Chicken meat	**Pork**	**Sheep meat**	**Beef**
Retail portions	0.30	0.30	0.27	0.33
Hides			0.24	0.24
Pet food	0.09	0.09	0.09	0.09
Secondary Rendering Products				
Animal protein meals	0.60	0.50	0.50	0.50
Tallow	1.00	1.00	1.00	1.00
Blood meal	0.85	0.85	0.85	0.85

The very high levels of utilizable protein and energy in the rendering products was because the rendering process removes excess moisture in comparison to meat, hides and pet food which are all high moisture products. This led to high allocation fractions to these products (Table 5) which were not meaningful considering the minor importance of these products.

Table 5. Allocation fractions based on utilisable protein and energy in primary and co-products from meat processing

	Chicken meat	Pork	Sheep meat	Beef
Retail portions	0.63	0.67	0.48	0.49
Hides	0.00	0.00	0.07	0.07
Pet food	0.003	0.017	0.006	0.004
Secondary Rendering Products				
Animal protein meal	0.20	0.06	0.14	0.19
Tallow	0.16	0.25	0.28	0.23
Blood meal	0.01	0.01	0.02	0.02

Alternatively, we applied a hybridized method where we divided the rendering process from the system and used the utilizable protein and energy to perform a biophysical allocation on the retail portions, hides and pet food (Table 6), combined with a system expansion approach to handle the products from rendering.

Table 6. Allocation fractions based on utilizable protein and energy for retail portions, hides and pet food

	Chicken meat	Pork	Sheep meat	Beef
Retail portions	0.99	0.98	0.86	0.86
Hides	0.00	0.00	0.13	0.13
Pet food	0.01	0.02	0.01	0.01

Economic allocation was based on the value of products leaving the processing or rendering plant. While rendering is a separate process, many plants surveyed could not provide a separate break-down of energy inputs to rendering as distinct from meat processing. Hence we considered the output of meat processing to be inclusive of rendering. The value of hides was for the unprocessed raw product. While this was in line with the system boundary, it resulted in an inconsistency in the economic allocation method because the products were at a different stage of processing. In agricultural systems, product value is often disproportionately distributed to the wholesale and retail end of the supply chain. Hence, bias can be introduced if economic allocation processes are not performed at the same point in the production system for each product. This will result in lower impacts for less processed products (i.e. leather) and higher impacts for more processed products such as meat and animal meals. An interesting alternative not applied here would be to expand the primary processing system to include tanning of leather products to align the production stages for all products. Economic allocation proportions are provided in Table 7. The value of retail portions was based on the wholesale value of all meat products as reported by the meat processing plants and verified using Australian market data where available (APL 2009; MLA 2013a; MLA 2013b).

Table 7. Economic allocation factors for meat products and co-products from four species

Slaughter Products	Chicken meat	Pork	Sheep meat	Beef
Retail portions	97.2%	97.5%	88.3%	89.1%
Hides	0.0%	0.0%	8.0%	5.7%
Pet food	0.2%	0.4%	0.4%	0.5%
Secondary Rendering Products				
Animal protein meal	1.3%	0.5%	1.3%	2.5%
Tallow	1.2%	1.5%	1.7%	2.0%
Blood meal	0.1%	0.1%	0.2%	0.2%
Total	100.0%	100.0%	100.0%	100.0%

3. Results

3.1. Impacts from meat processing

Meat processing varied substantially between species for all impact categories of interest. Energy and GHG emissions were closely associated, though additional emissions also arose from anaerobic waste treatment systems were utilized. Sheep processing was the most energy and GHG intensive, followed by beef processing. These also used the highest amount of water. In the context of the whole supply chain, meat processing was a significant contributor to energy demand for all species.

Table 8. Meat processing impacts associated with processing four different species, expressed as per kilogram of Hot Stand Carcase Weight (HSCW)

	Units	Chicken meat	Pork	Sheep meat	Beef
Global Warming	kg CO_2-e / kg HSCW	0.42	0.40	0.91	0.80
Fossil energy (MJ)	MJ / kg HSCW	4.34	3.00	8.33	5.81
Consumptive Fresh Water Use	L / kg HSCW	2.43	6.57	7.53	8.75

3.2. Handling co-production

Results without allocation are provided in Table 9 using four different reporting units for comparison. The results for HSCW without processing impacts represent a common approach, where impacts are calculated to the farm gate then divided by an assumed dressing percentage without allocation or accounting for processing impacts. Including processing impacts contributed an additional 3-11% with the greatest proportional increase being for chicken meat and the least being for beef. Results are also presented per kilogram of retail meat without allocation.

Table 9. Greenhouse gas emissions (kg CO_2-e / kg product) from four species reported on an unallocated basis per kilogram of live weight, HSCW and carcase retail yield

	Chicken meat	Pork	Sheep meat	Beef
Live weight	2.5	4.4	6.4	11.7
HSCW (no allocation, no processing impacts)	3.5	5.7	13.6	21.3
HSCW (no allocation to co-products, processing impacts included)	3.9	6.1	14.5	22.1
Carcase retail yield (no allocation to co-products, processing impacts included)	5.8	9.8	22.7	34.3

GHG emissions for four species and four methods for handling co-production are shown in Figure 1. Impacts were lowest for the utilized protein and energy method and highest for the economic allocation method, with the system expansion and the hybrid method being intermediate. The utilized protein-energy method was not considered suitable because the allocation to minor rendering products was very high, resulting in higher impacts per kilogram of co-products than the primary product. The difference was primarily because of the difference in moisture content; the retail products have a high proportion of moisture which increases product mass, while the rendering products are dry (90% dry matter). Economic allocation tended to attribute slightly lower impacts to co-products than the comparative system expansion approach, though these were fairly similar across the species. The hybrid method was effective in allocating impacts between the utilized portion of the meat, hides and pet food while avoiding the errors created by including the minor co-products into this method.

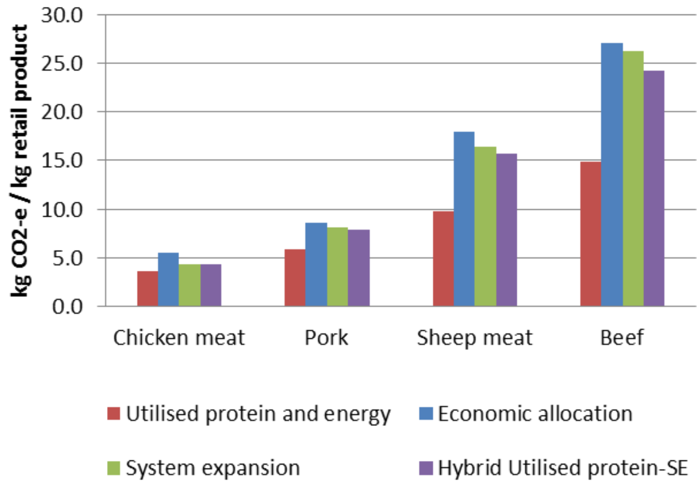

Figure 1. Greenhouse gas emissions for meat products with four alternative methods for handling co-production across four species

The assessment of energy demand (Table 10) followed the same trend as GHG for the allocation method because of the fixed ratios applied to both indicators, but showed strongly divergent results for the SE method for sheep and beef. This was largely influenced by the substitution process for hides, which were replaced by vinyl, which is an energy intensive product.

Table 10. Energy demand from four species reported using four different approaches for handling co-production

	Chicken meat	Pork	Sheep meat	Beef
Economic allocation	21.8	25.0	18.1	20.7
Utilized protein allocation	14.2	17.2	9.9	11.4
System expansion	21.7	24.8	-18.0	-25.5
Hybrid Utilized protein-SE	21.6	24.1	15.7	17.4

4. Discussion

A few Australian studies have found that meat processing contributes a relatively small amount of GHG to the total impacts from meat production, but higher amounts of energy (Peters et al. 2010; Wiedemann et al. 2010; Wiedemann et al. 2012). The contribution is greatest for ‘low impact’ meat species such as poultry where the contribution to GHG was 11% and to energy was 31%. Meat processing is a very important stage in the life cycle of meat products from the perspective of handling co-products. This analysis showed significant differences in the impacts attributed to the meat product depending on whether co-products were taken into account, and depending on which method was used. While it is common in the literature for results to be presented without allocating impacts to co-products, we found this induced a substantial error, over predicting the impacts associated with meat by between 6% and 42% depending on the species and method compared. The use of intermediate reporting units such as carcase weight introduced variation between the species, because of the different final yield relative to carcase weight and because dressing percentages do not take into account the yield of edible offal. For this reason, we preferred a functional unit that represents the retail yield from the animal when the focus is food production. Retail yield is still not uniform, because different species include or exclude different amounts of bone in the retail product and therefore provide a different amount of digestible protein and energy. While accounting for the edible portion of meat is part of the consumption phase of the life cycle, it is useful to report this and take it into account in the interpretation phase, particularly if considering different species. The error induced by reporting results on an unallocated basis related to a number of factors. Firstly, the practice of allocating to carcase weight and retail meat from the carcase, while excluding edible offal products, reduces the apparent product yield. We found no reason to exclude this from the functional unit as it contributes equally to human food supply. Including edible offal in the functional unit reduced the total live weight required for each kilogram of retail product by between 3% (poultry) and 12-13% (sheep and beef).

Of the allocation processes, economic allocation has been most commonly applied to date. Economic allocation resulted in a 6 to 27% reduction in impacts allocated to the meat product depending on species compared to the unallocated process, with the greatest differences coming from ruminants. Across the allocation and system expansion methods, the differences in comparison to the unallocated methods were greatest for ruminant species. This was partly because of the role of edible offal discussed above, and partly because of the handling of the animal hide. In poultry and pigs, animal skin is commonly sold with the retail product, where it becomes part of the consumed product or is thrown away by the consumer. In ruminant species, hides are commonly sent to an additional tanning process to produce leather. Leather is a global benchmark product that functions in the market in a fashion more similar to a primary product than a co-product. It is also a high value product at the wholesale and retail level, though this is not reflected in the raw hide value. Because of the point in the processing supply chain where hides are removed, hides receive a relatively small proportion of the environmental burden compared to the biophysical ‘cost’ of producing hides over the life of the animal. This was evidenced by the higher impacts attributable to hides when applying a biophysical allocation process based on utilized energy and protein in the product. However, we found it difficult to establish a meaningful biophysical allocation process that could cover both the major products (i.e. retail meat and hides) and the minor products from rendering. Similarly, we found it difficult to determine an appropriate system expansion process to handle hides, because they are a raw product rather than a final product. A more thorough analysis is required to assess this by expanding the system to take into account the tanning process also.

We presented here a hybrid method that used the favored biophysical approach to divide impacts between the major products while using system expansion to account for the minor rendering products. While it has been accepted for some time in LCA practice that multiple methods of allocation may be used at different points in the same study, we apply this here for a closely related co-product system coming from the same process. We consider this to be an ideal method for accurately attributing impacts to meat and hides, which are important primary products, while accounting for the lesser volumes of rendering co-products with a more appropriate system expansion method.

5. Conclusion

This paper presents new inventory data, product yields and an exploration of novel methods for handling co-products at the point of meat processing. We suggest here a re-definition of the functional unit for meat products to include the yield of edible co-products that are an important contribution to human food supply. With the re-definition of the functional unit and application of allocation or system expansion methods, impacts attributable to meat products declined by 6-42%. The difference in impacts attributed to the meat product was particularly important for ruminant species, which produced the largest mass of important co-products of all the species. The data and methods presented here provide a starting point for researchers to include this approach for future livestock and meat studies.

ABSTRACT

The impact of land use change (LUC) and water use was investigated using a a case study of beef production from grazing land. LUC from grassland to forest (afforestation) reduced greenhouse gas (GHG) emissions as a result of carbon sequestration, but also decreased runoff and consumptive fresh water availability compared to pre-LUC conditions. During the transition (LUC period), annualized carbon sequestration (reported as negative emissions) were an estimated –4.9 t CO_2-e / ha.yr. By the end of the transition period (post LUC) run-off declined by 30% (0.1 ML / ha.yr) as tree growth modified soil moisture conditions. Per kilogram of beef, net emissions changed from 10.9 kg CO_2-e / kg live weight (LW) (pre-LUC) to -3.0 kg CO_2-e / kg LW (LUC period). Consumptive water use increased from 305 L / kg LW (pre-LUC) to 632.7 L / kg LW during the LUC period. In the post LUC period, net sequestration was minimal as trees reached maturity, but reduced runoff and higher consumptive water use remained as a permanent change.

Keywords: beef, grazing, LUC, water, carbon, GHG

1. Introduction

It is now widely accepted that land use change (LUC) can be an important contributor to greenhouse gas (GHG) emissions in food production supply chains and is a necessary inclusion for agricultural and food product life cycle assessment (LCA) and carbon footprinting (CF). Land use change can also lead to carbon sequestration (GHG removals) if afforestation occurs. In Australia, efforts have been made to promote tree planting in grazing areas to provide improved production and environmental outcomes (Youl et al. 2006). Afforestation has also been promoted as a means to sequester carbon under a government scheme known as the Carbon Farming Initiative or CFI (Department of the Environment 2014). Accounting for LUC GHG emissions has shown large impacts may be attributed to agricultural systems where LUC occurs, i.e. Cederberg et al. (2011). Other authors such as Schmidinger and Stehfest (2012) have extended the discussion to consider not only the emissions that may have occurred from deforestation, but also the 'missed potential carbon sink' associated with land occupation. This approach treats all land as having the potential to sequester carbon if returned to forest.

Land use change is known to have an effect on water availability (Mila i Canals et al. 2009) though few case studies have considered this. Research in the field of hydrology is unequivocal; increasing vegetation cover will reduce runoff (water yield) while decreasing vegetation cover will increase water yield (Bosch & Hewlett 1982, Brown et al. 2005). Thus, a trade-off exists between net LUC impacts on GHG (emissions or removals) and water yield, and methods proposed to account for the impact of land management on GHG flux (i.e. Schmidinger & Stehfest 2012) should consider broader impacts such as water availability to provide a holistic analysis. In the context of greater global demand for food (FAO 2009), the complex interactions between GHG flux, livestock (food) production and water resource availability require careful investigation to avoid unintended outcomes. Australian grazing land is predominantly classified as grazing of native vegetation (Lesslie & Mewett 2013) and in these systems, livestock graze partly forested pasture lands. In such systems, there is some flexibility to alter the proportion of trees and pasture by promoting seedling establishment from established trees or alternatively, by controlling seedling recruitment. This paper investigates the interaction between these three factors at the local scale for an Australian beef grazing farm where afforestation had taken place as a result of changed farm management, resulting in changed tree density.

2. Methods

2.1. Goal and scope

This study used actual production data from a cattle grazing farm in Queensland, Australia to investigate the impacts of partial afforestation of pasture land. The case study was located in the headwaters of the Murray Darling river catchment of Australia, which has a high degree of competition for water resources. This study examined the impacts of LUC on global warming using IPCC AR4 global warming potentials (GWP) – (IPCC 2007). Consumptive water use was assessed using water balance methods (Bayart et al. 2010). The system boundary included all processes associated with the production of beef up to the farm-gate. The functional unit (FU) was chosen as 'one kilogram of live weight at the farm gate' and results were also reported as totals for the whole farm.

2.2. Inventory data

Livestock production data were collected from farm records over a two year period and were confirmed via discussions with the farmer and site visits in the year 2010 (Table 1). Land use change was initiated on the farm in 2008 as a result of a change in grazing species (sheep to cattle) when the farm was purchased. This resulted in natural regrowth of native woody perennial trees (afforestation) to take place on a 235 ha section of the property. On other parts of the property, regrowth was controlled as part of routine management. The association between cattle grazing and woody thickening has been reported large parts of Australia (Burrows et al. 1998, Burrows et al. 2002). On the case study farm, woody thickening was the result of a change in grazing species from sheep, which graze young trees and limit growth, to cattle which don't graze young trees to the same extent. Grazing livestock were changed from sheep to cattle eight years before the assessment period (in the year 2000), resulting in wide spread establishment of native trees that were suppressed by sheep grazing but not by cattle. While attribution of the impacts of LUC to livestock is generally accepted where livestock are grazed following conversion of forest to pasture, attribution is less clear when changed grazing management results in increased tree growth and GHG removals. On the case study farm, the management change from sheep to cattle was deemed the causal factor enabling establishment of trees, providing a causal association between cattle grazing and changed GHG flux.

The system was assessed over three time periods, before (pre-LUC, prior to year 2008), the LUC period (2008-2037) and the post-LUC period (2037+). The impact of afforestation was modelled over a forward estimate period of 30 years to approximate the time taken for trees to reach maturity. The modelling periods did not account for other possible changes in climate or management over the forward estimate period. Over the reforested land area, livestock grazing was predicted to decline by 10%, corresponding to the decline in grass growth as trees approached maturity. This was predicted to result in an equivalent 10% decrease in livestock numbers and beef production for the farm in the absence of other management changes.

Table 1. Case study farm characteristics

Parameter	Units	Value
Average annual rainfall	mm	661
Land and grazing		
Farm size	ha	2 017
Total area of pasture	ha	1 967
Afforestation area	ha	235
Sheep	%	0
Cattle	%	100
Cropping	%	0
Herd size (cow no.)	No.	212
Water supply		
Farm dam	%	83
Bore	%	0
Creek	%	17
Total livestock drinking water	ML	5.27

Consumptive fresh water use

The water use inventory was developed in accordance with Bayart et al. (2010), covering all sources and losses associated with beef production both in foreground and background systems. Primary sources of consumptive fresh water use for beef cattle production were associated with livestock drinking water, drinking water supply losses, and irrigation. Drinking water for grazing cattle was predicted from feed intake, climate and feed characteristics for the farm using equations from Ridoutt et al. (2012). Losses from farm dams occurred from evaporation, and to a lesser extent seepage (Nathan & Lowe 2012). Losses associated with water supply from farm dams were modelled using farm dam water balances constructed from long term climate data for the farm. Dams and catchment areas were assessed during site visits and were later mapped using aerial imagery. The dam water balances were modelled using a daily time-step water balance using long term rainfall and evaporation data obtained for each region as Patched Point Datasets (DSITIA 2013, Jeffrey et al. 2001). The balance accounted for extractions, seepage and evaporation losses. The dam water balances were calibrated using records of filling and emptying events, determined through discussion with the farm owner. Catchment runoff and dam inflow was modelled using USDA-SCS KII curve numbers (USDA NRCS 2007), with appropriate values determined from site observations of soil type and farming practices. Water use was determined from the difference between water flows leaving the farm in the presence of absence of the farming system. Water modelling took into account the degree of forest cover in prior to LUC (pre-LUC), during afforestation (LUC period) and post-LUC. Runoff predictions were calibrated at the local scale using farmer knowledge of the frequency of runoff events, and against catchment yields for similar catchments. Catchment yields (runoff as a percentage of rainfall) were 6% in the pasture system, declining to 4% in the reforested system after 30 years which was a conservative estimate (Brown et al. 2005), and similar to the estimated whole catchment water yield of 5% (CSIRO 2007). This corresponded to an annualised decline in runoff across the whole farm of 25.4 ML per year over the LUC period and an absolute decline of 31 ML between the pre and post-LUC periods.

Greenhouse Gas Emissions

Greenhouse gas emissions from livestock were determined using methods based on the Australian National Greenhouse Gas Inventory (DCCEE 2012) with the exception of the enteric methane prediction equation, which was based on a regionally representative enteric methane prediction model (Kennedy & Charmley 2012). All impacts associated with energy demand were included, based in the inventory of farm purchases (data not shown). No additional energy use associated with afforestation because this occurred naturally. Hence, emissions intensity associated with livestock emissions and energy use remained the same. Net LUC emissions were determined from Fensham and Guymer (2009) for sub-humid, Eucalypt woodland, which was assumed to have a net sequestration 40 t C ha and a total sequestration of 34,466 t CO_2-e over the 30 year period. As an annualized rate, this resulted in sequestration of 1149 t CO_2-e per year for the farm.

3. Results

Total beef production and GHG emissions are presented for the three time periods in Table 2. Land use change resulted in net removals from sequestration of -14.4 kg CO_2-e / kg LW, which resulted in a net negative emission of -3.5 kg CO_2-e / kg LW for all beef sold from the farm over a thirty year period with all emission sources taken into account. However, after the forest reached maturity, estimated total beef production declined by 10% and estimated net emissions returned to levels similar to the pre LUC emissions.

Table 2. Greenhouse gas emissions and sequestration associated with land use change reported over three time periods

Time period	Beef production	GHG	LUC GHG	total GHG	Emissions intensity
	total kg LW	t CO2-e	t CO2-e	t CO2-e	kg CO2-e / kg LW
2008 (pre LUC)	88,649	966	-	966	10.9
2008-2037 (LUC period)	82,443	899	- 1,149	- 250	-3.0
2037+ (post LUC)	79,784	899	-	899	11.3

Consumptive water use over the same time period changed in response to changing livestock numbers and changed vegetation cover. This resulted in a net decline in direct consumptive water use of 2% during the LUC period and 3% after the LUC period ended. This change in direct consumptive water use was in response to lower drinking water requirements for the smaller herd. Importantly, the decline was not a linear response to reductions in livestock numbers and production. This non-linear response was because the reduction in drinking water requirements had a negligible impact on water supply system losses from farm dam evaporation. In the present case study, the farm manager did not respond to reduced livestock numbers by changing either the number or size of dams. This is to be expected, because changing the number or size of dams would require considerable capital expenditure without providing any benefit to the farm. Hence, the supply losses associated with farm dams occur despite changed livestock numbers.

The large changes in water were the result of changed runoff conditions, which may be termed an indirect water use for the system. When attributed to the livestock system, this resulted in an additional 308 L / kg LW. This additional indirect water use continued as a permanent change to local hydrology after the LUC period finished, resulting in a large, long-term increase in consumptive water use that would be reduced only after another LUC event to reduce vegetation.

Table 3. Change in consumptive water use in response to land use change reported over three time periods

Time period	Beef production	Consumptive water use	Change in runoff (LUC)	Total water	Water use / kg beef
	total kg LW	ML	ML	ML	L / kg LW
2008 (pre LUC)	88,649	27.1	-	27.1	305.2
2008-2037 (LUC period)	82,443	26.8	25.4	52.2	632.7
2037+ (post LUC)	79,784	26.2	31.1	57.3	718.4

4. Discussion

There is a global imperative to reduce greenhouse gas emissions from livestock production, and emissions from land use change are understood to be a substantial contributor to total emissions (Opio et al. 2013). One possible option is to promote afforestation of grazing areas. The environmental impacts from this type of land use change are likely to be improved in some instances (i.e. improved biodiversity outcomes) but there are other impacts that must be addressed, such as the decline in runoff. In water footprint terms, this amounts to a change in the proportion of green and blue water use within a system, because runoff (blue water) declines in response to increased vegetative cover and subsequent evapo-transpiration (green water). This relationship between vegetation and runoff is well established at the global level (Bosch & Hewlett 1982, Brown et al. 2005). Mila i Canals et al. (2009) identified the need to address changes in runoff caused by alterations in the balance of green and blue water within a system. However, the choice of reference system is debatable. In the present example, we chose the land cover in 2008 as the reference. At this time, the land was open pasture used for grazing. However, if the reference system was considered the natural vegetation at the site prior to land clearing (which occurred around the 1900's for this region) then afforestation has a very different effect on sequestration and net water use. Such matters are not semantic, they demonstrate the importance of such methodological choices on the interpretation of results. In Australia, the relationship between vegetation cover, runoff and subsequent water available for competitive users is carefully monitored, and programs promoting afforestation must account for the impact on reduced runoff (NWC 2011). It would be clearly beneficial for LCA research to address this rather than considering LUC in the context of GHG emissions only. The implications of this research on deforestation are also apparent; local scale deforestation will result in increased runoff and greater water availability (Bosch & Hewlett 1982, Brown et al. 2005). This relationship has been assessed as a means to increase runoff and alleviate localized water stress in Australia (Li et al. 2011). In the present case study, increasing carbon storage in vegetation had a relatively short term effect (30 years) but resulted in a permanent decrease in water availability and beef production. The negative impact of lower water availability in river systems impacts both the environment and competitive water users such as irrigators elsewhere in the river system. It is a legislated requirement that afforestation projects funded under the Australian government CFI program account for reduced runoff, possibly via acquisition of irrigation water licenses to account for water consumption (NWC 2011). This aligns with an approach that considers this water an additional consumptive use in the LCA context. The focus on this paper has been to consider the localized impacts of this change only, rather than a full scale consequential analysis. The study only took into account one additional impact, consumptive water use, and further study should incorporate the impact on a broader range of potential impacts, including soil degradation and water quality. A full system consequential analysis is also required to understand the impacts of changes in water availability and beef supply. For example, reduced beef production in Australia (one of the world's two largest beef exporters –FAO (2011) may induce beef production in other regions where deforestation is a risk. Secondly, reduced water yield will constrain water supply to local river systems, causing stress to aquatic ecosystems and reducing irrigation water supply, with the latter having ongoing impacts on food and fibre production.

5. Conclusion

Afforestation is a plausible LUC option to remove atmospheric carbon dioxide via carbon sequestration in woody perennials. In a mixed grazing system, GHG removals from afforestation may be triggered by beef grazing, and as a result could provide reduce net emissions from beef production. However, such improvements can only be sustained for a limited period of time until trees reach maturity. After this time, the production system was estimated to return to a net GHG source, with lower overall productive capacity. Importantly, LUC resulted in reduced water yield which may place additional stress on water catchments, compromising aquatic ecosystem function and reducing water supply for irrigation and food production. This highlights the important trade-offs that exist when assessing LUC, particularly with respect to GHG emissions and water yield, and consideration of a broader suite of impacts such as impacts on soil condition would be beneficial. Detailed consequential modelling is required to explore the broader implications of these findings, accounting for environmental impact and the effect on global food supply. In the context of greater global demand for food and the environmental challenges such as climate change, this research should be seen as a priority.

ABSTRACT

A development of the top down method for accounting for all direct and indirect land use change emissions (LUCE) is presented, which reflects the relative rates of global crop expansion. It uses crop production and area data from FAOSTAT to derive expansion rates, reflecting global demand. Crops that drive land use change more, e.g. soy thus receive a heavier burden than other. It is thus more equitable than the original top down method. Alternative sources of values for LUCE and connected agricultural area are addressed. It still represents a method with relatively low computational and data demands.

Keywords: greenhouse gas emissions, land use change, crops, top down, soy

1. Introduction

Greenhouse gas (GHG) emissions (GHGE) from land use change (LUC) have a large effect on life cycle assessments (LCA) of food production, especially from livestock products (e.g. Audsley et al., 2009, Leinonen et al., 2013, Leinonen et al., 2014, van Middelaar et al. 2013, Meul et al., 2012, Cederberg et al., 2011). The relative importance is even greater in life cycle based studies such as determining product carbon footprints or if calculating GHGE from national or regional food consumption.

Determining the GHGE from land use change (LUCE) is relatively straightforward if the history of the land parcels is well known and if the initial conditions of soil and biomass carbon densities are known. This is not, however, always the case, neither does this address the consequences of indirect LUCE.

Current approaches to determine direct LUC GHG emissions (direct LUCE) include the UK publically-available specification PAS 2050, which started with one method as (BSI, 2008), and was later revised in (BSI, 2011). In BSI (2008), the default position if land history was not known was to assume the worst case scenario of LUCE: deforestation. This was revised in BSI (2011) to apply the weighted average of direct LUCE from the originating country, although it did not specify exactly how this should be applied. If dealing with a major commodity, such as soy, the data requirements are potentially very high, given the large areas of land and multiple countries. The method is based on the premise that one land use is succeeded by another, e.g. forest to arable. It does not address land that may have been deforested, then abandoned and regenerated towards forest. Fearnside (1997) addressed this with the concept of “net committed emissions”, which also requires much detailed data to be effectively applied. This approach was also used by Cederberg et al. (2011). These methods do not really address indirect LUC fully.

A radical alternative, the “top down” approach was developed by Audsley et al. (2009), revised by Vellinga et al. (2013) for the Dutch feed industry and compared with other approaches by van Middelaar et al. (2013). In the top down” approach, all global direct and indirect LUCE are applied uniformly to all economically connected agricultural land. The underlying principle is that commodity demand will be met by the world market, so that land expansion operates collectively in response to demand. LUC in one area may result from changed demand in any other, whether direct or indirect.

Data needs are relatively modest and can be derived mainly from FAOSTAT land use and production statistics. This is coupled with an estimate of global LUCE, of which several possible values exist. These differ in response to inclusion or not of emissions from source such as nitrogen transformations when soil C stocks are depleted. Values for total global LUCE range from 3.3 Gt CO_2e/year (DeFries, et al. 2002), through 4.94 Gt CO_2e/year (Audsley, et al., 2009) to 8.49 Gt CO_2e/year (Olivier, et al., 2005). Vellinga & Van Middelaar (2011) used 5.62 Gt CO_2e/year, as a result of averaging 14 different sources.

Another factor that affects the overall result is how much of the global agricultural area should be considered to be connected. Audsley, et al. (2009) used 3.47 Gha, whereas Vellinga & Van Middelaar (2011) estimated it as 4.9 Gha. Differences in the accounting procedure are evident.

A limitation of the original method is that all crops are considered to be “equally guilty” and carry the same burden per ha, whereas soy expansion by area exceeds other crops (e.g. 1.75 more than maize). In an attributional approach such as PAS2050, crops like soy typically have a high LUCE burden, while European wheat would have none. The reality is somewhere in between. This study presents an enhancement of the top down method, which addresses the relative expansion rates of global crop areas. It is thus still (a) relatively simple to apply, (b) responds to changes in commodity demands (hence reflecting economic drivers for LUC) and (c) avoids double counting. As before, indirect LUCE are also included.

2. Methods

Choices in the approach were compared that addressed calculating the rate of change of crop areas, calculating the global agricultural area and the global LUCE. The core feature, however, was including the rates of crop expansion.

Six measurements are considered in this study including the range (4.94, 5.62, 5.8 and 8.1 Gt CO_2e/year).

2.1. General approach

The world’s top 25 crop commodities (by weight produced) were analyzed individually. All other crops were treated as one and grassland as another crop. The top 25 commodities accounted for 85% production on a fresh weight basis or 74% of cropped area. Production and crop area data came from FAOSTAT (2014).

2.2. Calculating land area changes

Annual rates of area expansion (ARE) for the top 25 crops were determined using time spans of 3, 5, 7, 10, 15 and 20 years, with the last year being 2010. 20 years is the period used by the IPPC and in PAS2050 used to capture the bulk of LUCE, although in reality, these may continue beyond 20 years.

Three approaches were tried by Dominguez (2013). The first was simple difference between the final year under scrutiny (A_F) and the initial year (A_i), Equation 1.

$$ARE = \frac{A_f - A_i}{T_f - T_i} \qquad \text{Equation 1}$$

The second used interval proposed in PAS2050-1:2012 interval, in which the average of three years is used in order to reduce fluctuations (Equation 2).

$$ARE = \frac{\left(A_{f-1} + A_f + A_{f+1}\right) - \left(A_{i-1} + A_i + A_{i+1}\right)}{3\left(T_f - T_i\right)} \qquad \text{Equation 2}$$

The third method was simple linear regression. Dominguez (2013) compared the three methods and found similar results, but regression has the advantage of including an estimate of uncertainty. Hence, it is the only method presented here.

The expansion of the other 137 smaller crops was simply derived by the difference between global harvested areas and those of the top 25 crops and treating them as one lumped crop.

The rate of expansion of grassland required screening out the area used by subsistence graziers, e.g. those in sub-Saharan Africa. Audsley et al. (2009) filtered out countries that did not fulfil the following three criteria. (1) Producing less than 0.5% of global production of meat from cattle, sheep and goats. (2) Importing less than 0.5% of globally produced meats. (3) Exporting 0.5% of globally produced meats. Hence, the area expansion of grass only included that from the countries that met all the 0.5% thresholds.

The sum of both crop and grass expansions gave the total annual net rate of expansion (ANRE) for a given period. This is the area that commercial agriculture varied annually, expanding or contracting according to global trends.

The next step is to obtain the proportion of each commodity $Ppt_{(ARE_c)_t}$ in the ANRE.

$$Ppt_{(ARE_c)_t} = \frac{(ARE_c)_t(100)}{ANRE_t} \quad \text{Equation 3}$$

$(ARE_c)_t$ is the annual rate of expansion for a commodity c in a period t, $ANRE_t$ is the annual net rate of expansion in a period t.

2.3. Normalization

The question of dealing with declining crops areas was addressed through normalization. All expansion rates (as proportions of the total) were made positive by adding the smallest integer possible, i.e. 1. Each rate was then divided by the mean expansion rate to give the normalized values for each crop (NV_C), such that the sum of all expansion rates would still sum to the total. These normalized values were then used to scale the total estimate of LUCE for all crops. This was applied because the general trend for the cropped area is expansion and that some "responsibility" should be held by all major crops. The main effect was thus to cause all major crops to incur a portion of global LUCE.

2.4. Baseline emissions from land use change

The baseline emissions from land use change are the LUCE per unit of agricultural land as used by Audsley et al. (2009) and by Vellinga et al. (2013). Two terms are needed for the top down method: the global agricultural area to be considered (Table 1) and the global estimate of LUCE (Table 2). These represent estimates of cumulative LUCE from agriculture.

Table 1. Values used for global agricultural areas harvested

Value, Gha	Source
3.47	Audsley, et al. (2009)
4.90	Vellinga and Van Middelaar (2011)
2.88	Method here studied, includes grassland area from screening

Table 2. Values used for global land use change GHG emissions

Value, Gt CO_2e/year.	Source	Comments
3.30	DeFries, et al. 2002.	
4.94	Audsley, et al., 2009.	58% CO_2e from IPCC 2007 AR4 dedicated to commercial agriculture
5.62	Vellinga and Van Middelaar 2011.	
5.80	Vellinga and Van Middelaar 2011.	Including effects of soil degradation
8.10	Houghton, 2003.	Revised estimates of the annual net flux of carbon to the atmosphere from changes in land use and land management 1850-2000
8.49	Olivier, et al. 2005.	

The value of 1.42 t CO2e/ha derived by Audsley et al. (2009) is simply the result of dividing the global land use change GHG emissions (4.94) by the global agricultural areas harvested (3.47).

3. Results

3.1. Land use change 1990 to 2010

Crop areas expanded from 1990 to 2010 at an average rate of 7.0 Mha/year, with a considerably greater expansion rate from 2002 (Figure 1). The overall increase in cropped area was 12% of the 1990 value. In contrast, grassland expansion increased up to 1996 and declined to 2010, at 1% below the 1990 area. This is a net effect with some grassland being created from deforestation and some being lost to cropping. The overall agricultural expansion is clearly dominated by crops. Linear regression accounted for 86% of the variance in crop area expansion from 1990 to 2010 and 92% from 2001 to 2010.

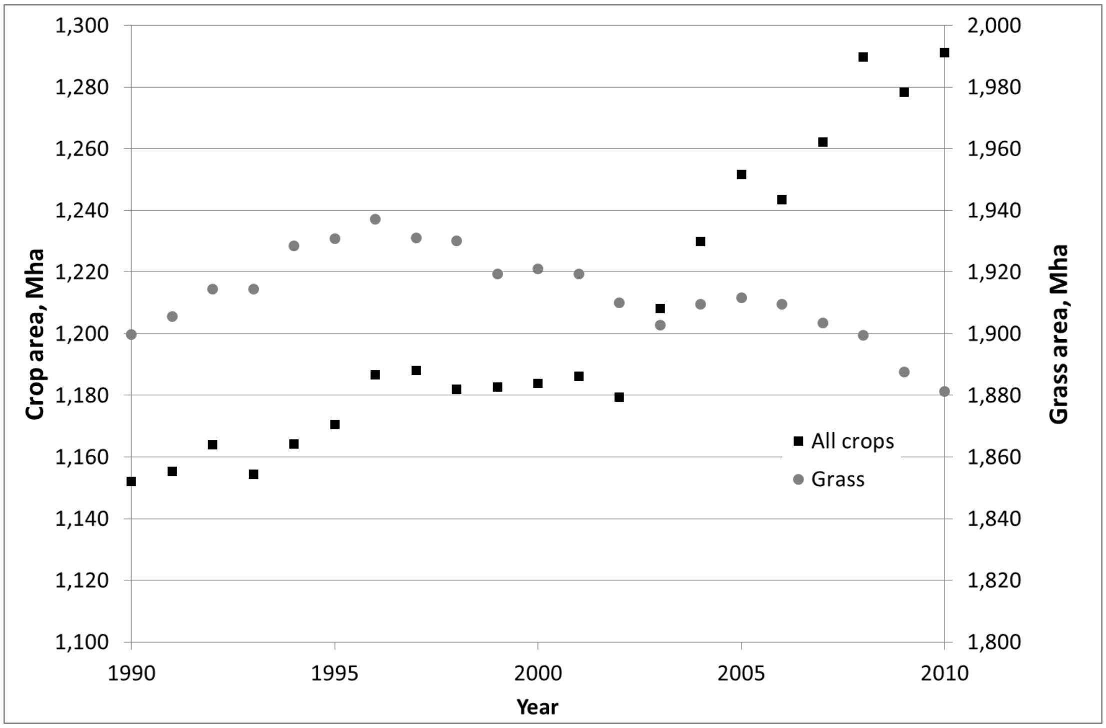

Figure 1. Changes in annually recorded global crop and grassland areas from 1990 to 2010 using data from FAOSTAT and screening out economically isolated grasslands.

3.2. Rescaled land use change emissions 1990 to 2010

When crop area expansion is broken down, it is clear that soy dominates, with maize following at about 55% of the soy rate (Table 3). Rice and rapeseed expanded at about 25% of the rate of soy from 1990 to 2010. In contrast, the area of wheat, the main grain consumed in the UK, has decreased at about 15% of the rate of increase of soy. The effect of normalization is to increase the LUC impact of soy by 36% compare with the single top-down value of Audsley et al, (2009) and to decrease barley by 21% (Table 3). This is a factor of 1.7 between crops in the top 25 of global production and clearly reflects a major difference in demand. Onion is the crop that lies closest to the mean.

These scalars thus increase the LUCE factor per ha of soy from the single value of 1.4 to 1.9 t CO_2e/ha and to decrease the values for wheat and barley to 1.3 and 1.1 t CO_2e/ha respectively. One value is given for all other crops together for convenience, but a separate value should be determined for any other individual crop of interest.

Table 3. Rates of expansion of crops from 1990 to 2010, normalized scalar for each crop and revised LUCE emissions. Crops are ordered by global production in 2010

Commodity	Rate of expansion, kha/year	Normalized scalar of LUC impact	Revised value for LUCE by crop from the single value of Audsley et al, (2009), t CO_2e/ha
Soybeans	2,502	1.36	1.94
Maize	1,431	1.20	1.71
Rice	616	1.07	1.53
Rapeseed	593	1.07	1.53
Oil palm fruit	488	1.06	1.50
Vegetables, fresh	443	1.05	1.50
Sugar, cane	315	1.03	1.47
Cassava	168	1.01	1.43
Onions	110	1.00	1.43
Tomatoes	98	1.00	1.42
Bananas	89	1.00	1.42
Watermelons	79	1.00	1.42
Coconuts	71	1.00	1.42
Cucumbers	47	0.99	1.41
Oranges	39	0.99	1.41
Potatoes	38	0.99	1.41
Cabbages	30	0.99	1.41
Grapes	-26	0.98	1.39
Sorghum	-47	0.98	1.39
Sweet potatoes	-52	0.98	1.39
Apples	-54	0.98	1.39
Cotton	-65	0.97	1.38
Sugar, Beet	-227	0.95	1.35
Wheat	-373	0.93	1.32
Barley	-1,228	0.79	1.13
Other crops	1,887	1.25	1.78
All crops	6,972	1	1.42

3.3. Effect of choice of baseline LUCEs and different estimated agricultural areas dedicated

The choice of what values to use for global land use change emissions and connected agricultural area has major effect on the results (Table 4). The potential baseline values range from 0.67 to 2.95 t CO_2e/ha: a range of 4.4 to 1. However, the more recent review by Vellinga and Van Middelaar (2011) seems likely to give the best estimate for global land use change emissions. The identification of connected agricultural areas depends on a degree of arbitrariness in identifying disconnected grasslands. This study applied the same broad approach as Audsley et al. (2009), but with more recent data and by applying more than one test. It is thus more discriminating.

Table 4. Baseline land use change emissions resulting from combining six sources of land use change emissions with three sources of the areas of connected agricultural activity. Results are in t CO_2e/ha.

		Harvested area data source		
		Audsley el al. (2009)	Vellinga & Van Middelaar (2011)	This study
Global LUC emissions data source	Audsley et al. (2009)	1.42	1.01	1.72
	Vellinga & Van Middelaar (2011)	1.62	1.15	1.95
	DeFries et al. (2002)	0.95	0.67	1.15
	Houghton (2003)	2.33	1.65	2.81
	Olivier et al. (2005)	2.44	1.73	2.95
	Vellinga & Van Middelaar (2011), including soil degradation.	1.67	1.18	2.01

3.4. Effects of time horizon on emissions

The time horizon used for calculating rates of change of crop areas includes market influences coupled with the technical change of generally increasing yields, which increase at a lower rate. There were evident differences over the time scales of 3 to 20 years, e.g. with the factor for soy being 50% larger over 15 than three years (Table 5). Overall, the effects of changing the time scale were relatively small, given the coefficients of variation over the six time periods analyzed. This is particularly the case for onions: the crop that was closest to the mean. The choice of time is arguably arbitrary, but it is rational to use a relatively long period to avoid short term influences.

Table 5. Range of LUCE values for emblematic crops using different time horizons to obtain the rates of change of crop area. Results are in t CO_2e/ha and use the baseline LUCE of Audsley el al. (2009). Onion is the crop closest to the mean.

	Time period of area change analysis up to 2010, years							
Commodities (integers show order in 20 year analysis)	20	15	10	7	5	3	Mean	Coefficient of variation, %
1. Soybeans	2.2	2.5	2.0	2.1	2.3	1.6	2.1	14%
2. Other crops	2.1	2.3	2.1	2.3	2.4	1.6	2.1	15%
3. Maize	2.0	2.2	2.0	2.3	2.6	1.5	2.1	17%
4. Rice	1.8	1.9	1.8	2.0	2.1	1.5	1.9	12%
6. Oil palm fruit	1.7	1.9	1.7	1.8	2.0	1.5	1.8	9%
10. Onion	1.6	1.8	1.6	1.7	1.9	1.5	1.7	7%
25. Wheat	1.5	1.7	1.7	2.0	2.1	1.5	1.7	13%
26. Barley	1.3	1.5	1.5	1.5	1.5	1.4	1.5	6%

4. Discussion

The top down approach offers a method of including both direct and indirect land use change GHGE in analyses, especially for animal diets or addressing national dietary consumption. This study indicates how the approach can be developed to address the relative expansion rates of crops at a global level and hence overcome a perceived limitation of the original method, i.e. all crops are equally “responsible” for land use change. It is evident that the global demand for soy outstrips all others and this approach accounts for that. Crop area expansion is effectively a measure of demand, although tempered by the generally increasing annual crop yields. Thus, where technical effectiveness is greater in increasing yields, the impact in area expansion is reduced. It is still relatively simple method to apply, with much lower disaggregated data needs than if trying to apply the bottom up approach that is implied by adherence to PAS2050 or any similar procedure for a particular crop.

There is opportunity for debate about values of some of the terms used, e.g. time scale, connected area of agricultural land and the global GHGE from land use change. The time scale needs to be sufficiently long to avoid short term fluctuations, but not so long as to miss global market trends and a scale of seven to ten years seems to be appropriate. The connected area of agricultural land is one that could be explored further by scrutinizing the trade in arable commodities to that including any subsistence farming is avoided. One problem that arose in dealing with grassland area changes is that of countries changing borders through major political transformations, e.g. the breakup of the Soviet Union. This presented some obstacles in determining whether grassland should be included or not over the time series.

Vellinga et al. (2013) reviewed the data sources on global land use change emissions and their assessment of the most suitable term seems a reasonable choice. Its continued application also makes analyses compatible with the Dutch *FeedPrint* approach.

5. Conclusion

A development of the top down method for accounting for all direct and indirect land use change emissions is presented, which reflects the relative rates of global crop expansion. This, in turn, reflects global demand and so puts a heavier burden on those commodities that are most dominant in driving land use change, e.g. soy. It is thus more equitable than the original top down method. It represents a method with relatively low computational and data demands.

Environmental performance of traditional beer production in a micro-brewery

Adrian G. Williams*, Seyoum Mekonen

School of Applied Sciences, Cranfield University, Bedford, MK43 0AL, UK
* Corresponding author. E-mail: *adrian.williams@cranfield.ac.uk*

ABSTRACT

A life cycle assessment of traditional English beer brewed in a microbrewery has been made with blue water, cumulative energy and greenhouse gas emissions as used as measures of environmental performance. The boundary was delivery at the point of consumption. Cumulative energy demand was 4.4 MJ/l, greenhouse gas emissions were 0.38 kg CO_2e/l and blue water volumetric consumption was 3.4 l/l. The main burdens arise from raw material production (especially barley and then malt production), brewing operations, delivery and with waste management relatively small but not negligible. Other studies are not fully comparable, but these results are in the range reported for other beer types, countries and boundaries. Opportunities for environmental performance are limited by the small scale of a microbrewery. More detailed auditing is needed to establish what could be achieved. Existing water consumption appears to be relatively low. Solar generated electricity could be of benefit.

Keywords: Beer, Brewing, Micro-brewery, Water, Carbon footprint

1. Introduction

Beer (or ale) is the traditional alcoholic beverage in Britain. It is brewed in a different way from the globally widespread Pilsner type beer, ("lager" in the UK). Traditional beer (also known as "real ale") is brewed at a higher temperature than lager, is flavored with fertilized hops and is matured and served with live yeast in the casks (barrels), so that secondary fermentation provides the CO_2 when consumed. Lager is usually pasteurized, filtered and gassed with compressed CO_2. The LCA of lager has been studied in Estonia (Talve, 2001), Greece (Koroneos et al., 2003) and Italy (Cordella et al., 2008). The carbon footprint of a bottled ale was determined in the USA by Climate Conservancy (2009). Hotspots from these studies included crop production and processing, brewing and bottling. The UK is second largest brewer and consumer of beer in the EU, after Germany and the UK brews about 4,500 ML beer annually. The UK is the largest producer of cask beer in Europe. Brewing uses much energy and water. Parts of brewing's environmental performance have been studied in isolation in the UK, this is the first LCA and applies to cask rather than bottled beer.

2. Methods

Activity data were obtained from a local microbrewery on brewing operations, resources and fuel for distribution. Crop production was taken or derived from Williams et al. (2006). Energy and water requirements for malting came from the industry. Life cycle inventory (LCI) values for energy carriers and waste management came from the ELCD (2013). LCI values for minor ingredients came from Cranfield-derived data or were estimated by analogy. Co-product (spent brewers' grains) valuation was made by system expansion. The focus was energy use, greenhouse gas (GHG) emissions (GHGE) and water use.

2.1. Goal and Scope definition

The overall goal was to evaluate and determine the energy and water use and greenhouse gas (GHG) emissions (GHGE) as indicators of the environmental impact of the production of beer at a microbrewery and hence to assess its current environmental performance.

2.2. Functional Unit

The functional unit is one liter of "Shefford" beer (3.8% alcohol by volume), the main product, delivered to the point of consumption in pubs and to other distributers, in 2013. It is a draught beer often sold in pubs to the local community and other breweries. It is unpasteurised and unfiltered and so has also a short shelf life. Delivery was in casks that are cleaned and reused for many years, not bottles.

2.3. The system boundary

The product system includes all the life cycle steps from primary production (and associated inputs) through crop processing, brewing, waste management and delivery to outlets. Barley is the main ingredient, which is then malted (steeped, germinated and kilned) to produce malt. Hops are used for flavouring and are grown, harvested, dried and packaged. Brewing uses thermal and electrical energy, water and some minor inputs. Beer is matured in large tanks, casks are filled, the stored for about two weeks for the beer to mature and finally delivered. Wastewater from cleaning etc. is treated in the public sewerage system, spent hops and other wastes go to landfill and most spent brewers grains are mainly used for animal feed (with an estimated 5% sent to landfill).

2.4. Data sources and exclusion criteria

Primary data on the brewery activities, sourcing materials and beer delivery came from the brewers. These were derived from the records of six months brewing. An existing life cycle inventory (LCI) was used for barley (Williams et al., 2006) and one was extensively adapted for hops from oilseed rape (Williams et al., 2010). Energy and water use in malting came from the industry. LCI data for other minor ingredients came from analogues that were developed by Williams et al. (2006) or the literature. Energy use and waste management LCI data were taken from the European Life Cycle Database (ELCD 2012).

All GHGE were expressed on the 100 year basis using based on the IPPC (2007) coefficients. Water use was limited to the volumes of abstracted water used in malting, brewing and cleaning. Blue water used in energy production was not considered, but is thought to be much lower than these quantified sources.

Minor components that were likely to contribute less than 1% to any impact were excluded, e.g. yeast, which may be reused between brews. Fixed assets, like buildings, brewing equipment and casks were excluded.

2.5. Allocation methods

Economic allocation between barley grain and straw was as in Williams et al. (2010). Brewers' grains, when used as animal feed, were assumed to have the same feed value as the milling co-product, wheatfeed, on a dry matter basis, so that the avoided burdens method could be applied. No allocation was required if grains were sent to landfill.

3. Results

3.1. Resource use

The resource use in the production of one batch 1 l of Shefford Bitter beer is given in Table 1 and transport data in Table 2.

Table 1 Resource in the production of one batch (1475 l) of Shefford Bitter beer

Material input	Unit	Quantity
Malt	kg	0.15
Hops	kg	0.0020
Yeast	kg	0.0028
Water	l	3.39
Gypsum($CaSO_4$)	kg	0.00017
Calcium carbonate	kg	0.00017
Lactic acid	l	0.00037
Electricity	kWh	0.11348
Natural gas	kWh	0.12
Sodium hydroxide	l	0.00068

Table 2 Delivery distances and transport types of main raw materials

Product	Transport method	Distance, km
Malt	Bulk lorry	225
Hops	Bulk lorry	572
Hops	Large sea ship	15849
Ancillary material	Medium sized lorry	200
Packaging	Medium sized lorry	200

3.2. Burdens of production and delivery

The cumulative energy demand was 4.4 MJ/l, GHGE were 0.38 kg CO_2e/l and blue water volumetric consumption was 3.4 l/l.

The breakdown of burdens (Figure 2) shows that brewery activities itself dominates energy use (41%) with production of raw materials at 28%, transport at 26% and waste management at 5%. Almost all of the material production was for malt (including growing barley). Thermal energy and energy for temperature control were the most important aspects of the brewing stage. Most of the transport energy was for delivering the beer itself.

The distribution of GHGE was broadly similar with 28% from brewery activities, 30% from raw materials, 20% from transport, but waste management at 20%. Differences are mainly because of emissions of gases like nitrous oxide in agriculture and wastewater treatment.

Blue water use was mostly in the brewery activities (87%) and the rest from malting. The blue water in the brewery is split with 24% going into the beer itself and 63% as process and cleaning water.

In the brewery operations, most energy use is as electricity (73%) and thermal energy (natural gas) the remaining 27%. About 60% of the electricity is used for temperature control of the beer while it matures and awaits distribution.

In waste management, the treatment of brewery effluent in the local public sewerage system is the main process and has a magnitude of about eight times the solid waste management. Net solid waste management has a small negative impact owing to the use of brewers' grains for animal feed. If for practical or economic reasons, brewers' grains are sent to landfill, the cumulative energy use and GHGE increase by 4% and 5% respectively.

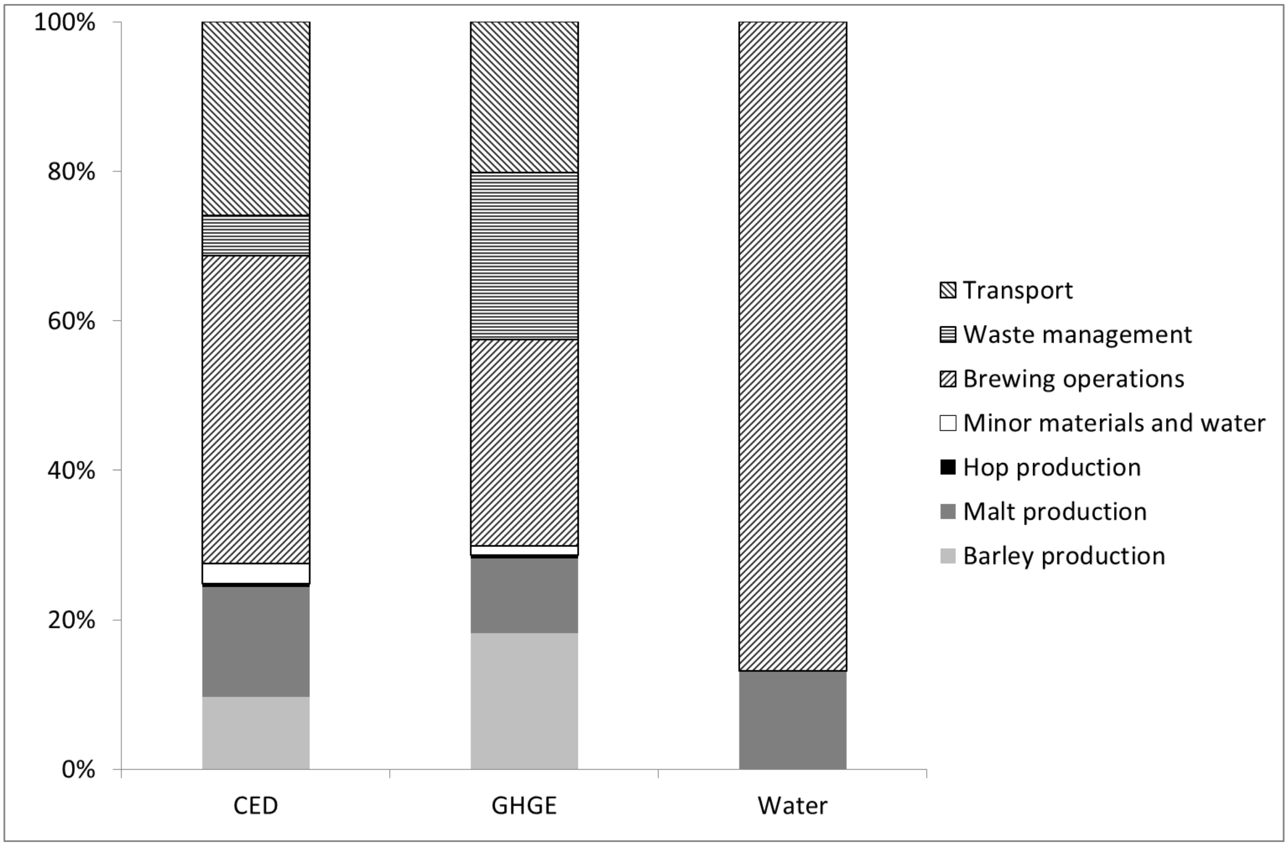

Figure 1 Breakdown of burdens of producing and delivering beer

3.3. Additional transport

Some beer gets sold on to other distributors or breweries to be sold in the free trade or as "guest beers". Extra transport is needed for delivery. The additional burdens caused by this are linearly related to delivery distance. The increase in energy use and GHGE depends also on vehicle type and the effect is estimated in Table 3. Guest beers can readily be found over 500 km from the brewery, which would increase burdens in the range 12% to 40%, depend on vehicle type.

Table 3. Increase in energy use and GHGE at the point of consumption caused by increasing delivery distance by 100 km.

Vehicle type	Cumulative energy demand	GHGE
Bulk lorry transport	2.6%	2.1%
Medium sized lorry	5.8%	4.7%
Small delivery vehicle	8.7%	7.0%

4. Discussion

This is the first LCA of traditional British beer production. It provides an interesting contrast with that of continental styles of beer. It is also applied to a micro-brewery, which will use similar recipes for brewing as larger breweries, but other features will be different owing to economics of scale.

4.1. Opportunities for improvement

The three main stages of raw material production, brewing and delivery dominate most aspects of the burdens, although waste management has a larger relative role in GHGE. A small brewery such as this has little control over raw material production and waste management, especially of effluent. Control over brewing and temperature controlled beer storage in under brewery management control, but these tend to be more constrained in micro-breweries owing to their small scale.

Water use in brewing was relatively low at 3.4 l/l. The brewers of Europe (2002) reported that an efficient brewery uses 4 to 10 l/l and Goldammer (2008) noted that some brewers even uses more water, particularly the small breweries. In this case, there seems to be relatively little scope for improvement, but a more detailed audit could indicate possibilities.

A larger brewery would have its own effluent treatment plant, which if new, could minimize emissions and make positive use any upgrading technologies possible. While this brewery uses heat exchange, there may well be more opportunities for general heat recovery in a larger scale operation. Further, larger scale operations tend to incur lower heat losses. Larger breweries can also capture the CO_2 produced by fermentation for use in its own products, e.g. carbonated beers. This brewery produces no such products.

While the brewers' grains are usually used for animal feed, this does not always occur for practical reasons, such as the farmer having other priorities or not enough animals. An opportunity that is more open to larger brewers is using low grade heat to dry grains so that transport costs are reduced and the market becomes wider.

With a large amount of electricity being consumed, there could be opportunities for using the roof to mount solar panels hence to generate low emissions electricity.

The transport of beer is energetically intensive and this brewery is constrained by having one delivery vehicle for all goods. The delivery routes are not complex and need little optimizing. A larger operation can obtain environmental benefits from a delivery fleet such that loads and vehicles can be better matched. One distinct benefit of the delivery (and subsequent serving) system is that the weight of packaging overheads of cask beer (2.5%) is much smaller than for bottled beers (about 60%).

4.2. Data quality

The activity data was of high quality with good access to data from the brewery and a major maltster in England. The LCI data for processes such as waste management, from the ECLD, are of very high quality, although the effluent treatment data set is generic rather than specific.

A formal uncertainty analysis was not undertaken, but the overall uncertainty of the energy use and GHGE would be in the order of 10%, based on studies undertaken by Wiltshire *et al*., 2009.

4.3 Comparison with other studies

Other studies have inevitably used different boundaries, data sources, data inclusion and beer types, hence all comparisons require great caution.

Cordella et al. (2008) reported a range of energy consumption for Italian lager beer of 3.14 to 5.2 MJ/l, which is similar to the present study at 4.4 MJ/l. Talve (2001), in Latvia, only included electricity in energy use and found much lower value of 0.48 MJ/l. Koroneos et al (2003), in Greece, reported energy use of 0.69 MJ/l, of which beer production was only 6%. It seems to be a considerable underestimate or very efficient processing.

In contrast Koroneos et al (2003) reported GHGE of 754 kg CO_2e/l, compared with 0.38 kg CO_2e/l in the present study. Their value seems to be barely credible and some error seems likely, e.g. unit conversion, such that the real value was likely to be 0.75 kg CO_2e/l. Talve (2001) reported an order of magnitude lower GHGE of 0.065 kg CO_2e/l, but this appeared to omit features like N_2O and CH_4 emissions from agriculture, at least. The Climate Conservancy (2009) calculated carbon footprint for "Fat Tire Amber Ale" in the USA up to and including retail and use as 3.2 kg CO_2e/l. The study is very detailed and covers almost activities including business travel. Making an estimate of equivalent stages to those of the present study suggests GHGE of about 1 to 1.4 kg CO_2e/l and so three to four times higher than in the present study.

Our results seem to be in a reasonable range, but other studies have different locations, boundaries and features so that finding systematic differences is not really possible.

5. Conclusions

A life cycle assessment of traditional English beer brewed in a microbrewery has been made with blue water, cumulative energy and greenhouse gas emissions as used as measures of environmental performance. Cumulative energy demand was 4.4 MJ/l, GHGE were 0.38 kg CO_2e/l and blue water volumetric consumption was 3.4 l/l. This is up to delivery to the point of consumption.

The main burdens arise from raw material production, especially malted barley, brewing operations, delivery and with waste management relatively small but not negligible.

Other studies are not fully comparable, but these results are in the range reported for other beer types, countries and boundaries.

Opportunities for environmental performance are limited by the small scale of a microbrewery. More detailed auditing is needed to establish what could be achieved. Existing water consumption appears to be relatively low. Solar panels could help reduce the burdens of electricity use for temperature control.

ABSTRACT

The program AGRIBALYSE® was an initiative launched by the French authorities (ADEME) to create a public Life Cycle Inventory (LCI) database of French agricultural products. The results and their uncertainties obtained for seven main French arable crops (soft wheat, maize, barley, rapeseed, sunflower, pea, and potato) are discussed here. A focus is made on four impact indicators: energy demand, GHG emissions, acidification, and eutrophication, while identifying the most contributing steps during crop life cycles. For the seven LCIs presented with the selected environmental impacts, the main contributors were field emissions. The assessment of practices such as organic fertilization or the introduction of intermediate crops could stress out some improvements on environmental impacts, but some impacts are opposed and emission models may be too simplified to simulate all their environmental benefits. These results represent a step forward to be shared with the agricultural sector in order to promote environmental evaluation and good farming practices.

Keywords: arable crops, LCI, national inventories, emission models, agricultural practices

1. Introduction

AGRIBALYSE launched in 2010 and finished in 2013, was a research program aiming to create a public database of Life Cycle Inventories (LCI) of French agricultural products. Among the 136 LCIs covering the main French agricultural production systems (arable and horticultural products, livestock products), this paper focuses on seven arable crops: maize, malting barley, rapeseed, soft wheat, spring pea, starch potato and sunflower.

This program had two goals: to produce agricultural LCIs for incorporation into the ADEME IMPACTS® database, in order to provide necessary information for environmental labelling, and to share data and methodologies to enable agricultural and food industries to assess their production chains and reduce their environmental impacts.

AGRIBALYSE datasets have several strengths. Firstly, LCIs of crops were constructed with a shared and harmonized methodology to ensure a consistent database and the comparability between LCIs (Koch and Salou 2013, Colomb et al 2014). This homogeneity is found for infrastructures and crop input. Specific adaptations were made for fertilizers, machinery, fuel consumption or input transport to correspond to French agricultural productions. Identical and adapted input data were used in all LCIs of crop productions. In addition to harmonized input data, pollutant flows are calculated with shared direct emission models best suited to the French context (Tailleur et al 2014). The allocation rules, between crops in cropping systems applied to all main crops, ensure the agronomic validity and strengthen the consistency of the database. The second asset of AGRIBALYSE is the data quality control. At different stages of the program, from data collection to Life Cycle Inventory Assessment (LCIA), experts and program partners validated data and intermediate results to ensure the quality of the AGRIBALYSE database.

The first aim of this paper is to present and discuss the LCIA results obtained for seven main French arable crops. The focus is on four impact indicators: energy demand, GHG emissions, acidification and eutrophication, while identifying the most contributing steps during crop life cycles. Emissions of phosphorus, nitrous oxide and ammonia calculated within AGRIBALYSE were compared to bibliographical references and experimental data. The second objective of this paper is to consider the use of these results by the agricultural sector. Improvements of cropping practices identified as a potential to lower environmental impacts were applied to these LCIs in order to estimate their efficiency.

2. Methods

Main methodological choices made in the AGRIBALYSE project for crop productions are summed up in Table 1. More detailed information is available in Koch and Salou 2013 and Tailleur et al 2014.

Table 1. Methodological choices for AGRIBALYSE crop productions

Products	Maize, malting barley, rapeseed, soft wheat, spring pea, starch potato and sunflower
Technology	Conventional production – average of farming practices in the different French regions
Time period	2005 to 2009
Boundaries	From cradle to farm gate - all up-stream processes (input production) are included but post-harvest operations (drying and storage) are excluded (for example maize LCI is expressed in kg of gross content with 28% of humidity).
Functional unit	AGRIBALYSE's functional unit is one kilogram of harvested product, in order to assess the environmental impacts of food products. However the functional unit used during data collection was one hectare of arable land and results per kilogram have been assessed using average yields. Both units are used in this article to better describe the multi-functionality of agriculture
Data collection	Mainly national statistics adjusted with experts' judgment.
Inputs data	Indirect emissions associated to crop inputs are based on existing data, mainly from the database Ecoinvent® V2 with many adaptations to the French context.
Direct emissions from polluting substances	Direct emissions were defined as flows of potentially polluting substances into the environment, directly associated with arable crop production on field: nitrous oxide (N_2O), carbon dioxide (CO_2) ammonia (NH_3), nitric oxide (NO), nitrate (NO_3^-), phosphorus (P) and phosphate (PO_4^{3-}), trace metals, soil loss, active substances, and land occupation and transformation. Changes in soil carbon stock were not taken into account in these results.
Allocations	Economic allocation between products / co-products (grain/straw). Animal systems carry the impacts of storage and processing organic manures and so they enter without burden in crop systems, except for a transport between farms. Direct emissions from manure application are allocated to crop productions. Allocation of fertilizers inputs, crop residues and nitrate leaching in crops sequences.
Data quality	Quality control was carried out during two phases of the program: at the end of the data collection process by French agronomic experts external to the AGRIBALYSE program and after the first calculations for the validation of calculated LCI and LCIA by the Technical Institutes as they did not carry out calculation. The Ecoinvent 2.0 pedigree matrix (Frischknecht et al, 2007) is used to assess the quality of individual inputs data and the quality of results of direct emissions models. In addition a global note is given to LCIs to fulfill ILCD requirements.

For impact assessment, no specific choice of midpoint indicators was made in the AGRIBALYSE project, its main goal being to develop a LCIs database; thus for each impact category several midpoint indicators were calculated. The data collection was relatively large to make sure of including the main impacts and methods presented in ADEME-AFNOR Working Group 1 (GT1) "Feed and fodder for domestic animals" or in the BPX 30-323 good practices guide (AFNOR, 2011). The indicators and methods selected for this communication (ILCD recommendation and CML) are presented in the Table 2.

The indicators aquatic ecotoxicity and human toxicity were not selected in this paper because there are large uncertainties in their calculation: the model to estimate direct emissions of pesticides is a rough method that quantified maximal emissions (100% of applied substances finish on the soil), only some active substances of pesticides are characterized in current characterization methods and the impact may strongly vary according to molecules used in the data collection. Methods are not mature enough to allow comparisons with references and to discriminate practices. Moreover, using national statistical data led to include a very large number of molecules in the LCIs. It does not reflect what is really happening in a specific field. Hence, a toxicity indicator using our national average LCIs would not reflect a real local impact on the environment.

Table 2. Selected midpoint indicators

Midpoint indicators	Direct flows and required data	Methods
Greenhouse gas emissions	Nitrous oxide (direct and indirect) and carbon dioxide	IPCC 2007 100 yrs - kg CO_2 eq
Energy consumption	Renewable and non-renewable energy	Cumulative Energy Demand (CED 1.8) - MJ
Acidification	Ammonia and nitric oxide	CML2001 - kg SO_2 eq
		Accumulated Exceedance (AE) - molc H^+ eq
Eutrophication	Substances involved in land and aquatic eutrophication (ammonia, nitrate, nitric oxide, phosphorus and phosphate)	CML baseline 2000 2.05 - kg eq PO_4^{3-}
	Substances involved in marine eutrophication (nitrogen flows : ammonia, nitrate and nitric oxide)	ReCiPe1.05H - kg N eq
	Substances involved in freshwater eutrophication (phosphorus flows : Phosphorus and phosphate)	ReCiPe1.05H - kg P eq

3. Results and discussion

3.1. Impact indicators

The main results of the chosen impact indicators are presented in Table 3. Results are expressed per hectare in order to compare the same agricultural land unit.

Table 3. Results of impact indicators for the seven studied crops, per surface unit (ha)

Impact indicators	Maize	Malting barley	Rapeseed	Soft wheat	Spring pea	Starch potato	Sunflower
Global warming - IPCC 2007 (kg CO_2 eq /ha)	3380	2480	2840	2820	940	3200	1210
Non renewable Energy (fossil + nuclear) CED 1.8 (MJ eq/ha)	27210	15490	15650	16720	9390	27480	8500
Acidification - CML 2001 (kg SO_2 eq/ha)	52.3	29.9	31.8	35.7	7.4	38.6	12.0
Acidification - Accumulated Exceedance, ILCD2011 (molc H^+ eq/ha)	92.6	51.8	55.0	62.2	11.2	64.7	19.9
Eutrophisation - CML baseline 2000 2.05 (kg PO_4^{3-} eq/ha)	29.5	22.4	24.2	25.2	20.6	25.2	18.7
Marine eutrophication - ReCiPe1.05H (kg N eq/ha)	37.1	33.6	38.2	37.9	37.5	39.3	27.9
Freshwater eutrophication - ReCiPe1.05H (kg P eq/ha)	1.8	1.5	1.1	1.3	1.2	1.3	1.7
Crop yield (kg raw material/ha)	10672	6618	3243	7100	4600	45780	2410

3.1.1. Greenhouse gas emissions (GHG)

GHG emissions range from 940 to 3380 kg eq CO_2/ha depending on the crop (Figure 1). In France, spring pea and sunflower have low global warming impacts because of no nitrogen fertilization on pea and an average of only 40 units of nitrogen per hectare for sunflower. When results are expressed in the functional unit, a kilogram of agricultural product, crops with low GHG emissions per hectare can have on average a bigger impact per kilogram of product or vice versa. Considering that 1 kg of rapeseed and 1 kg of potato, for example, have completely different characteristics in their water contents, energy contents and nutritional values, it could be difficult to compare their environmental impact per mass of product.

As already shown in previous studies (Gac et al. 2010, Carrouée et al. 2012, Nemecek et al 2014), fertilizers production and emissions of nitrous oxide (N_2O) are the main contributors of GHG emissions, representing from 63% (sunflower) to 81% (rapeseed) of the total GHG impact for crops with nitrogen fertilization in AGRIBALYSE results. The authors of the French program P-C-B[1] showed that mineral nitrogen production weighted from 29 to 75% of the total GHG impact and it reached from 52 to 83% of the total GHG impact if N_2O emis-

[1] CASDAR-7175 (“Pois-Colza-Blé” project) ‘Improvement of the economic and environmental performance of crop rotations with oilseed rape, wheat and peas’: the main objective was to assess and optimise the environmental and economic performance of crops’ rotations including oilseed rape and wheat, with and without grain legumes, with both field experiments and modeling studies

sions were added. Likewise the GES'TIM project, a French program to assess GHG impact and energy consumption of agricultural systems, led to the same conclusions, as for example 31% of the GHG impact of soft wheat is due to nitrogen production and 50% to N_2O emissions. As spring pea does not need nitrogen fertilization, crop residues account for most of the N_2O emissions (58%) with the method IPCC tier 1 whereas for the other crops, their crop residues represent only 15 to 31% of N_2O emissions and the rest of N_2O emissions is due to denitrification of the nitrogen fertilizers. In addition, machine use including fuel consumption has a higher GHG impact (41%) on spring pea than for other crops such as soft wheat where mechanization represents only 11%.

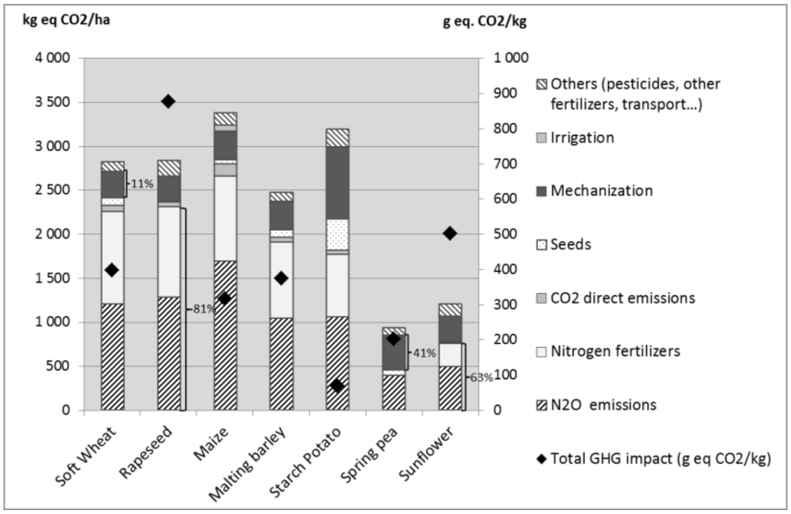

Figure 1. GHG impact of the seven studied crops per hectare (bars) and per kilogram of product (points)

3.1.2. Non-renewable energy demand

The non-renewable energy demand (fossil and nuclear) ranges from 8500 MJ/ha (sunflower) to 27480 MJ/ha (starch potato). The production of nitrogen fertilizers and mechanization are the main contributors to this impact. For soft wheat, rapeseed and malting barley, nitrogen fertilizers represent more than 50% of this impact (respectively 57%, 59% and 50%). Previous studies also showed that nitrogen fertilizers production requires a lot of energy and represents from 21 to 63% of the total energy demand (Carrouée et al. 2012, Nemecek et al 2014). Mechanization impacts the most on non-renewable energy consumption for starch potato, spring pea and sunflower (47%, 64% and 53%). In the GES'TIM project (Gac et al. 2010) mechanization for spring pea production represents 68% of the energy consumption. While this high contribution is explained by a comparatively low or

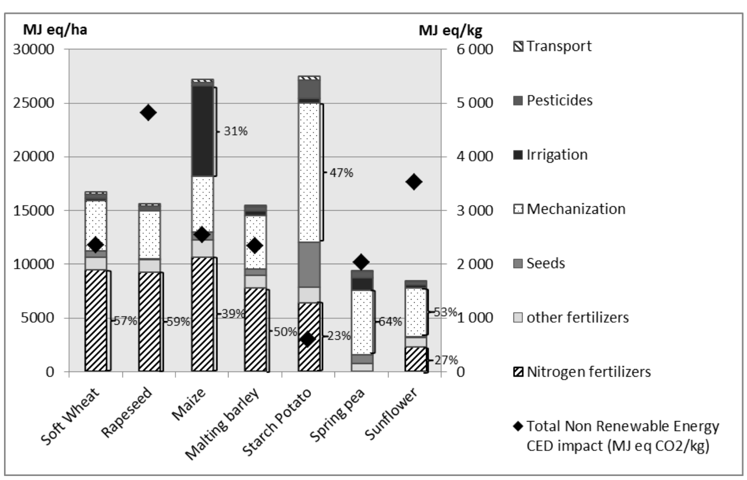

Figure 2. Non-renewable energy (fossil + nuclear) of the seven studied crops per hectare (bars) and per kilogram of product (points)

no mineral N fertilization for sunflower and pea, it is explained for starch potato by a high fossil energy demand for agricultural practices as soil management and harvest. For maize, the energy required for irrigation represents 31% of the impact.

3.1.3. Acidification

Acidification methods characterize fluxes of nitrogen and sulfur in the air, but direct emissions calculated for crop productions are only flows related to nitrogen (ammonia and nitric oxide), as SO_2 from combustion is included in mechanization. These direct emissions weight from 61% (starch potato) to 83% (maize) of the acidification indicator CML (Table 5), except for spring pea (31%) which receives no mineral nitrogen fertilizer. With the Accumulated Exceedance indicator, direct emissions represent a similar burden (67% to 87%) for crop systems.

3.1.4. Aquatic eutrophication

With the CML method, results range from 18.7 (sunflower) to 29.5 kg PO_4^{3-} eq/ha (maize). Direct nitrogen emissions (mainly NO_3^- leaching, but also NH_3 and NO flux) are the main contributors to the eutrophication impact (from 68% for sunflower to 81% for rapeseed of the total eutrophication impact), while phosphorus emissions weight from 9% (rapeseed and soft wheat) to 24% (sunflower). With the ReCiPe method, N and P emissions are separated in two midpoint indicators. Concerning marine eutrophication (N-dependent), impacts range from 27.9 (sunflower) to 39.3 kg N eq/ha (starch potato), the biggest impact being from nitrate emissions, 71% (potato) to 90% (sunflower) (table 5). For freshwater eutrophication (P-dependent), results span between 1.1 (rapeseed) to 1.8 kg P eq/ha (maize). Direct phosphorus emissions weight between 54% (soft wheat) to 79% (sunflower) of this total impact, mainly driven by phosphorus losses from soil erosion. The production of P fertilizers has also a significant impact on freshwater eutrophication, since it weights from 19% (sunflower) to 41% (soft wheat) of this impact. Regarding Ecoinvent references (Swiss crops) some AGRIBALYSE LCIs have the same freshwater eutrophication impact as soft wheat or malting barley. At the same time, some crops, like maize, have an impact nearly 50% higher than Ecoinvent data (due to higher direct phosphorus emissions).

3.1.5. Uncertainty analysis

An uncertainty analysis on AGRIBALYSE results shows that selected impact indicators are quite reliable, with coefficients of variation close to 10%. In Table 4 (uncertainty analysis on SimaPro®, 5000 runs), coefficients of variation for maize crop are presented as an example. Only eutrophication indicators with the ReCiPe method have a higher coefficient of variation (17.6 and 15.8% for marine and freshwater eutrophication).

Table 4. Coefficients of variation (CV) (%) of impact indicators for maize

CV (%)	Global warming	NR Energy	Acidification CML	Acidification AE	Eutrophication CML	Marine eutrophication ReCiPe	Freshwater eutrophication ReCiPe
Maize	10.5%	12.2%	9.1%	9%	9.9%	17.6%	15.8%

3.2. Field emissions impacting midpoint indicators

For crop productions, field emissions are the main contributors to the different presented environmental impact indicators except for energy demand (Table 5). Nevertheless, estimates of direct field emissions depend on the existence of valid models for a chosen scale. So, the AGRIBALYSE national scale has resulted in the choice of models that were valid for France and consistent with the available national data. Depending on the quantified substance, models can be really simple such as the quantification of N_2O with the IPCC method tier 1 or specifically developed to take into account the French environment as the nitrate leaching model (Tailleur et al 2014). Aware of the limits of models, some selected direct emissions have been studied and compared to French experimental data in order to identify possible ways of improvement for the future.

Table 5. Contribution of field emissions to impact indicators for the seven crops

Impact indicator	Main contributor flux	Range of value	Crops
Global warming - IPCC 2007 (kg CO2 eq)	Field emissions (N_2O, CO_2)	35 - 54%	All studied crops
	Nitrogen fertilizers production	21 - 37%	All studied crops (except pea)
Acidification - CML2001 (kg SO2 eq)	Direct field emissions	63 - 83%	All studied crops (except pea)
	Including NH_3 emissions	54 - 76%	
Marine eutrophication – ReCiPe 1.05H (kg N eq)	Direct field emissions	80 – 94%	All studied crops
	Including NO_3^- emissions	71 - 90%	
Freshwater eutrophication – ReCiPe 1.05H (kg P eq)	P emissions	54 – 79%	All studied crops

3.2.1. Nitrous oxide emissions

The NO GAS 2 project[2] collected experimental data of N_2O field emissions. 90% of the measured emissions in different parts of France vary from 0.2 to 2.3 kg N-N_2O/ha. Direct emissions calculated with the IPCC 2006 tier 1 method, are globally the same level (0.6 for spring pea to 3.1 kg N-N_2O/ha for maize). For two French crops, specific average emissions data are available from the NO GAS 2 project: 1.18 kg N-N_2O/ha/year for soft wheat (30 plots) and 1.08 kg N-N_2O/ha/year for rapeseed (34 plots). So AGRIBALYSE results tend to be over-estimated as calculated N_2O direct emissions of soft wheat and rapeseed crops are 1.9 to 2.2 times higher than measured emissions.

A sensitivity analysis was carried out to assess the impact of using these specific French references instead of the IPCC 2006 tier 1 method on the global warming impact of soft wheat and rapeseed. In the soft wheat and rapeseed AGRIBALYSE LCIs, calculated direct N_2O flux were replaced by the average measured emissions of N_2O from the NO GAS 2 project. The total GHG impact decreases with measured data from 2830 kg eq. CO_2/ha to 2250 kg eq. CO_2/ha for the soft wheat and from 2840 kg eq. CO_2/ha to 2220 kg eq. CO_2/ha for the rapeseed, representing a 20% reduction of the GHG impact.

As shown with the NO GAS 2 project, N_2O direct emissions are overestimated with the IPCC tier 1 method. In the short term, the ongoing development of a new equation tier 2 for France will allow a more accurate estimation of N_2O direct emissions and GHG impacts, given that N_2O is the major greenhouse gas from crop productions.

3.2.2. Phosphorus emissions

Phosphorus emissions represent 54 to 79% of the marine eutrophication impact (ReCiPe 1.05H). Few models exist to evaluate losses of phosphorus in surface water and ground water. The SALCA-P model (Nemecek et Kägi, 2007 and Prasuhn et al, 2006) was selected for its generic scope and its validity for all sources of emissions for major crops including grasslands. However this model was programmed for a Swiss situation, in particular the P-content of the soil, and it appeared that such data could not be adapted to the French context.

The SALCA-P model was used in the Ecoinvent datasets for crop productions and we compared Ecoinvent phosphorus fluxes with AGRIBALYSE's. SALCA-P estimates three fluxes: emissions of phosphorus from soil losses which reach rivers (soil losses were calculated with the RUSLE equation), emissions of phosphate in river by run-off and in groundwater by leaching. These three fluxes are turned into phosphorus for comparison and are showed in figure 3. On average, P losses in French agricultural systems vary between 0.6 and 1.1 kg P/ha whereas in Ecoinvent database, P losses are lower with values between 0.26 and 0.53 kg P/ha. There are no P losses by run-off with AGRIBALYSE assumptions, the slope being supposed to be 2% on average to restrain heavy metal

[2] NO GAS 2 project (still ongoing) aims to elaborate a new method to estimate direct N_2O annual emissions from cultivated soils (except pastures) based specifically on French experimental data. These data were collected through several national and European projects, from 2006 to 2012. The results presented here for soft wheat and rapeseed are the means of annual N_2O emissions measured on 30 and 34 plots for soft wheat and rapeseed respectively, located in Northern and South-West of France.

fluxes, and phosphorus in river from soil losses represents 90% of the direct P losses in the environment. P losses repartition is different in the Swiss references where run-off losses have the biggest contribution to P losses (45 to 64% of P losses).

Another important fact to point out is the difference between crops especially in AGRIBALYSE. The rapeseed, soft wheat and barley have close P emissions (around 0.6 kg P/ha) whereas spring pea and maize have higher losses (0.8 and 1.1 kg P/ha respectively). The difference is driven by losses of P from erosion and notably by crops factors used in the RUSLE equation. No specific data are actually available to validate these differences between crops.

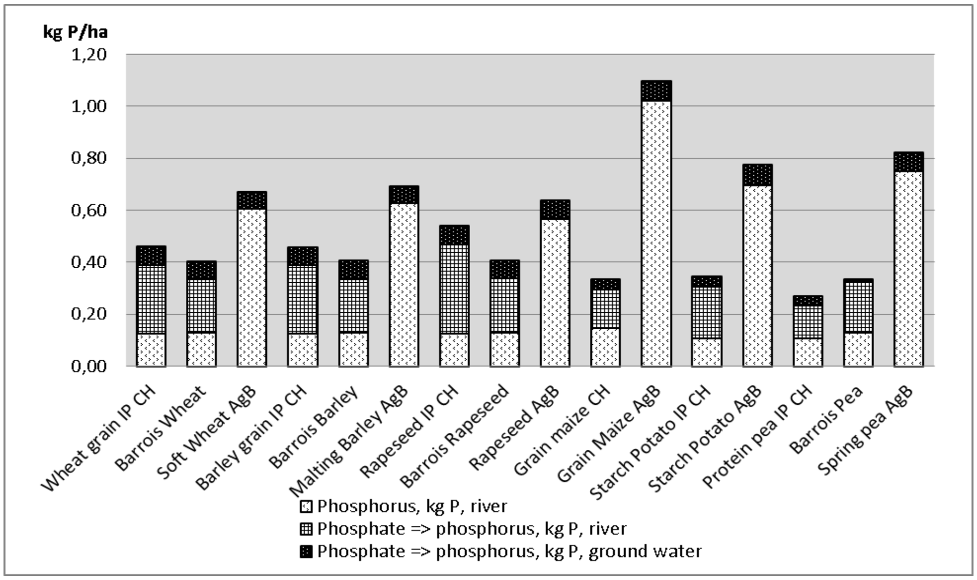

Figure 3. Comparison of phosphorus fluxes in AGRIBALYSE and Ecoinvent crops LCI. IP CH: Ecoinvent LCI for Swiss crops; Barrois: Ecoinvent LCI for a North-Eastern French region; AgB: AGRIBALYSE LCI

In addition, we compared calculated data with specific measured data from La Jaillière, an experimental site situated in the western part of France, where P losses have been measured for more than 10 years. Up to eleven plots have been studied with different agricultural practices and various privileged water circulations. Three selected plots with similar cropping systems are used for this comparison. They only differ from the water circulation in the plot: with or without drainage and with or without runoff. Two datasets were calculated using the SALCA-P model with the same agricultural practices: the first dataset was constructed with AGRIBALYSE asumptions for the model configuration and the second was configurated with La Jaillière specific data (for example, plot slope or P-content in the soil). The comparison of both datasets with experimental data brought out multiple results and outlooks.

First of all, P losses in characterization methods do not correspond to measured P fluxes in field experiments, which makes the comparison between experimental results and calculated data complicated. SALCA-P calculates emissions of phosphorus by erosion, and fluxes of phosphate by runoff and leaching whereas on experimental sites, losses by drainage and runoff are followed and data available for dissolved and particle phosphorus. Secondly, the SALCA-P model is not adapted for the La Jaillière site. When using accurate experimental data such as the soil phosphorus composition of La Jaillière, phosphorus fluxes calculated are lower than measured fluxes. Depending on the plot, measured data (on a 4-year period varying on average between 1.1 and 1.4 kg P/ha) are 2 to 7.6 times higher than calculated data (ranging from 0.2 to 0.6 kg P/ha) (Figure 4). This strong difference comes from the soil P-content and SALCA-P programmation. SALCA-P does not simulate all types of water circulation in a given field, it mainly represents orthonien runoff related to the slope and does not take into account hydromorph runoff linked to the water saturation of the soil. Eventually with AGRIBALYSE assumptions for SALCA-P configuration, total phosphorus losses are close to measured data in La Jaillière, even if the repartition between fluxes is completely different.

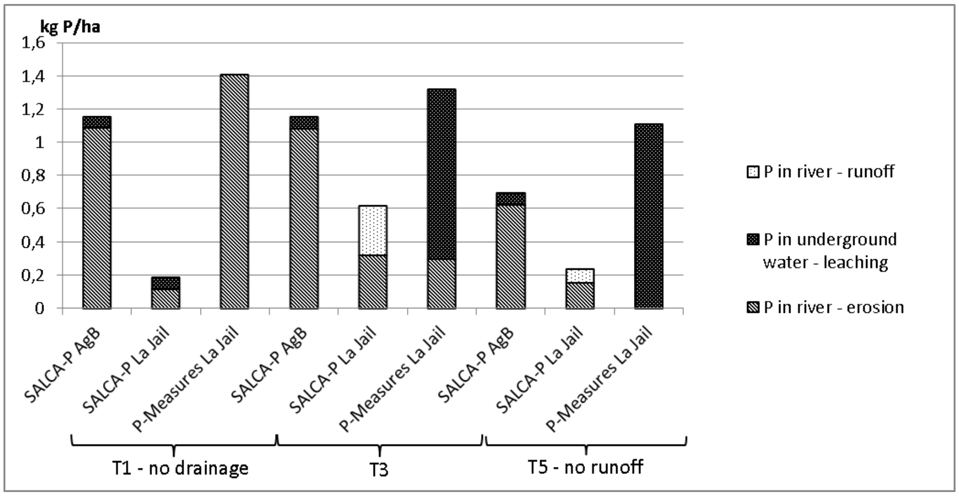

Figure 4. Comparison of phosphorus (2008-2011) fluxes in 3 plots of La Jaillière (T1, T3 and T5) – SALCA-P AgB: AGRIBALYSE assumptions; SALCA-P La Jail: specific site data; P-measures La Jail: experimental data

To conclude, AGRIBALYSE produced data near existing LCI references with the SALCA-P model. SALCA-P takes into account main phosphorus losses during crop productions but it is only partially adapted to the French context. SALCA-P is designed for a small scale such as an agricultural plot because it needs precise topographic data (slope, distance with a water body…) that are not available or too simplistic at a national scale. The choice of an average slope or the presence or absence of drainage at a large scale has a significant impact on phosphorus fluxes ; for example there is runoff of dissolved phosphorus in France even if factors used in AGRIBALYSE shows the opposite and precipitations (causing erosion and runoff) have an important impact on phosphorus losses (Breil et al. 2009). The absence of runoff with AGRIBALYSE assumptions limits also the sensitivity of the model to phosphorus nutrients, as mineral phosphorus inputs are only considered in losses of P by runoff. This work also shows that all phosphorus losses observed in France cannot be simulated by dynamic models. Few experimental data are available from French experimental stations. For example, P-losses were measured in the Parisot site in the south of France, between 1999 and 2007, and average P-losses by drainage were less than 0.1 kg P/ha. But it is only one more example that needs to be repeated. It means that further studies will be needed to gather experimental data, validate an average magnitude of P fluxes in the environment and develop models to assess phosphorus losses in relation to agricultural practices in the French context.

3.3. To identify good practices with LCA approach

The Life Cycle Assessment, a multi-criteria evaluation, allows a holistic approach of any production. It can be used to measure the environmental impact of some proposed agricultural practices while controlling that environmental fluxes are not transferred to other environmental compartments. One of the goals of the AGRIBALYSE's project is to help eco-design of food products, providing a methodological framework to assess impacts of production systems and first average references. Also AGRIBALYSE results should allow us to evaluate possible improvements of farming practices in the future.

Among good agricultural practices, introducing a leguminous crop in the rotation can be highlighted with AGRIBALYSE results. The analysis of crops LCIA confirms the significantly lower potential impacts of pea, a N-fixing crop, or of a low input crop such as sunflower, compared to crops requiring a significant amount of nitrogen fertilization. This was already underlined by Nemecek et al (2014) both at crop level and at rotation level and confirmed by field experiments (Jeuffroy et al. 2013) which enabled to estimate a decrease in N_2O field emissions by 20–25% when introducing a pea crop in a three-year rotation.

Here a specific work was done to evaluate the sensibility of AGIBALYSE methodology to farming practices with the substitution of some nitrogen mineral fertilizers by organic manure. For this simulation, boundaries of the LCA were extended from a single crop to a whole crop rotation with rapeseed, soft wheat and spring barley, regarding the fact that fertilization and especially organic fertilization is thought at a cropping sequence scale. Apart from that, choices for allocation and emission models were from AGRIBALYSE. When fertilizing an agricultural plot with organic manure, only a part of the organic nitrogen will be available for the crop depending on the type of manure (pig slurry, cattle manure, compost…), the period of application and the receiving crop. We compared a scenario with only mineral fertilization, based on data collected within the AGRIBALYSE project, to a scenario designed with pig slurry spreading. This scenario was built to apply the same amount of nitrogen as in the mineral scenario using equivalence factors for available organic nitrogen. It was also important to manage the quantity of total phosphorus brought to the plot with animal slurry. We supposed that the soil had a medium P-content and that the farmer wanted to keep this balance. So the total amount of phosphorus fertilizer (mineral and organic) is equal to the total P-exports of the rotation crop products. In values, 175 kg of mineral nitrogen are spread on rapeseed in both scenarios, respectively 164 and 133 kg of mineral nitrogen fertilizer on soft wheat and spring barley for the mineral scenario, and 121 and 85 kg N mineral/ha for the manure scenario with a total organic manure of 130 kg N/ha shared between the soft wheat and the spring barley. All other inputs and agricultural practices are AGRIBALYSE data.

LCA were calculated for both systems to compare the environmental impact of a chosen fertilization. Depending on the midpoint indicator, both systems did not evolve in the same way. Regarding GHG impact, there was no significant difference between both scenarios: the substitution of mineral fertilizers by pig slurry resulted in the diminution of the impact of nitrogen production but increased indirect nitrous oxide from airborne deposition of volatized nitrogen. The EMEP/EAA method tier 2 estimates important quantities of NH_3 from the organic fertilization (40% of the N-NH_4^+ brought from pig slurry is estimated to be emitted to the environment). In terms of energy, the scenario with organic nitrogen needs less non-renewable energy and decreases from 16460 MJ/ha/year to 13700 MJ/ha/year for the rotation, representing a diminution of 17% of the non- renewable energy use. With those two indicators the scenario with organic manure tends to have better environmental impacts than the scenario with only mineral nitrogen. Only when analyzing the acidification impact, because of important NH_3 emissions linked with manure fertilization, the all-mineral scenario has an acidification impact 40% lower than the scenario with pig slurry.

This scenario comparison brings out many challenges. When using a multi-criteria approach, the difficulty is to weight the different impact indicators to be able to correctly judge the different practices. In the analyzed case for example, organic fertilization has a better impact on non-renewable energy, but a worst impact on acidification than the scenario with only mineral nitrogen. No conclusion can be highlighted without defining which of energy use or acidification is the most important criteria. As the selected emission models do not take into account all agricultural practices, only few agricultural practices recommended as beneficial to the environment, such as replacing mineral fertilizers with organic manure, introducing intercrops or increasing the length of the rotation with protein crops, could be identified and tested with an LCA approach. When spreading organic manure, NH_3 emissions can be reduced if manure is incorporated to the soil after application (Sommer et Hutchings 2001). The EMEP/EAA method does not differentiate the mode of manure application or post-application practices, and tends to overestimate NH_3 emissions. We used experimental data to approach the potential reduction of incorporating the pig slurry after its spreading. Data collected in the site of Bignan - West of France – showed that only 11% of the N-NH_4^+ was emitted as N-NH_3 if the pig slurry was incorporated after spreading (Cohan et al. 2013). This reference used in the pig slurry scenario decreased by 36% the total acidification impact of the organic scenario and in that case both scenarios have the same level of potential acidification on the environment (respectively 86.9 kg SO_2 and 91.7 kg SO_2 eq/ha/yr for the mineral scenario and the pig slurry scenario).

Eco-design and practices assessment require accurate emission models and detailed agricultural data which are not always compatible with a national scale. In this context, AGRIBALYSE methodological choices correspond to a compromise between national database and accurate emission models.

4. Conclusion

With the AGRIBALYSE project, the most relevant choices were made to evaluate French agricultural productions on a national level and to produce valid LCI references to supply the ADEME IMPACTS® database, thus providing necessary information for environmental labelling. This first analysis of AGRIBALYSE LCIA validated analyzed LCIs and has to be continued especially for the other crops (durum wheat, alfalfa, etc.). Crop LCIs meet the need for harmonized data and give keys to evaluate environmental impacts of agricultural practices; it is a first step in using LCA for eco-design in agriculture even if the complexity of LCA (which requires large quantities of data) is a constraint for its application to agronomy. Nevertheless, remaining work needs to be done to reduce the lack of simplified emission models and to develop agricultural practices more accurately.

AGRIBALYSE LCIs of arable crops should be updated with regard to current input data on one hand (changes in agronomic practices, production of inputs, …) and on the other hand in respect of the evolving methods and models for calculating emissions (new EMEP methodology tier 2 was released in 2013 for mineral fertilizers, ongoing work on a tier 2 equation for direct N_2O emissions) which could take the specific characteristics of crops, agricultural practices and soil-climate characteristics better into account. Further developments will be needed for some flows such as the dynamics of carbon in the soil or the fate of pesticides after their application, and some environmental impacts, as biodiversity or water consumption. Finally, these results represent a step forward for the calculation of French agricultural systems LCA to share with the agricultural sector in order to promote environmental evaluation and good farming practices. LCA provides tools to weight different potential impacts and to compare different scenarios while identifying major damaging activities of an agricultural product or a production system. That is why LCA is complementary to other environmental assessment methods (assessment of farms, local scale, impact studies, etc.) and will help to improve agricultural practices.

ABSTRACT

Brazil is one of the most important producers, exporters and consumers of swine in the world. Among all states, Santa Catarina stands out in the national scenario. The main producing area in this state is about 500 km away from the nearest seaport, so that the logistic involves two steps: (a) live weight transportation to the slaughterhouse, and (b) frozen carcass through refrigerated transportation to market. Those features influence the environmental performance of the final product. We applied the Life Cycle Assessment methodology to analyze five different scenarios performing carbon footprint (CF) and energy demand (ED), varying slaughterhouse location and thus distances of cooling and live transportation. In general, results showed that lower live weight distances would represent lower impacts on CF and ED, although it is possible to reach an optimum mortality rate that would invert scenarios rankings.

Keywords: LCA; Logistics; Post-farm, Swine, Brazil

1. Introduction

Brazilian swine production is an important activity, with a herd of 35 million heads, representing the fourth largest producer (3 millions ton/year), fourth largest exporter (600 thousand ton/year) and the sixth largest consumer (11–13 kg/inhabitant/year) in the World (Kunz et al. 2009; USDA 2013). In this context, Santa Catarina state (southern Brazil) is the largest producer in the country, with 19.3% of the national herd (IBGE 2012).

The swine production chain in Santa Catarina can be described in 5 major steps, commonly known as piglet production, weaning to finishing, slaughtering (meat processing), market and consumption. Several Life Cycle Assessment (LCA) studies concluded that its main environmental hotspot lies in the livestock processes (Basset-Mens; van der Werf 2005; Dalgaard, 2007; Elferink et al. 2008; Eriksson et al. 2005; Kingston et al. 2009; Kool et al. 2009; Nguyen et al. 2011; Wiedemann et al. 2010) due feed production and animals emissions. With reflection, this step has been widely studied in order to reduce impacts.

Nonetheless, there are other production processes that can be assessed in order to improve pork's ecoprofile, or indicate preferable paths inside its production chain. For instance, after the weaning-to-finishing process, swine have two logistic steps before reaching the final consumer: (a) liveweight transportation to the slaughterhouse, and (b) frozen carcass transport through refrigerated transportation to market (internal or external).

Food transport refrigeration is a critical link in the food chain not only in terms of maintaining the temperature integrity of the transported products but also its impact on energy consumption and CO_2 emissions (Tassou et al. 2009). In these processes mechanical refrigeration technologies are invariably employed and they contribute significantly to the environmental impacts of the food sector (Tassou et al. 2010).

The impact of this technology varies depending on the distances and types of transportation involved. Those features also influence the environmental performance of the food final product. Transportation type (a) can have lower environmental impacts than type (b), since refrigerated transportation requires more inputs (e.g. fuel and refrigerant gases). However, long distances for live weight transportation are related with animal's welfare reduction, what can bring high mortality for the swine (up to 1%) (Alverós et al. 2008; Gonsalvez et al. 2006; Vecerek et al. 2006).

When it occurs, swine loss (during handling and transport) is usually preceded by a period of poor welfare (European Commission, 2002). Potential factors influencing this issue have been compiled (Adams, 1994; European Commission, 2002; Broom, 2005; Schwartzkopf-Genswein et al., 2012) and strategies have been developed to provide better welfare (European Commission, 2002; Broom, 2005; Silveira, 2013).

Brazilian laws are out of date (Silva et al. 2009) and are more focused on breeding and slaughtering processes (Brasil, 1952; 2000; 2008; 2011). Although, EMBRAPA and Brazilian Association of Swine Breeders have created a Manual of Good Agricultural and Livestock Practices in Swine Production (2011).

Since meat products have its main environmental hotspot in the livestock processes, any loss on finished swine represents higher environmental impacts.

Therefore, the aim of this study was to find the best combination on swine logistics post finishing to market. We applied LCA methodology to compare possible scenarios for Santa Catarina state, an important swine producer in Brazil. Seeking for lower Carbon Footprints (CF) and Energy Demand (ED), we evaluated five different scenarios to deliver frozen swine to São Francisco do Sul's City Seaport, 500 km away from the producer city, Concórdia.

2. Methods

Lived swine on conventional transportation (normal truck) to the slaughterhouse, and then refrigerated transportation to the harbor (for export) or storage (for national consumption), was varied in five scenarios, as shown in Table 1.

The Functional Unit (FU) was 10 tons of refrigerated swine delivered at the seaport. Therefore, the reference flow was 10 tons of frozen carcass in refrigerated transportation and 13.5 tons in live weight transportation.

Scenario 01(SC 01) was designed to represent a swine that is entirely transported frozen until the seaport. In this case, the slaughterhouse is hypothetically located beside the swine producers, therefore there is need for only a 50 km range of live weight transportation, from producers to the meat processing industry. This scenario featured a transportation with minor live swine losses due the lower distance attributed to the live weight transport, although represents a higher diesel consumption for refrigerated transport and other inputs and outputs such as refrigerant gases, due to cooling.

Scenario 05 (SC 05) is the opposite, with meat processing near to the seaport, and all the transport by regular trucks until the slaughterhouse. In this case, live transport does imply in meat losses, but on the other hand, fuel consumption is lower.

Scenario 03 (SC 03) is equalized with the same distances between producers, slaughterhouse and the seaport. Thus was modeled in 250 km for both kinds of trucks. Scenarios 02 (SC 02) and 04 (SC 04) were designed to have the slaughterhouse near the producers or near the seaport respectively, in a range of 100 km, varying transportations types.

Other characteristic of live weight transportation is that it carries more mass due to inedible offal. Although some parts are allocated after slaughtering, it means 35% more ton.kilometers^{-1} compared to frozen transportation. This difference is equalized by reference flow.

Table 1. Distances for modeled scenarios.

Scenario	Live weight transportation	Frozen transportation
SC 01	50 km	450 km
SC 02	100 km	400 km
SC 03	250 km	250 km
SC 04	400 km	100 km
SC 05	450 km	50 km

To create the inventory, primary data were collected from an Agroindustry for trucks, both refrigerated and regular, diesel consumption, truck type and capacities, live and deadweights, transport losses and city locations. The swine mortality accounting was from Cherubini et al. (unpublished data). For welfare conditions and swine losses rates, see Alvaróz et al., (2008); and table 2 based on not fasted pigs (Alvaróz et al., 2008) respectively. Other data was collected from literature and Ecoinvent Database® (for refrigerant gases). Data from cooling machinery production were not included.

Table 2. Life Cycle Inventory.

Scenario	Live cargo transportation	Amount	Frozen cargo transportation	Amount
All	Transport, lorry 16-32 ton/Euro3/EUR R	Table 1	Adapted from Transport, lorry 16-32 ton/Euro3/EUR R (135% higher diesel consumption**; Refrigerant gas[1])	Table 1
SC 01	Swine Losses*	33.7 kg	-	-
SC 02	Swine Losses*	43.2 kg	-	-
SC 03	Swine Losses*	54.0 kg	-	-
SC 04	Swine Losses*	70.2 kg	-	-
SC 05	Swine Losses*	80.8 kg	-	-

[1] Personal communication, from south Brazilian agroindustry.

The Life Cycle Impact Assessment was performed with the software SimaPro® 8.0 using the CML-IA method for CF and the Cumulative Energy Demand method for ED.

3. Results and Discussion

Results have shown better environmental performance to the SC 01 with the shortest distance between producer and slaughterhouse (50 km), despite of the long distance covered by refrigerated transport (450 km). This scenario had 1.07 ton CO_2 eq. and 18,268.05 MJ eq. (Table 3), values 27% and 15% lower than the worst scenario (SC 05), with the slaughterhouse near the seaport (Figure 1). These emissions represent approximately 3% of the total cradle-to-gate swine production chain, based on Dalgaard (2007).

Table 3. Life Cycle Impact Assessment.

Impact category	Unit	SC 01	SC 02	SC 03	SC 04	SC 05
Global warming (GWP100)	ton. CO_2 eq.	1.07	1.13	1.25	1.39	1.46
Total cumulative energy demand	MJ eq.	18,268.05	18,745.15	19,883.33	21,111.71	21,611.36

The other scenarios are between SC 01 and SC 05 for both impact categories, with SC 02 representing lower impact than SC 03 that represents lower impacts than SC 04.

As it can be seen in Figure 1, SC 02 is 4% higher on CF and 2% higher on ED than SC 01, while SC 03 is 9% and 5% higher than SC 02 and SC 04 also presents this pattern with values 10% and 6% higher than the last scenario.

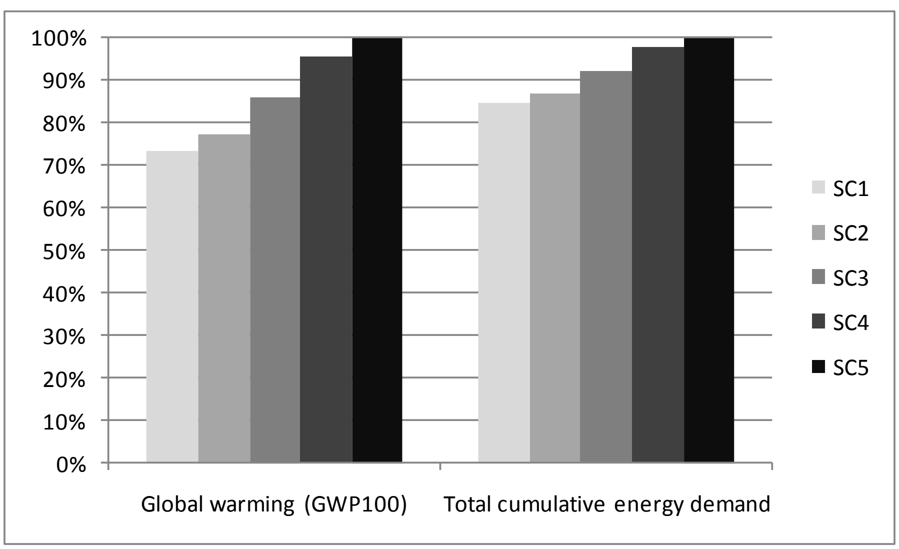

Figure 1. Environment impact comparison.

The difference in performance between lower and higher scenarios (SC 01 and SC 05) occurs due to swine losses during the long live weight transportation and also due to higher mass transported per km, even allocating slaughterer byproducts (i.e. offal). Swine losses means that impacts from feed production and animal rearing are attributed to live weight transport.

Analyzing extreme scenarios (SC 01 and SC 05) without live swine losses, we found that the CF is still higher for live weight transport, i.e., SC 01 remains better. On the other hand, for ED, SC 05 becomes preferable to SC 01. On top of that, it is possible to indicate an optimum rate of mortality where live weight transport could be the best choice.

5. Conclusion

This paper performed a LCA of swine logistics scenarios post-farm to market, varying conventional transportation (live weight) and frozen carcass transportation (cooling trucks) distances, with different inputs and outputs. Scenarios were based on the Santa Catarina state reality, from Concórdia until São Francisco do Sul, with support from an Agroindustry for providing primary data.

Locating the slaughterhouse as near as possible to producers would reduce the impacts around 27% and 15% for CF and ED, respectively, if compared to locate the meat processes near final destination (i.e. seaport for exportation).

It is clear that for CF, the reduction of live weight transportation yields better environmental performance. This statement is also true for ED results (for scenarios assessed). Although for ED, decreasing swine losses in live weight transport would allow one to reach lower energy consumption than frozen transport. Hence, it is possible to reduce mortality rates to invert scenarios' rankings. Nevertheless, the first step to reach a better environmental performance is to reduce swine losses on transportation.

These results lead us to a conclusion that they are in accordance with the recent reports on livestock as well as recent laws, where animal welfare provision is recommended and required. Besides its ethical side and influence on meat quality, animal's welfare can lead to a decrease on potential environmental loads through swine's death reduction.

Other environmental impact categories would be relevant to evaluate the overall environmental performance. For instance, frozen transportation could be a significant source for toxicity and ozone layer depletion impact categories. There is lack of cooling machinery data in this study, but it would not change the results significantly because the machinery lifespan is long and could be used for many FU, such that its impacts would be diluted.
