Following the method described in the previous chapter, we calculated net LULUC emissions for those 175 nations, for which sufficient data were reported in FAO (2012) and Olivier and Janssens-Maenhout (2011). Figure 1 describes average annual net agriculturally-related LULUC emissions (NL_k) per ha of agricultural land, which are combined from a country's agricultural LULUC emissions (AG_k) and the balance NI_k of (a) imported (positive) iLUC emissions and (b) exported (negative) dLUC emissions (see Eq. 3 above). The average global iLUC emissions pool was calculated to be 1.2 Pg per year. This is approximately one fourth of all LULUC-CO_2 emissions from the 175 countries included in the study.

In special cases, countries such as Australia and Japan are assigned no net LULUC emissions (value 0; see also Table 2); in these countries, two conditions applied: (i) neither imports nor exports increased, i.e. no national LULUC emissions are exported to the global iLUC pool, nor is iLUC imported from the pool, and (ii) national LULUC emissions are fully attributed to settlement (infrastructure) area expansion while agricultural land areas declined (compare Eq. 2 above). Other net exporting countries such as Argentina or the USA even show (theoretical) negative net LULUC results per ha (Figure 1). This is a consequence of rapidly increasing (LHV-energy) net export volumes and little or no LULUC import increases (resulting in a negative net import increase balance NI_k), combined with low national LULUC emissions (AG_k). The highest average annual net agriculturally-related LULUC emissions in Table 1 were computed for Indonesia. Of the Indonesian LULUC-related CO_2 emissions, 53 % are attributed to peat fires, 20 % to peat drainage/oxidation, 22 % to deforestation and only 5 % to palm oil and timber plantation establishment (Boer et al 2010, Indonesia's Second National Communication to UNFCCC). This illustrates that emissions may stem not only from deforestation, but also from other LULUC effects. Results for the USA and for Brazil demonstrate details about the calculations and results of net LULUC emissions: Agricultural LULUC emissons AG_k of 0 and 993 Tg were calculated per year in the USA and Brazil, respectively. These national LULUC emissions were corrected by -185 and -110 Tg LULUC emission shares from negative – and therefore export-dominated – net import increases of emissions to the global iLUC pool for the USA and Brazil, respectively. Dividing by the domestic agricultural area ($414*10^6$ ha for USA and $276*10^6$ ha for Brazil), we arrived at net LULUC emissions NL_k per average ha of agricultural land of about -0.3 and +3.0 Mg a^{-1} ha^{-1} for USA and Brazil, respectively.

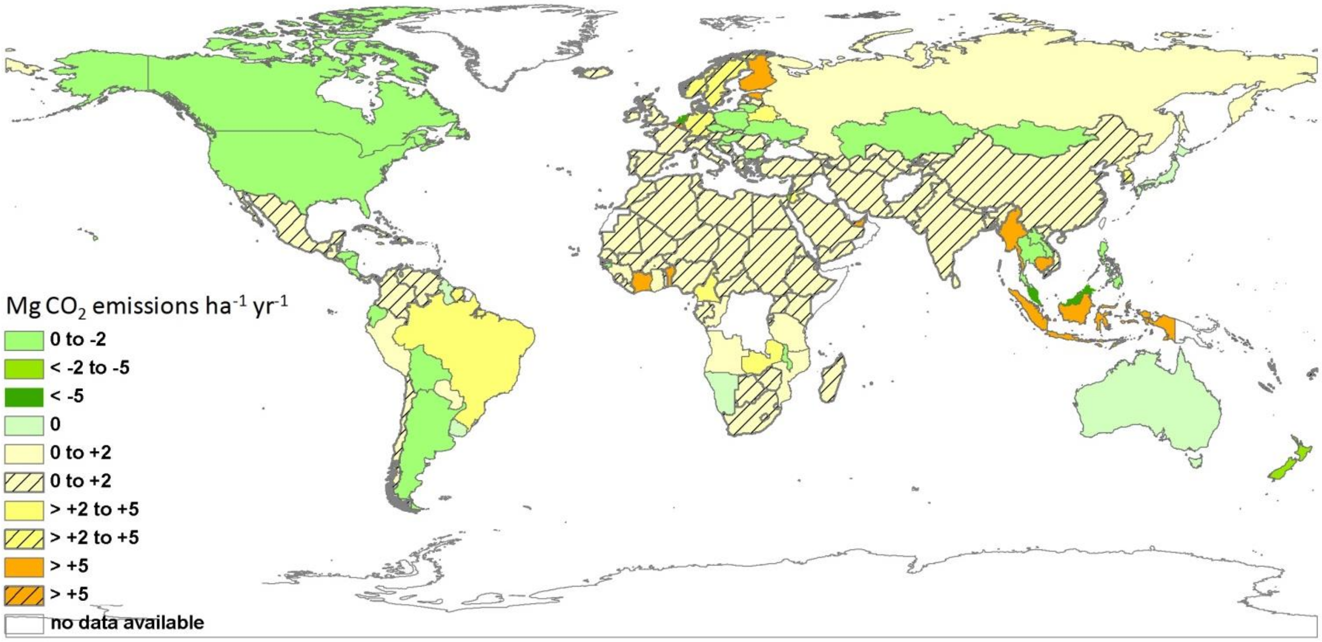

Figure 1. Average annual net agriculturally-related LULUC emissions per ha of agricultural land (Mg ha^{-1} yr^{-1}) corresponding to "NL_k" in Eq. 3 divided by agricultural land area). Hatched areas designate countries where iLUC due to net import increases is more than half of net agricultural LULUC emissions.

In addition to countrywide net agricultural LULUC emissions, we calculated net LULUC emissions specifically for product groups (as listed in FAO 2012) that are consumed within the specific countries. Table 1 illustrates for the example of Brazil the allocation factors ($ni_{k,p}$, Eq. 13) for net-import-increase related iLUC emissions. Some of the allocation factors are negative, indicating net export increases that shift emissions into the global iLUC pool. The product groups with the largest export increases and therefore with the largest negative allocation factors are oil crops (mostly soy), sugars (from sugar cane), and cereals (mostly wheat and maize).

Table 1. Allocation factors for specific product groups' net import-increases for the example of Brazil.

Product group	Allocation factor $ni_{k,p}$ for net import-increase	Product group	Allocation factor $ni_{k,p}$ for net import-increase
Alcoholic Beverages	-1.1%	Sugar crops	0.0%
Cereals - Excluding Beer	-19.6%	Tobacco & Rubber	0.0%
Fruits - Excluding Wine	+0.9%	Tree nuts	-0.1%
Miscellaneous	0.0%	Vegetable Oils	-3.6%
Oil crops	-42.7%	Vegetables	-0.1%
Pulses	0.0%	Animal Fats	-0.2%
Spices	0.0%	Eggs	0.0%
Starchy Roots	+0.1%	Meat	-4.3%
Stimulants	-1.0%	Milk - Excluding Butter	-0.5%
Sugar & Sweeteners	-27.3%	Offals	-0.4%

To complete the picture, the product-specific net LULUC emissions $nl_{k,p}$ are shown in Table 2 for Brazil and other selected countries as well. For Brazil, the strong export growth of oil crops, sugar/sweeteners and cereals (negative contribution to net LULUC emissions) is masked by a larger increase in domestic production $AG_{k,p}$ (Eqs. 9 and 10). However, only for the product group offals are the export increases large enough to result in negative overall LULUC emissions. In contrast, the product groups of tree nuts, vegetable oils, spices and oil crops are assigned large net LULUC emissions, pointing to high domestic emission increases and low export increases.

Table 2. For domestic supplies of individual product groups, average mass-specific net agricultural emissions $nl_{k,p}$ from selected countries in kg CO_2 per kg product (AR = Argentina, AU = Australia, BR = Brazil, CA = Canada, CN = China, FR = France, ID = Indonesia, JP = Japan, UK = United Kingdom, USA = United States of America).

The countries of Australia and Japan show no net agricultural LULUC emissions for their product groups – in these countries, agricultural land use decreases, and thus all land expansion is assigned to infrastructure growth according to Eqs. 2 and 9. In addition, both agricultural exports and imports from Australia and Japan decreased during the accounting period. In contrast, export-dominated countries such as Argentina, Canada and the USA show mostly negative net LULUC emissions; in the case of the USA, this applies to fewer product groups than in Argentina. Countries like France and the United Kingdom show positive net agricultural LULUC emissions for most product groups, mainly due to import increases. Emissions for Indonesia are much higher than for the other countries because of large domestic LULUC emissions AG_k, regardless of the product group.

Figures 2 and 3 show for selected countries, which product groups are associated with large positive or negative net LULUC emissions.

Plant-based product groups with high net emissions include spices, stimulants, oil crops, vegetable oils, tree nuts and cereals (Fig. 2). With regard to vegetable oils, Argentina and China are clearly net exporters, and Brazil generally has large positive net LULUC emissions due not to imports, but large domestic production increases. This applies also to production of Argentinean and Brazilian tree nuts.

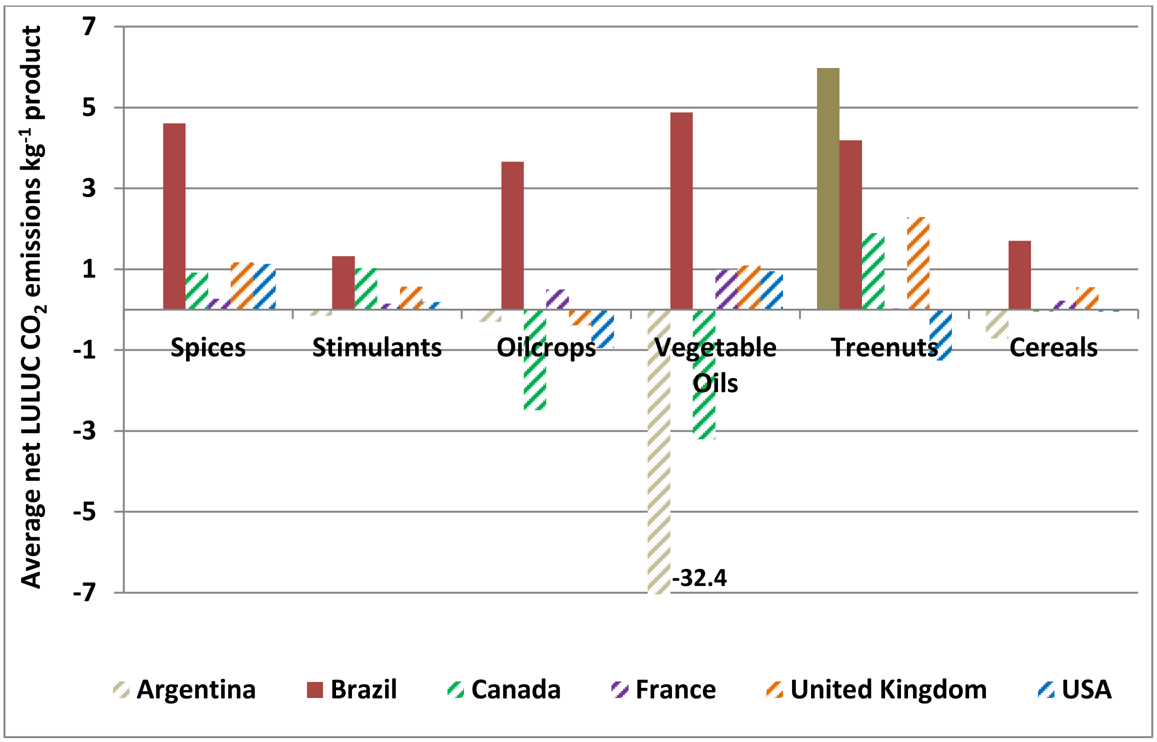

Figure 2. Average net LULUC emissions of specific vegetable product groups with comparably high emissions per kg of product (kg LULUC-CO_2 kg^{-1} product). Hatched columns represent a dominating contribution of iLUC emissions to the net LULUC emissions per unit of product from different groups; solid columns indicate that net LULUC is dominated by emissions assigned to domestic production increases.

Livestock products in Figure 3 show a dominating export role of animal fats and – to a lesser degree – of offal in Argentina, while Chinese imports of offal increased and thus lead to positive net LULUC.

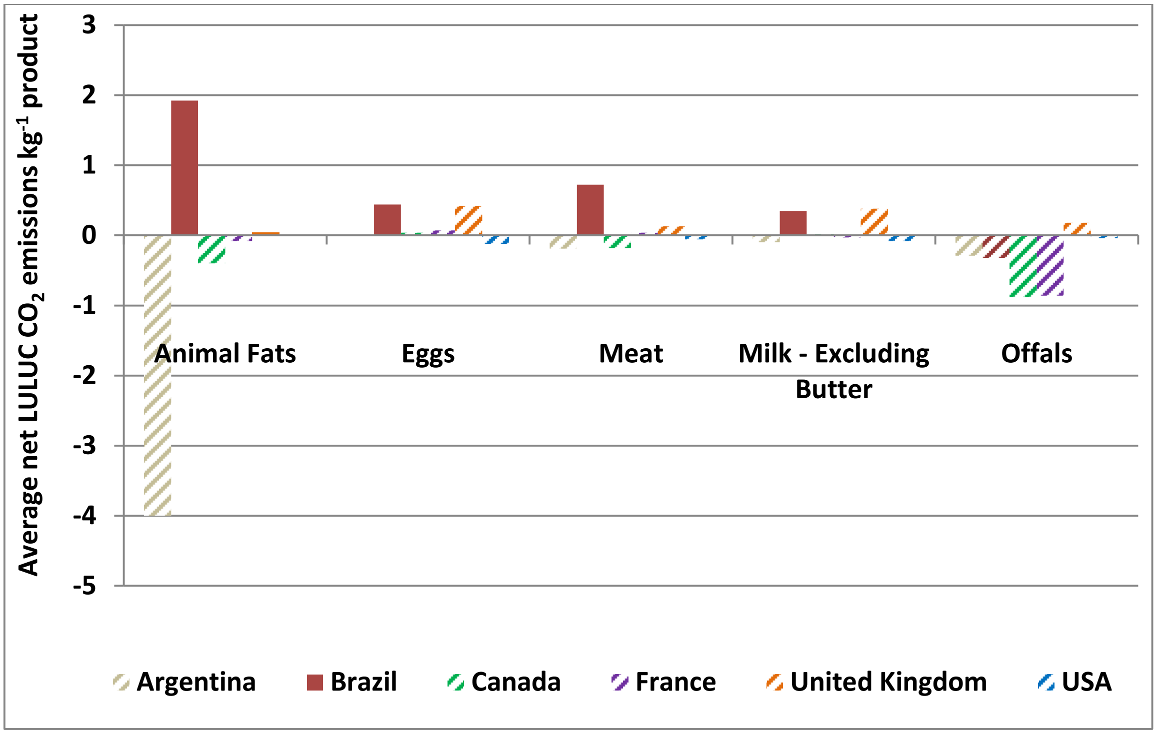

Figure 3. Average net LULUC emissions of specific livestock product groups with mainly comparably high emissions per kg of product (kg LULUC-CO_2 kg^{-1} product).

4. Discussion

Our method assumes that agricultural LULUC is a consequence of increasing demand for agricultural products and thus for land. We derive emission shares based on the dynamic development of agricultural production energy content (e.g., increases of exported energy content), rather than on static, absolute shares of production (e.g. exported energy content itself). This focus on dynamic developments has the advantage of capturing the trends underlying land use change, but it also requires up-to-date information on rapidly changing global agricultural developments, making it hard to extend the method to smaller geographical entities than countries for which such statistics usually are collected (FAO 2012).

By constructing a global iLUC emissions pool, we chose to ignore direct commodity flows between individual countries, to better reflect the global interrelationships of the agricultural commodity marketplace. As stated above, emission shares are allocated in proportion to the energy-content of agricultural product groups. Such an allocation factor has the advantage that it does not fluctuate much over time. As has long been debated in LCA (e.g. Curran 2007) allocation could also be based on commodity prices, but for the purposes of this study the required data were not available. Such an economic aggregation would emphasize the role of monetary drivers for cultivation and agricultural management decisions, but on the other hand, it would be subject to confounding factors such as currency exchange rate fluctuations and fluctuations of auxiliary material prices (fuels, fertilizers, pesticides).

In most countries, the larger part of increased food and feedstuff production is for domestic purposes; in our approach this means that most of a given country's LULUC emissions (globally approximately 70%, authors' calculation) are assigned to that country. The remainder (approximately 30% of worldwide LULUC emissions) are exported or imported and are thus assigned to a global iLUC emissions pool. In many countries though, LULUC from import increases accounts for more than half of the net LULUC (hatched areas in Fig. 1).

In general, country-wide LULUC results suggest that the net LULUC emissions are determined by a combination of a country's agricultural productivity and economic (infrastructure and affluence) development. Product-group specific LULUC emissions vary widely across countries and within a country; high country-wide LULUC emissions – if not caused by infrastructure growth – are a necessary but not sufficient condition for high net LULUC emissions of product groups.

On a general note, the method illustrated here is predicated on the principle of assigning an environmental burden (LULUC emissions) to the consumer (importer of an agricultural commodity) whose demand for the commodity is seen as causing the burden. Conceivably, one could also argue that it is the producer, not the consumer, who decides to satisfy a perceived demand and who therefore should be assigned the LULUC emissions. Applied to LULUC, this shifted perspective would mean that export – related LULUC emissions are still assigned to the producing country/product groups - no "iLUC emissions pool" would be necessary. As a side note, these two opposing approaches are not unknown to LCA practitioners: They are also reflected in two methods used to solve the recycling allocation problem – the cut-off method and the disposal-load method (e.g. Ekvall and Tillman 1997). As a third, compromise approach (similar to the "fifty-fifty" approach in recycling allocation), one could also choose to evenly divide the LULUC emissions from imports and exports between producer and consumer. Mathematically, this would correspond simply to cutting the size of the iLUC emissions pool in half.

Uncertainties of the proposed method's results may be introduced by input data, i.e. FAO (2012, 2013) data concerning areas, yields, national consumption or traded amounts. These data are ultimately collected by the national statistic offices. In addition, the aggregation of single commodities into product groups such as "cereals" causes uncertainties, as different commodities within a group (e.g., types of cereal grains show) will have different lower heating values (LHVs), which even further vary under practical conditions. For example, for the average LHV of the product group "cereals" we used as a surrogate the lower heating value of the globally dominant cereal commodity wheat. A comparison of the wheat LHV with the actual weighed average of the US cereal grain production mix shows a difference of 1.9% between the surrogate and the actual mix. The production mix is based on production data queries (http://quickstats.nass.usda.gov/) of the US Department of Agriculture's statistical data sets for the years 1998-2000 and 2007-2009. Additional uncertainty stems from the conversion of volume based production information (bushels) to mass-based production data, as well as the range of literature-based LHV values for grains. For example, literature values for the LHV of wheat (as fresh matter) range from 14.11 MJ/kg (83 % dry matter) to 14.96 MJ/kg (at 88 % dry matter; Fehrenbach et al. 2008).

5. Conclusion

With the suggested method, we propose an integrated dynamic treatment of LULUC emissions from domestic agricultural production and from iLUC linked to international agricultural commodity trade. We assign LULUC emissions not only to growing agricultural areas in a given country, but also to increases in land occupied by infrastructure and built-up land. Ignoring the latter LULUC emissions (caused by infrastructure growth) and focusing instead on agriculture-related LULUC emissions, we calculate net country-specific agricultural LULUC emissions. We do this essentially by adding LULUC emissions from increased domestic production and iLUC emissions from a country's net import increases. Net import increases are the balance of (a) imported (positive) iLUC emission increases and (b) exported (negative) dLUC emission increases. Using increases of production, exports, or imports in place of their absolute values allows a dynamic rather than static accounting of agricultural commodity production and trade.

Data on agricultural commodity production and trade are converted to the commodity's corresponding energy content as LHV. This allows aggregation of agricultural product group data on a national and global scale.

A country's iLUC emissions are allocated from a (hypothetical) global iLUC pool; this corresponds to assuming a worldwide average import mix which reflects the global interconnectedness of agricultural commodity trade und thus "traded" LULUC emissions.

In addition to national results (e.g. per average hectare of agriculturally used land), our method is able to allocate emissions specifically for product groups that are consumed in a country. The method's allocation of emissions on diverse product groups provides new results with indirect (LU)LUC effects for 175 nations (with full data).

We demonstrate this approach for selected nations (e.g. Brazil, China, Indonesia, USA) by presenting net average annual emissions per ha for each selected country in general and for these countries' product groups in particular (e.g. for cereals, oil crops or livestock products such as animal fat, milk or meat). The application of the method delivers interesting results for the analyzed nations, with widely varying results between nations on one hand and product groups within a nation on the other hand.

Due to the novelty of the method, we have unfortunately not been able to compare our results to those of similar LCA-related dynamic approaches, which account for international agricultural commodity trade. A comparison of our method's results with those of direct (LU)LUC approaches seems not appropriate: By accounting for country-specific domestic LULUC and iLUC net-emissions, we attempt a more spatially accurate attribution of iLUC effects than existing iLUC models. We are thus suggesting a computational basis for a more equitable approach to LUC-related GHG-accounting between "LULUC-emitting/exporting nations" and "LULUC-importing nations" as well as between (LU)LUC-driving product groups and product groups with little or no effects on LULUC-emissions. Further work should address the issue of the verification and improvement of the model and its input data.

ABSTRACT

As China's dairy consumption is growing, both the domestic milk production and the importation of dairy products are increasing to meet demand. Life cycle assessment (LCA) has recently been applied to assess the water availability footprint for dairy production systems in the major production region of Heilongjiang (Huang et al. 2014). Comparisons were also made with milk produced in the US (California) and New Zealand. The water footprint of milk (cradle to farm gate) produced in Heilongjiang was around 11 L H_2Oe (H_2O-equivalents) kg^{-1} fat-protein-corrected milk (FPCM). This compared to 461 and 0.01 L H_2Oe kg^{-1} FPCM for milk in California and New Zealand respectively. These results suggest that large-scale milk production systems in north-east China, with little dependence on irrigation, have only a modest impact on freshwater availability. Further expansion of the Chinese dairy industry should avoid farming systems with high consumptive water requirements in water-stressed regions.

Keywords: dairy farming, agri-food sector, life cycle assessment, water footprint, sustainable water use

1. Introduction

The environmental burdens of livestock production are a major concern (Herrero and Thornton 2013), especially impacts related to greenhouse gas emissions, land and water use (IDF 2010; Mekonnen and Hoekstra 2012; Stehfest et al. 2013). As livestock production in developing countries is expected to increase, these problems are likely to become even more pressing. China is the world's most populous country and with rapid economic growth diets have shifted toward more calories from animal fats and proteins. From 1990 to 2009, China's dairy consumption increased from 6 to 30 kg per capita per annum (FAO 2012). In response to the growing demand, domestic milk output has increased as well as net imports of dairy products. The expanding Chinese dairy industry has been examined from a range of environmental perspectives (Liu et al. 2004; Sun et al. 2010; Wang et al. 2010). This paper, based on a recent article (Huang et al. 2014), specifically addresses concerns related to water depletion, which is a prominent environmental concern in much of northern China.

According to previous studies using the virtual water approach, which only reports the volumes of water used in production, the increase of livestock production was reckoned as the main driver of China's water scarcity (Liu et al. 2008; Liu and Savenije 2008). However, this argument is built on the general situation that animal products have higher virtual water than crop products (e.g. 1,644 m^3 ton^{-1} of cereals; 15,415 m^3 ton^{-1} of beef) (WFN, 2012). Such volumetric water footprints, which give no consideration to the environmental relevance of water being used, have been described as potentially confusing and misleading (Ridoutt et al. 2009; Zonderland-Thomassen and Ledgard 2012), often giving the largest values to rain-fed agricultural production systems which are actually not associated with any water withdrawal. Environmental relevance should be taken into consideration if the water footprint indicator is to inform wise decision making and policy development (Pfister et al. 2011; Ridoutt and Huang 2012), and this is the direction a new international standard for water footprint is taking (ISO 14046). Several LCA-based water footprinting methods which enable accounting and impact assessment of water use are now available (e.g. Bayart et al. 2010; Mila i Canals et al. 2009; Pfister et al. 2009; Ridoutt and Pfister 2010). Compared to volumetric-oriented indicators such as virtual water, impact-oriented indicators are recommended as being more revealing for decision making (Berger and Finkbeiner 2013; Ridoutt and Pfister 2010; Zonderland-Thomassen and Ledgard 2012).

However, to our knowledge, the application of LCA-based water footprinting to Chinese dairy production is scanty. We conducted a detailed inventory of life cycle water consumption of dairy production in Northeast China (Huang et al. 2014). The water footprints of milk of Chinese origin were subsequently compared with milk produced in countries which are significant in their exports of dairy products to China. Our main purpose was to offer strategic insights to the Chinese food industry about ways to improve the sustainability of products

Jing Huang and Ling Du contributed equally to this study.

containing dairy ingredients from a consumptive water use perspective. The wider dissemination of results is also intended to increase understanding of sustainable water use in relation to China's expanding dairy industry.

2. Methods

2.1. System description

The growth of China's milk output over the past decades has mainly resulted from the expansion of the national dairy herd (0.64 million head in 1980 to 14.2 million head in 2010, DAC 2011) and a shift in production patterns from household to large-scale dairy farms. Milk production mainly occurs in northern China, which in 2010 had more than 80% of the national herd (NBSC 2011). This study concerns the large-scale milk production systems in the north-eastern province of Heilongjiang which is the second largest in terms of milk output. In this region, dairy cows are predominantly raised in mixed farming systems where crop products such as maize, wheat bran and soybean meal are used as feed for the cows. The annual rainfall ranges between 400 and 600 mm, and is concentrated during spring and autumn. Supplementary irrigation is necessary for maize, wheat and soybean. Forage crops such as silage maize and grass are generally rain-fed.

2.2. Life cycle inventory

An LCA based-water footprinting method was used to assess consumptive water use in the production of raw milk (Ridoutt and Pfister 2010). This study only took into account the way the production system limits the availability of freshwater for the environment and for other human uses. As such, only the consumptive water use from surface and groundwater (so-called blue water) was considered. The consumption of soil moisture derived from natural rainfall (so-called green water) was included to estimate the blue water consumption. However, green water will be disregarded in the impact assessment phase (section 2.3) because green water does not generally contribute to regional freshwater scarcity in water bodies (Mila i Canals et al. 2009; Ridoutt and Pfister 2010).

The dairy farming subsystem was modeled using first-hand survey data collected from four large-scale dairy farms and covered the 2011 financial year (Table 1). Capital goods used in production (e.g. machinery and buildings) and dairy farm services (e.g. veterinary and business services) were not included in the assessment as these items are difficult to ascertain and are of minor environmental relevance in most open farming systems (Ridoutt et al. 2012). Maize, maize silage and hay were either grown on-farm or purchased from local crop farmers. Soybean meal and wheat bran were purchased from local oil extraction and grain milling industries which were processing local crop products. In this region, on-farm water use was from groundwater. Effluents such as urine and dung were regularly collected and stored in ponds for 30 to 180 days then returned to local croplands for feed production. Further information regarding the irrigation and other farm inputs used to produce purchased feed crops were collected from local farms and by consultation with local experts (Table 2).

Water consumption associated with the production of farm inputs (fuels, fertilizers, etc) was determined using the Chinese Life Cycle Database (CLCD; www.itke.com.cn). Water consumption was expressed relative to the amount of fat and protein corrected milk (FPCM, 4.0 % fat and 3.3 % protein, FAO 2010). For the allocation of water consumption from processes with multiple co-products, there are several available methods such as the biophysical, economic and protein-based allocation methods (Gerber et al. 2010; Guinée et al. 2004; Thoma et al. 2013). This study applied both the biophysical and economic approaches, enabling the results to be compared with other studies applying these same methods. Application of the biophysical approach followed Thoma et al. (2013). The incoming feed energy was estimated from the surveyed quantity of beef and milk produced and the known nutritional characteristics of the specific feeds consumed by the animals (Gao 2009). The ratio of the feed energy deposited as milk to the total feed energy deposited as milk and beef was then used to define the allocation ratio. The economic approach to allocation used average prices over the last five years.

2.3. Impact assessment

Impact assessment was used to assess the environmental relevance of consumptive water flows in relation to freshwater scarcity. Local characterization factors for freshwater consumption were taken from the Water Stress

Index (WSI) of Pfister et al. (2009). The WSI of the study region was 0.125 and the national average WSI for China (0.478) was used in relation to farm and industrial inputs where the location of production was uncertain. As for the water footprint, each instance of consumptive water use was multiplied by the relevant WSI and then summed across the product life cycle. To enable comparisons between products produced in different regions, the water footprint was then normalized by dividing by the global average WSI (0.602; Pfister et al. 2009) and expressed in the units H_2O equivalents (H_2Oe).

Table 1. Characteristics of the dairy farming subsystems in Heilongjiang, China.

Variable [a]	**Value**
Livestock	
Average number of heifers <2 yr old, head	90
Average number of milkers, head	110
Average number of dry cows, head	30
Average number of bulls, head [b]	0
Average number of mortality and replacement, head	15
Annual milk production, t farm^{-1}	693
Fat content, %	3.5
Protein content, %	3.0
Feed	
Maize, t farm^{-1}	439
Maize silage, t farm^{-1}	1128
Soybean meal, t farm^{-1}	165
Wheat bran, t farm^{-1}	97
Hay, t farm^{-1}	222
Other Farm inputs	
Drinking water use, t farm^{-1}	7300
Dairy shed water use, t farm^{-1}	1460
Electricity, kwh farm^{-1}	2000
Coal, t farm^{-1}	20
Diesel, t farm^{-1}	4

[a] All figures are presented on a yearly basis, yr^{-1}.
[b] Artificial insemination

Table 2. Characteristics of the crop farming subsystems in Heilongjiang, China.

	Maize (grain)	**Maize (silage)**	**Wheat**	**Soybean**	**Hay**
Irrigation, m^3 ha^{-1}	266	0	1260	115	0
Diesel, kg ha^{-1}	23	0	22	21	0
Pesticide, kg ha^{-1}	1.9	2.4	1.3	2.8	0
Fertilizer, kg ha^{-1}					
N	160	200	240	45	60
P_2O_5	50	90	130	80	19
K_2O	45	45	53	45	50
Yield, kg ha^{-1}	9500	85000	3350	1850	2000

2.4. Sensitivity analysis

LCA studies are frequently influenced by uncertainties arising from different factors (Bjorklund 2002). Following ISO 14044 (2006), this study applied sensitivity analysis to the allocation rules and data uncertainty, using the data collected from high and low input farms identified from the four that were surveyed.

2.5. Comparison of milk produced in other countries

The water footprint of milk produced in Heilongjiang was compared with production in the US (California) and New Zealand as imports of dairy ingredients from these regions are important to the Chinese food industry. Lacking detailed information on dairy farms in these two regions, related data for raw milk at farm gate were collected from literature and adjusted to the FPCM functional unit where necessary (Asselin 2012, USDA 2007, Zonderland-Thomassen and Ledgard 2012).

3. Results

3.1. Water consumption of milk produced in Heilongjiang and sensitivity analysis

For large-scale dairy production systems in Northeast China, the allocation of resource use to milk was 92.3% using a biophysical allocation method and slightly higher at 95.2% using an economic allocation method. Consumptive water use also varied between farms, such that the water use allocated to the production of 1 kg fat-protein-corrected milk (at farm gate) varied from 65.4 to 75.3 L (biophysical allocation method) and from 67.3 to 77.7 L (economic allocation method) (Table 3). The average blue water consumption across the four surveyed dairy farms in Heilongjiang was 69.0 L kg^{-1} FPCM (biophysical allocation), with 83% occurring in the production of feed (Table 4). The sensitivity analysis indicated that the variations between high and low input farms were more important than choice of allocation method. That said, the uncertainty associated with data was not regarded as significant in terms of influencing the comparative ranking of water footprint results for milk originating from Heilongjiang, NZ and California (Section 3.2 following).

Table 3. Water consumption of milk produced in Heilongjiang and sensitivity check on allocation rule.

Water consumption per unit milk	High input farm	Low input farm	Difference
Biophysical allocation method, L kg^{-1} FPCM	75.3	65.4	9.9
Economic allocation method, L kg^{-1} FPCM	77.7	67.3	10.4
Deviation, L kg^{-1} FPCM	2.4	1.9	0.5
Deviation, %	3.2	2.9	5.1

Table 4. Water consumption of milk produced in Heilongjiang and sensitivity check on data uncertainty.

Water consumption per unit milk [a]	Feed production	Dairy farm operation	Total
Average value, L kg^{-1} FPCM	57.3	11.7	69.0
High input farm, L kg^{-1} FPCM	62.8	12.5	75.3
Deviation, L kg^{-1} FPCM	5.5	0.8	6.3
Deviation, %	9.6	6.8	9.1
Low input farm, L kg^{-1} FPCM	54.7	10.7	65.4
Deviation, L kg^{-1} FPCM	-2.6	-1.0	-3.6
Deviation, %	-4.5	-8.5	-5.2

[a] The calculation was based on the biophysical allocation method.

3.2. Water footprint of milk produced in Heilongjiang, California and New Zealand

The average water footprint of milk produced in Heilongjiang was 11 L H_2Oe kg^{-1} FPCM (by biophysical allocation), with 76% occurring in the production of feed (Table 5). This can be interpreted as meaning that the production of 1 kg milk in Heilongjiang had an equivalent potential to contribute to freshwater scarcity as the direct consumption of 11 L of water at the global average WSI. Milk produced in California had a higher water footprint (461 L H_2Oe kg^{-1} FPCM), with relatively high consumptive water use (470 L kg^{-1} FPCM) and high water scarcity. New Zealand milk had the lowest water footprint (0.01 L H_2Oe kg^{-1} FPCM, Table 5).

Table 5. Water footprint of milk produced in Heilongjiang, California and New Zealand at dairy factory gate.

	Heilongjiang, China	California, USA	New Zealand
Blue water consumption [a], L kg^{-1} FPCM	69	470	1
WSI (local) [b]	0.125	0.996	0.011
WSI (national) [b]	0.478	0.499	0.023
Water footprint [a], L H_2Oe kg^{-1} FPCM	11	461	0.01
Feed production, %	76	>95	<5
Dairy farm operation, %	24	<5	>95

[a] Based on data from Asselin (2012) and Zonderland-Thomassen and Ledgard (2012).
[b] Data from Pfister et al. (2009).

4. Discussion

4.1. Water footprint of large-scale dairy farming in China

For large-scale milk production systems in Heilongjiang province, most consumptive water use is associated with feed production and this life cycle stage is the first focus for mitigation. Strategies for reducing consumptive water use might include increasing irrigation water use efficiency in crop production, importing feed from other regions where less irrigation is needed or where local water scarcity is even lower, and increasing feed conversion efficiencies for milk production. Although water consumption associated with other dairy farm activities (e.g. animal drinking water, dairy shed water use and water associated with farm inputs) was small, strategies such as reducing the evaporation and wastage of drinking water and the use of recycled water for cleaning could have additional potential to reduce water consumption.

To appropriately address the environmental impacts of consumptive water use, the local water scarcity where production occurs must be taken into consideration. The water availability footprint of milk produced in Heilongjiang was only 11 L H_2Oe kg^{-1} FPCM, much lower than that of cereals produced in some of China's water-scarce regions (e.g. 367 L H_2Oe kg^{-1} for maize in Huang basin, 931 L H_2Oe kg^{-1} for wheat in Hai basin) (Huang et al. 2012). Although plant and animal-derived products cannot be directly compared because of differing nutritional attributes, these water footprint results illustrate that animal products can have lower environmental impact in terms of water resource depletion than some crop products. Even for the same agricultural commodity, farming systems and local environmental context can differ greatly. When considering a large country, such as China, variation in local water stress can be extreme with WSI values (at the province scale) ranging from 0.02 to 1.00 (calculated using data from Pfister et al. (2009)).

The blue water consumption associated with milk produced in grazing and mixed systems has typically been found to be less than that in industrial dairy systems where all feed components are purchased and there is a greater tendency to rely on irrigated crops (Mekonnen and Hoekstra 2012). In China, the majority of dairy cows are raised in these grazing and mixed farming systems (DAC 2011). In addition, the relatively low water stress in Heilongjiang resulted in the milk products derived from this region having only a modest water footprint. As a general principle, low resource input, predominantly non-irrigated, grass and crop-based livestock production systems have little impact on freshwater resources from consumptive water use. As such, similarly modest water footprint results might be expected for livestock products in many other parts of China and the general assertion that livestock production is a major driver of water scarcity in China should not be hastily accepted. We recommend that the water footprints of dairy and other livestock products produced in the different regions of China should be explored in future research using the LCA approach.

To meet the increasing demand for dairy products, China needs to significantly expand its dairy production. As mentioned in section 2.1, more than 80% of the milk production currently occurs in northern China. Unlike Heilongjiang, some of the other provinces in the north (e.g., Inner Mongolia, Hebei and Shanxi provinces) have regions which are already under serious water stress. Increased water consumption for milk production in these provinces may cause serious environmental impact. Water footprint assessment is therefore essential to guide the sustainable development of China's dairy industry.

4.2. Impact mitigation options for the agri-food industry

Nowadays, many consumers have become more critical and not only wish to be informed about the safety of their food but also its origin and the sustainability of its production (Wognum et al. 2011). Manufacturers in the food sector can respond to these changing consumer demands by implementing strategies to reduce environmental impact and by public reporting of product environmental footprints. This study has highlighted a range of practical interventions for food companies to reduce the negative impacts arising from water consumption in the life cycles of food products with dairy ingredients.

Due to the importance of water consumed in primary production, one approach that food companies can take is to source agricultural ingredients from locations with low water stress and from regions where there is low irrigation water demand. For example, Page et al. (2011) reported the water footprint of tomato grown for the Sydney market in Australia and found that the water footprint of local produce was about 8 times higher than alternative suppliers from other regions. Similarly, the water footprints of beef ranged from 3 to 221 L H_2Oe kg^{-1} at the farm gate between six beef cattle production systems in Australia (Ridoutt et al. 2012). These results illustrate the enormous variability in water footprints that exists and therefore the great potential to alleviate water scarcity through selective procurement of agricultural commodities. In the case of dairy-based confectionary (Huang et al. 2014), dairy ingredients supplied from California, where both the local WSI and irrigation water demands were highest, might be avoided or otherwise highlighted for strategic water footprint reduction initiatives. Another consideration to reduce the water footprint of the dairy-based processed foods might be to source more dairy ingredients from New Zealand or Heilongjiang. That said, for some ingredients, it may be more difficult to change the supply region in the short-term because of the structure and location of the established agricultural industries. The opportunities for impact mitigation in such cases are to source ingredients from farms which have higher irrigation water use efficiency within the region. Investments in farming systems which increase the efficiency of irrigation water use, decrease runoff and increase the productivity of rain-fed production systems should be encouraged. These activities could be driven by the food industry by making water-saving agreements with their suppliers.

4.3. Limitations of this study

This study has been the first application of LCA-based water footprinting in Chinese dairy production. There are several limitations arising from the available data and calculation method. Firstly, the dairy farming subsystem was modeled using data collected from only four dairy farms. Although the sensitivity analysis indicated that the overall findings were not affected by farming system data uncertainty, it remains desirable to expand the sample size in future research and to include additional regions of milk production. Furthermore, this study only assessed consumptive water use in the context of water stress. However, water pollution is also an acknowledged problem in parts of China and in certain cases the dairy sector is implicated (Liu et al. 2004; Wang et al. 2010). It is therefore desirable that future water footprint research of dairy products in China investigate nutrient and other emissions to water in addition to consumptive water use.

The limitation of the water footprint metric is that it focuses on the single issue of water scarcity and is not an indicator of overall environmental sustainability. There are frequent tradeoffs between water consumption, greenhouse gas (GHG) emissions and other sources of environmental impact. For example, tomato production systems in Australia with lower water footprint were also found to have a higher carbon footprint (Page et al. 2012). Actions to reduce water footprints might require more energy use and consequently increase GHG emissions, and interventions to reduce GHG emissions might increase water consumption. Therefore, priorities for overall environmental improvement should be carefully considered.

5. Conclusion

As the first application of LCA-based water footprinting in the dairy industry in China, this study has illustrated that livestock products can be produced with modest potential to contribute to freshwater scarcity. Thus, the generalization that the growing demand for livestock products is the major driving factor for China’s water scarcity is not supported in this case. We conclude that it is necessary to examine the regionalized variation in water footprints of all major agricultural commodities as the heterogeneity within sectors is large and the opportunities for water footprint reduction are widespread. This study has demonstrated the large variability in the water footprints between dairy farming systems. As China's domestic milk production is expanding to meet the growing demand, expansion of dairy farming in water-stressed regions should be avoided, unless dairy systems in these areas can predominantly rely on rain-fed crops and pastures. Strategic opportunities also exist for China to reduce its external water footprint associated with dairy products imported from other countries. Food companies can reduce their burden on freshwater systems by sourcing dairy ingredients from regions with low water stress and low water consumption demand. However, interventions to reduce water footprints should not be taken without due consideration given to the potential consequences for other environmental impact categories (e.g. GHG emissions), as well as social and economic factors.

6. Acknowledgement

This paper is based on a recent journal article (Huang et al. 2014) and arises from a project financed by Mars Foods (China) Co. Ltd. We thank the many Mars employees who assisted the study and especially Yu Li and Yueyue Wang for kind support and co-operation.

ABSTRACT

Improving the sustainability of the dairy food chain involves a reduction of the environmental impact of dairy farming, as a large part of the environmental impacts associated with dairy product consumption is generated in the agricultural phase of the milk life cycle. In this paper, we combine life cycle assessment and farm accountancy data to analyze the factors affecting the environmental performance, defined as the eco-efficiency of food production, and the economic performance of Swiss dairy farms in the alpine area. The results of the analysis show the existence of synergies in the enhancement of farm economic and environmental performance. Unfavorable natural production conditions (high altitudes and unfavorable topography) have a strong negative impact on both areas of performance. Conversely, organic farming, farm size, full-time farming and a high agricultural education level have a positive effect on the two dimensions of the sustainable performance of a farm.

Keywords: sustainability, dairy farming, economic performance, environmental performance, Switzerland

1. Introduction

Dairy products are of high relevance in terms of environmental sustainability of final consumption. According to a study conducted for the EU-25 by Tukker et al. (2006), dairy products are—within the food and drink consumption area—the second highest contributors[1] to the environmental impact of final consumption by private households and the public sector. Only a few studies have assessed the relative contribution of each phase in the life cycle of milk to milk's total environmental impact over its whole life cycle from production through consumption to disposal. Focusing on the milk production and processing phases, Hospido et al. (2003) showed for the Galician dairy sector that of these two phases the production phase (farming) was—for the impact categories (i) global warming potential, (ii) eutrophication potential and (iii) acidification potential—the main contributor to the total environmental impact generation (with a contribution to the total impacts of 80%, 74% and 58%, respectively). Performing a comprehensive life cycle assessment encompassing the farming, processing and consumption phases, Eide (2002) showed for Norwegian dairies that the agricultural phase was—for (i) the energy consumption, (ii) the acidification potential, (iii) the eutrophication potential and (iv) the global warming potential—the greatest contributor to the total environmental impact of the whole dairy supply chain. Assessing a very large sample of dairy farm operators from the United States and considering all phases in the dairy supply chain, Thoma et al. (2013) found that 72% of the greenhouse gas emissions associated with the consumption of fluid milk in the United States was accrued by the dairy farm gate. Analyzing—within a comparative study between Switzerland, Germany, France and Italy—the life cycle of cheese up to its point of sale, Bystricky et al (2014) found that the farming stage was responsible—for all environmental impact categories considered (demand for non-renewable energy resources, global warming potential, ozone formation potential, land use, eutrophication potential, acidification potential, terrestrial and aquatic ecotoxicity, and human toxicity) for more than 70% of the environmental impacts generated from the "cradle to the point of sale". These four studies provide evidence that, within the dairy supply chain, the "cradle-to-farm gate" link is for most environmental impact categories the most important contributor to the environmental impact of the full chain. A thorough understanding of the factors affecting the environmental impact generation at this level is therefore a pre-requisite if we want to improve the environmental sustainability of the dairy food chain and thus reduce its contribution to the environmental impacts related to the final consumption of products by private households and the public sector.

The present paper focuses on the Swiss dairy food chain of the alpine area, which is of particular importance for the Swiss agricultural sector (see Jan et al. 2012b). By using life cycle assessment (LCA) in combination

[1] The most important contributor is meat and meat products.

with farm accountancy data, we aim to identify the factors influencing the environmental and economic performance of Swiss dairy farms located in the hill and mountain region.

2. Materials and methods

The present work is based on the same data as those used in Jan et al. (2012a). Hence, we forgo a comprehensive description of this dataset and refer the reader to this publication for detailed information on the data and especially on the environmental impact assessment carried out.

2.1. Sample of farms

The investigation relied on a pooled[2] sample of specialized dairy farms located in the hill and mountain regions. The sample encompassed 56 farm observations. The hill and mountain regions included the hill zone as well as the mountain zones 1 to 4 as defined in FOAG (2008). The hill and mountain regions, also called alpine area in the present paper, can be defined roughly as the agricultural production area located between 500 and 1'500 meters above sea level. A specialized dairy farm was defined as a farm whose revenues from dairying generated at least 60% of total farm agricultural revenues without any direct payments. Farms with a proportion of revenues from para-agricultural activities above 20% of total farm revenues as well as farms whose revenues from forestry activities generated more than 10% of total farm agricultural revenues were excluded from the analysis to ensure that the observations were homogeneous in terms of production activities.

The data were collected within the framework of a broader project, the LCA-FADN (Life Cycle Assessment–Farm Accountancy Data Network) project, aiming at conducting a joint economic and environmental assessment of Swiss agriculture at the farm level (see Hersener et al. 2011). The farms of the sample were not selected according to a random procedure. The participation in the project occurred on a voluntary basis due to the complexity and comprehensiveness of the environmental data collection.

2.2. Environmental impact assessment using the SALCA approach

For each farm, a precise and comprehensive environmental impact assessment was conducted by using the SALCA (Swiss Agricultural Life Cycle Assessment) approach (see Baumgartner et al. 2011). The system investigated was made up of the agricultural production system defined in a narrow sense (see Jan et al. 2012a). The assessment covered the agricultural stage, that is, the "cradle-to-farm gate" link, of the milk life cycle. All agricultural inputs, production processes and outputs were taken into account. The environmental impacts were quantified based on very precise and detailed production inventories collected at the farm level. The following eight impact categories were quantified (the impact assessment method used being given in parentheses): (i) demand for non-renewable energy resources (ecoinvent method, Frischknecht et al. 2004), (ii) global warming potential over 100 years (IPCC method, IPCC 2007), (iii) eutrophication potential (EDIP97 method, Hauschild and Wenzel 1998), (iv) acidification potential (EDIP97 method, Hauschild and Wenzel 1998), (v) aquatic ecotoxicity (CML01 method, Guinée et al. 2001), (vi) terrestrial ecotoxicity (CML01 method, Guinée et al. 2001), (vii) human toxicity (CML01 method, Guinée et al. 2001) and (viii) land use (CML01 method, Guinée et al. 2001).

2.3. Analysis level

In the present work, the analysis was carried out at the whole-farm level and not at the level of the product "milk." This choice was motivated by the high degree of specialization in dairying of the farms investigated and by the associated homogeneity of their product mix (i.e., of their production activities). Choosing the farm unit instead of the product group "milk" as an analysis level furthermore enabled us to circumvent the typical problem of allocation of resources and emissions to different products (or product groups) encountered in life cycle assessment at product level in a multiple-product setting (e.g., Feitz et al. 2007, who showed—using a dairy manufacturing plant as a case study—how sensitive the product-level results of LCA studies were to the allocation approach used).

---

[2] The observations of a three-year period from 2006 to 2008 were pooled.

2.4. Economic performance

There exist many possible indicators to assess the economic performance of a farm. Basically, these indicators can be divided into two sub-groups: (i) the efficiency measures from the field of productive efficiency measurement and (ii) the classical profitability indicators commonly used in practice within the field of farm management. However, productive efficiency measures were shown to be inappropriate to assess the overall economic performance of an enterprise (Musshof et al. 2009). Hence, we used here a classical profitability indicator from the field of farm management, namely the work income per full-time family work unit. It assesses the farm income available per unpaid full-time family labor force after equity capital has been remunerated to its opportunity cost. This latter is defined as the interests that would be generated would the equity capital be remunerated to the interest rate on ten-year Swiss government bonds. The work income per annual full-time family work unit was derived from the accountancy data of the farms.

2.5. Environmental performance

Relying on the considerations of Halberg et al. (2005), Jan et al. (2012a) distinguished between the local and the global environmental performance of a farm. The local environmental performance of a farm was measured by means of a so-called area-based[3] indicator assessing the amount of environmental impact generated on-farm (i.e., at the level of the local ecosystem of the farm) per hectare farm area. The global environmental performance of a farm was quantified by means of an eco-efficiency indicator, eco-efficiency[4] being defined as the farm agricultural output per unit of environmental impact generated in the "cradle-to-farm gate" link of the food chain.

For the same reasons as those exposed in Jan et al. (2012a), the present work concentrated on the global environmental performance of a farm. Eco-efficiency was specified here as the amount of digestible energy (in MJ) produced by the dairy farm per unit of environmental impact. Specifically, nine eco-efficiency indicators were estimated: one for each of the eight environmental impact categories considered (this first type of indicator being called partial eco-efficiency indicator as it considered only one environmental impact category at a time) and an aggregate eco-efficiency indicator considering several impact categories at the same time and estimated according to the Data Envelopment Analysis–based approach described in Jan et al. (2012a). The aggregate eco-efficiency was expressed in percent and can be interpreted as the result of a benchmarking in which a farm is compared to its peers in terms of digestible energy production per aggregate environmental impact. Further details on the interpretation of this aggregate eco-efficiency are available in Jan et al. (2012a). To better understand the effect of the factors considered on each partial eco-efficiency indicator, partial eco-efficiency was decomposed into its sub-constituents, namely partial eco-efficiency at the input-group (e.g., energy carriers, fertilizers) level defined as the amount of digestible energy produced by the farm per unit of environmental impact attributable to this input group. To facilitate the analysis, the partial eco-efficiency indicators were converted into environmental-intensity indicators, environmental intensity being defined as the inverse of eco-efficiency (Verfaillie and Bidwell 2000). This conversion enabled us to separate per input group the environmental impact generation per MJ digestible energy produced[5,6].

2.6. Analysis of the factors affecting environmental and economic performance

As mentioned in the introduction, the objective of the present contribution was to analyze the factors affecting the environmental and economic performance of Swiss dairy farms located in the alpine area. Numerous fac-

[3] Term used by Halberg et al. (2005).

[4] Eco-efficiency is the inverse of environmental intensity, also called product-based indicator by Halberg et al. (2005).

[5] The use of eco-efficiency for this decomposition would have been associated with problems of additivity between the average eco-efficiency at whole-farm level and its constituents at input-group level. These problems result from the fact that eco-efficiency, like any ratio variable, is undefined if its denominator, in the present case the environmental impact generation, equals zero. Such a situation is met often at input-group level. This problem does not occur when environmental intensity is used.

[6] Eleven input groups were defined: (i) fertilizers and nutrients, (ii) energy carriers, (iii) purchased animal feed, (iv) buildings and equipments, (v) machinery, (vi) plant protection products, (vii) purchased seeds, (viii) purchased animals, (ix) on-farm emissions from animals (stable), (x) own animals not present on the farm (e.g., outsourcing of heifers rearing, summering of cattle) and (xi) other inputs.

tors[7] can impact farm economic and environmental performance. These factors can be classified into two groups: factors pertaining to the general environment of the farm and those related to the farm itself as economic agent (Jan et al. 2011). The first group can be split up into three major sub-groups: the legal/regulatory environment, the socio-economic environment and the natural environment. The second group encompasses three sub-groups: the structural factors, the management factors and the human factors. Taking into account the variable availability and the limited sample size, we focused in the present work on the following factors: natural production conditions, farm size, farm type (full-time or part-time farm), production form and agricultural education of the farm manager. The natural production conditions were represented by the categorical variable "agricultural production zone," this variable being made of three modalities: hill zone, mountain zones 1&2 and mountain zones 3&4. The agricultural zone classification was based on criteria regarding (i) the climatic conditions and especially the vegetation period length, (ii) the accessibility in terms of transport and (iii) the topography (FOAG 2008). Within the mountain region, the favorableness of the natural production conditions decreases from mountain zone 1 to 4. Farm size was measured in terms of food production quantity defined as the amount of digestible energy produced by the farm. Farm type was represented by a dummy variable (full-time *versus* part-time farming). Full-time farms were defined as farms whose household income originated from at least 90% agricultural income. Part-time farms were farms with at least 10% of their household income originating from non-agricultural activities. Production form had two categories: organic *versus* conventional farming. The variable related to the agricultural education of the farm manager considered two levels: (i) completed apprenticeship or lower agricultural education level and (ii) agricultural education level higher than a completed apprenticeship (e.g., master craftsman diploma or university degree).

Taking into account the limited sample size as well as the number of independent variables analyzed and considering the requirements in terms of number of observations for performing a multiple linear regression analysis[8], we had to reject this multivariate approach, which would have suited best for the purpose of the present work. Instead, we investigated separately the effect of each factor on each performance indicator considered. Owing to the limited size of the sample and to the fact that the assumptions (*inter alia* normal distribution assumption) required for performing parametric tests were not fulfilled, this effect was investigated by means of non-parametric statistical tools. If the determinant was interval-scaled, we used the non-parametric Spearman's rank correlation to assess the relationship between this determinant and the performance indicator considered. In the case of a categorical determinant, its effect on the performance indicator was analyzed by means of a Mann-Whitney U-test if the factor in question had two categories or of a Kruskal-Wallis test if the factor considered had more than two categories.

Based on this analysis, we could identify the factors presenting synergies (i.e., influencing both the economic and environmental performance in the same direction) and those showing trade-offs (i.e., affecting the two dimensions in an opposite direction) in the enhancement of farm economic and global environmental performance.

3. Results

The results of the analysis of the factors affecting the economic and global environmental performance of Swiss dairy farms in the alpine area are presented in the following five sub-sections[9]. Each sub-section is devoted to one of the factors presented previously in section 2. Due to the high correlation of the environmental intensity between terrestrial and aquatic toxicity (Spearman's rho=0.91, $p<0.001$) and for the sake of conciseness of the paper, the results regarding the aquatic toxicity are not presented here.

[7] The terms "factor," "determinant," "independent variable" or "predictor" are used here as synonyms.

[8] Harrell (2001, p. 61) stated, as rule of thumb, that at least 10 to 20 observations should be available per predictor to obtain a reliable fitted-regression model. Applied to the present investigation, this rule would imply that at least 60 to 120 observations would be needed since the model encompassed six predictors and the categorical variable regarding the natural production conditions was transformed into two dummy variables.

[9] Owing to the paper length limit, we could not provide all detailed figures from the statistical analyses and tests carried out and had to focus on the most important results.

3.1. Effect of unfavorable natural production conditions

As obvious from Figure 1, the natural production conditions were shown to have a statistically significant effect on the aggregate eco-efficiency ($p<0.001$). Whereas farms located in the hill zone showed an average aggregate eco-efficiency of 86%, the average aggregate eco-efficiency of farms located in the mountain zones 1&2 and 3&4 was 68% and 36%, respectively[10]. With respect to the single environmental impact categories, we observed that the natural production conditions significantly influenced the environmental intensity regarding the demand for non-renewable energy resources ($p<0.001$), the global warming potential ($p<0.001$), the eutrophication potential ($p<0.001$), the terrestrial ecotoxicity ($p=0.06$), the human toxicity ($p<0.001$) and the land use ($p<0.001$). Farms located in the hill zone showed a significantly lower environmental intensity than those located in the mountain zones 1&2 and 3&4, the farms of the mountain zones 3&4 registering the highest environmental intensity for all impact categories considered. The environmental intensity differences between the three groups of zones were substantial and varied in their relative amplitude depending on the impact category considered. For example, the differences between the hill zone and the mountain zones 3&4 varied between a factor of 1.6 for the terrestrial ecotoxicity and 3.7 for the land use. A more detailed analysis at the input-group level showed that the differences were not due to a specific input group but concerned almost all input groups relevant for the impact category considered.

With respect to the economic performance, measured by the work income per family work unit, we observed significant differences between the three groups of zones considered ($p=0.07$, see Figure 2). The highest average income was observed for the hill zone (46'315 CHF per family work unit). The mountain zones 1&2 and 3&4 showed, compared to the hill zone, a lower work income per family work unit (29'930 and 34'550 CHF, respectively).

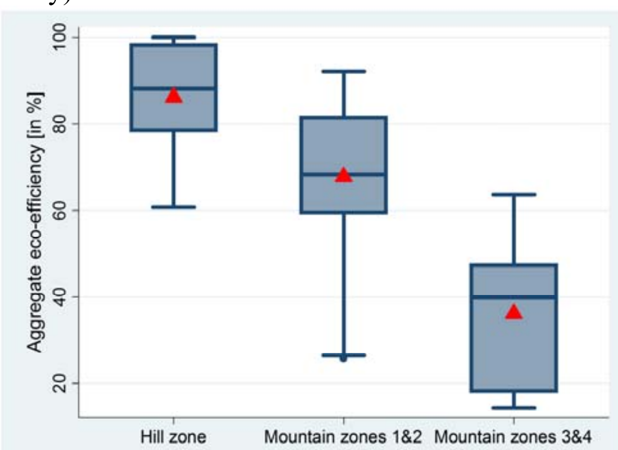

Figure 1. Effect of the natural production conditions on the aggregate eco-efficiency

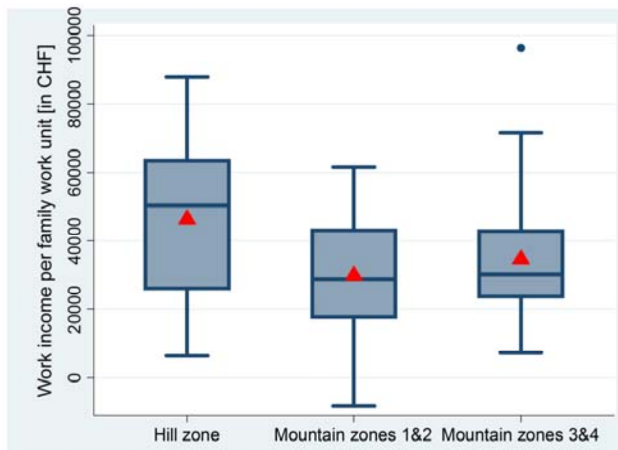

Figure 2. Effect of the natural production conditions on the work income per family work unit

3.2. Effect of farm size

The results of the non-parametric Spearman's rank correlation analysis showed the existence of a strong positive monotonic relationship between farm size, measured as farm digestible energy output, and farm aggregate eco-efficiency ($rho=+0.75$, $p<0.001$, see Figure 3).

The Spearman's rank correlation between farm size and environmental intensity was -0.73 ($p<0.001$) for the demand for non-renewable energy resources, -0.81 ($p<0.001$) for the global warming potential, -0.57 ($p<0.001$)

[10] All boxplot representations in this paper have to be interpreted as follows. The upper line of the box represents the upper quartile (Q75), the lower line of the box the lower quartile (Q25), the line subdividing the box the median (Q50). The lower whisker spans all data points within the range]Q25-1.5 IQR; Q25[(where IQR=interquartile range defined as Q75-Q25). The upper whisker spans all observations within the range]Q75; Q75+1.5 IQR[. Outliers (i.e., observations outside the whiskers) are marked as blue points. The red triangle represents the average.

for the eutrophication potential, -0.34 (p=0.01) for the terrestrial ecotoxicity, -0.70 (p<0.001) for the human toxicity and -0.80 (p<0.001) for the land use.

The negative correlation between farm size and environmental intensity proved to be related not to a particular input group but to the most important input groups for the environmental impact category considered.

A positive monotonic relationship was found between farm size and the work income per family work unit (rho=+0.37, p=0.005, see Figure 4).

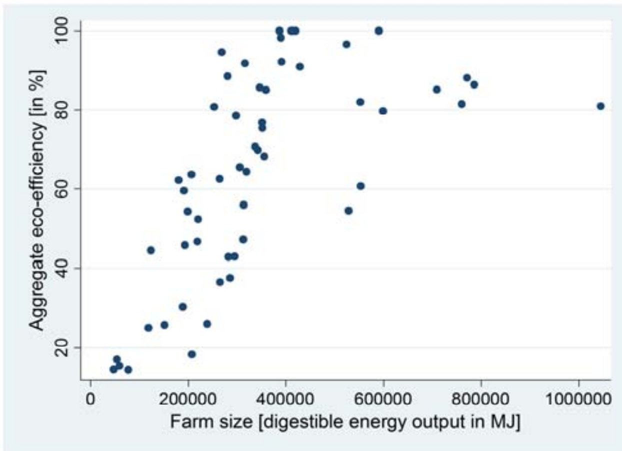

Figure 3. Effect of farm size on the aggregate eco-efficiency

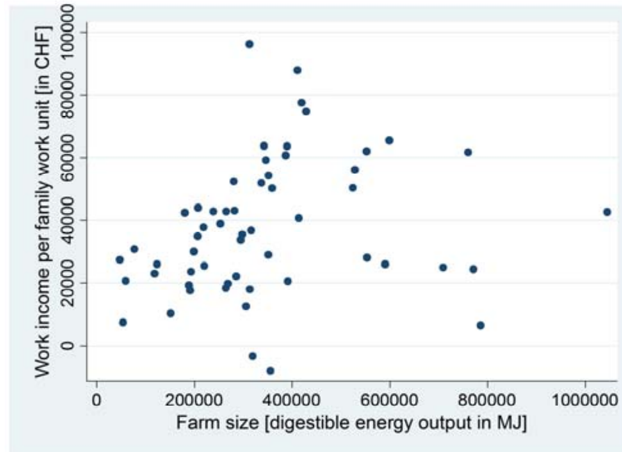

Figure 4. Effect of farm size on the work income per family work unit

3.3. Effect of farm type

Even if, based on a visual analysis of Figure 5, it would seem that full-time farms exhibited a higher aggregate eco-efficiency than part-time farms, the outcome of a Mann-Whitney U-test (p=0.15) showed that the differences were not significant at a 0.10 level. However, at the level of the environmental intensity for each single impact category, we observed some significant differences between these two groups of farms. Full-time farms tended to exhibit a lower environmental intensity than part-time farms regarding the demand for non-renewable energy resources (p=0.10), this being attributable to the input groups (i) purchased animal feed and (ii) buildings and equipments. With respect to the global warming potential, full-time farms also were characterized by a lower environmental intensity (p=0.04) being imputable to the input groups (i) purchased animal feed and (ii) buildings and equipments. In terms of eutrophication potential, full-time farms also showed a significantly lower environmental intensity than part-time farms (p=0.02). This better performance resulted from the input group fertilizers and nutrients. The lower environmental intensity of full-time farms compared to part-time farms observed for the impact category human toxicity (p=0.005) was ascribable to three input groups: (i) energy carriers, (ii) buildings and equipments and (iii) purchased animal feed.

In terms of economic performance, full-time farms significantly differed from part-time farms (p<0.001, see Figure 6). The average work income per family work unit was 51’614 CHF for full-time farms and 27’764 CHF for part-time farms.

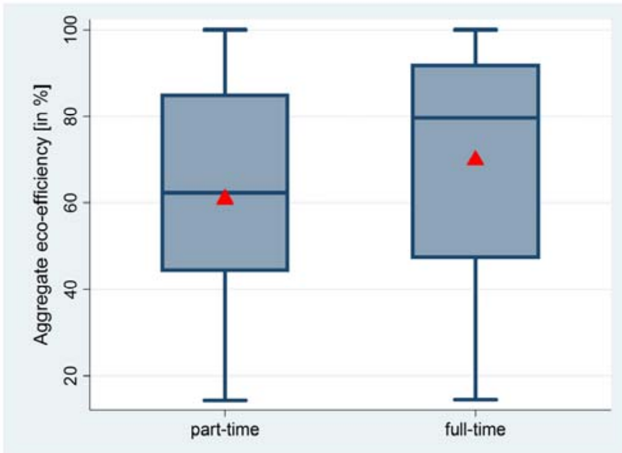

Figure 5. Effect of farm type on the aggregate eco-efficiency

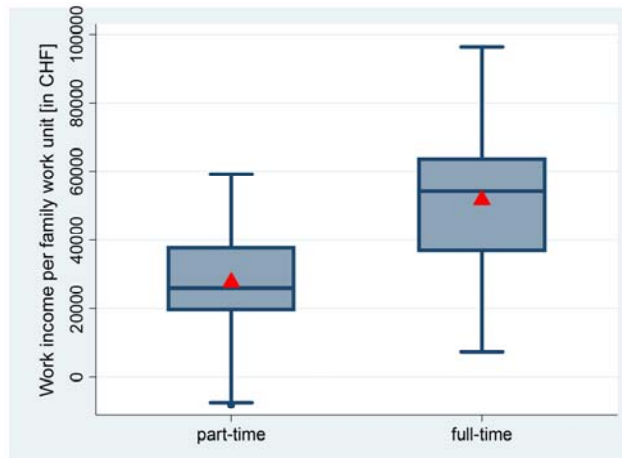

Figure 6. Effect of farm type on the work income per family work unit

3.4. Effect of production form

The boxplots of Figure 7 depict the variability of the aggregate eco-efficiency of the farms investigated for each production form (organic *versus* conventional farming). As apparent from this figure, organic farms showed a significantly higher aggregate eco-efficiency than conventional farms (p=0.06). The average aggregate eco-efficiency was 76% and 61% for the organic and conventional farms, respectively. A closer look at the environmental intensities revealed that—with the exception of the impact category land use—organic farms exhibited for all impact categories considered a significantly lower environmental intensity than conventional farms. Analyzing the environmental intensity at the input-group level, we found that the lower (p=0.09) environmental intensity regarding the demand for non-renewable energy resources was attributable to two input groups: (i) purchased animal feed and (ii) purchased animals. Two input groups accounted for the lower (p=0.06) environmental intensity regarding the global warming potential of organic farms: (i) purchased animal feed and (ii) fertilizers and nutrients. The better (p=0.02) environmental performance of organic farms in terms of eutrophication potential was found to result from their lower environmental intensity for the input groups (i) fertilizers and nutrients, (ii) purchased animal feed and (iii) purchased animals. With respect to the terrestrial ecotoxicity (p<0.001), the lower environmental intensity of organic farms could be ascribed to the input groups (i) purchased animal feed, (ii) plant protection products and (iii) purchased animals. Three input groups explained the better (p<0.001) performance of organic farms in terms of environmental intensity with respect to human toxicity: (i) energy carriers, (ii) purchased animal feed and (iii) purchased animals. Land use was the single impact category for which no significant differences in terms of environmental intensity was found between organic and conventional farming.

Compared to conventional farms, organic farms were characterized not only by a better environmental performance but also by a significantly better economic performance (p=0.01; see Figure 8). On average, the work income per family work unit was 53’712 CHF for organic farms compared to 32’676 CHF for conventional ones.

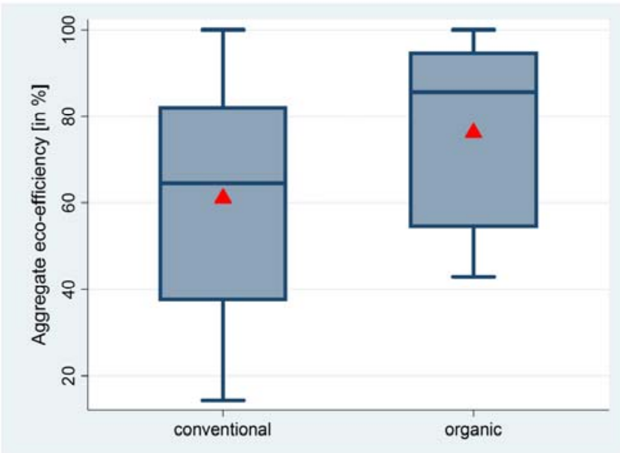

Figure 7. Effect of the production form on the aggregate eco-efficiency

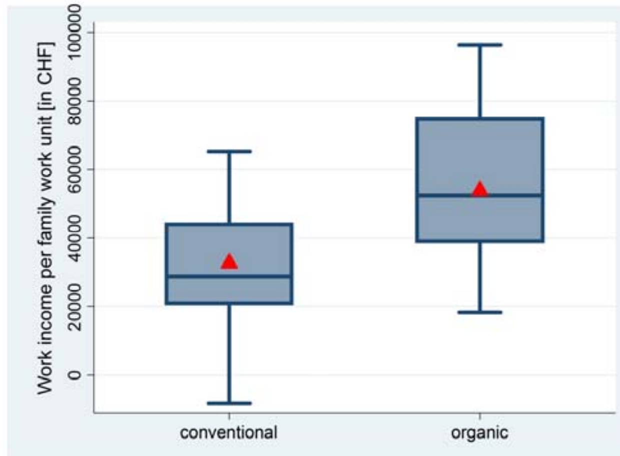

Figure 8. Effect of the production form on the work income per family work unit

3.5. Effect of agricultural education level

The effect of the agricultural education level on the aggregate eco-efficiency is depicted in Figure 9. A high agricultural education level was associated with a high aggregate eco-efficiency (p=0.009). The average aggregate eco-efficiency of farms whose managers had an agricultural education level higher than an apprenticeship was 77% compared to 57% for farms whose managers had an agricultural education level equivalent to or lower than an apprenticeship. A further analysis of the data revealed that a higher agricultural education involved a lower environmental intensity for all impact categories considered. This lower environmental intensity was not imputable to a particular input group but applied to almost all input groups relevant for the environmental impact category considered. A high agricultural education was revealed to be beneficial not only in terms of environmental performance but also in terms of economic performance (p=0.09, see Figure 10). The average work income per family work unit of a farm managed by a person with an agricultural education level higher than the apprenticeship was significantly higher than that of a farm managed by a person with an agricultural education level equivalent to or lower than the apprenticeship (44'439 CHF and 33'432 CHF, respectively).

4. Discussion

4.1. Main findings

The present work assessed the impact of selected factors on farm economic and environmental performance. Unfavorable natural production conditions were shown to strongly negatively influence both the global environmental and the economic performance of the farms investigated. The negative impact of unfavorable natural production conditions on farm eco-efficiency was not due to a specific input group but concerned all input groups. This finding highlights the systematic environmental but also economic competitive disadvantage of milk production under unfavorable natural production conditions. This finding also may question the appropriateness of milk production under such conditions. However, it should be considered here that dairy farms located in (unfavorable) mountain areas are characterized by their multifunctionality, that is, by their multiple functions going far beyond the simple food production function. The non-commodity outputs[11] that are associated with these additional functions and are by-products of the agricultural commodity outputs were not considered in the output variable used to assess eco-efficiency. This should be kept in mind when interpreting the results.

The result that farm size had a positive effect on the two considered dimensions of the sustainable performance of a farm emphasizes the substantial scale effects that exist in dairy farming regarding the use of not only economic but also environmental resources.

Compared to full-time farming, part-time farming, which was shown for Switzerland (see Jan et al. 2011; Roesch 2012) to be associated with a substantially lower economic performance, herein was also synonymous with a poorer global environmental performance. This seemed to result primarily from an inefficient use of purchased feed, of buildings and equipments and, in some cases, of fertilizers and energy carriers.

Whereas organic farming was shown in the literature to be associated with a—compared to conventional farming—higher eco-efficiency for some impact categories and with a lower one for others (see Tuomisto et al. 2012), in the present work it was associated with a higher eco-efficiency for all impact categories with the exception of land use, for which no significant differences were observed between organic and conventional farms. This higher eco-efficiency was attributable to the input groups purchased animal feed, fertilizers and nutrients and purchased animals[12], highlighting thus that this better performance resulted primarily from the feeding and fertilization strategies and practices of organic farming. This finding implies that—under the natural production conditions of the alpine area and the associated production restrictions and low forage yield potential—organic farming may be from both an environmental and an economic perspective a more appropriate technology than conventional farming for the dairy activity. Thus, a process of conversion from conventional to organic farming may be very likely to lead to economic and environmental benefits and to a substantial improvement of the sustainability of the dairy food chain in this region. This probably explains why the share of organic farms increases with the unfavorableness of the natural production conditions (e.g., in 2012, according to the Swiss Federal Statistical Office, the proportion of organic farms in the mountain zone 4 and in the plain zone was 35% and 5%, respectively).

Last but not least, agricultural education was shown to play an important role in terms of environmental and economic performance. A high agricultural education implied both high eco-efficiency and high work income per family work unit. All input groups were involved in this high eco-efficiency suggesting that better educated farm managers had better management capacities for the use of economic and environmental resources.

4.2. Limits of the study

For the interpretation and discussion of the results of the present investigation as well as their implications, attention should be paid to the following issues. Firstly, it should be noted that the investigation focused on only one of the two dimensions of the environmental performance of a farm, namely the so-called global environmental performance defined by Jan et al. (2012a) as the eco-efficiency of food production until the farm gate. The

---

[11] These non-commodity outputs, such as conservation of a mosaic rural landscape or contribution to the vitality of rural communities, are by-products of the agricultural commodity outputs.

[12] Some readers may be surprised that plant protection products are not mentioned here. This is because the present contribution focuses on farms located in the alpine area, a region in which the use of plant protection products in conventional farming is very limited and very often inexistent.

local environmental performance of a farm, which focuses on the environmental impact generation that occurs locally at the farm level and which is defined as the environmental pressure exerted by the farm on its local ecosystem, was not investigated in the present work. It is therefore necessary to remember that the findings of the present contribution regarding the factors affecting farm environmental performance apply to only the global dimension of farm environmental performance. Secondly, the sample was not selected at random due to the comprehensiveness and complexity of the data collection. This may have introduced a positive bias in the representativeness of the sample as it has to be expected that farm managers interested in environmental issues were more likely to participate in the project than those who did not feel concerned by such issues. Thirdly, an additional sample-related limitation of the investigation lies in the approach used to assess the effect of the selected factors on farm environmental and economic performance. As mentioned in section 2.6, due to the limited sample size, we had to refrain from applying multiple linear regression analysis and therefore investigated separately the effect of each factor on each performance indicator. Consequently, the effect measured for each factor is not a *ceteris paribus* one and may capture the effects of other factors correlated with the one investigated.

5. Conclusion

The present contribution provides initial evidence that the promotion of an economically viable alpine dairy farming sector as well as the enhancement of one with a high eco-efficiency are not antinomic but synergetic. By increasing farm size (i.e., through scale effects), by promoting organic farming as well as full-time farming and by raising the level of agricultural education among future farm managers, major enhancements in terms of economic and environmental performance could probably be achieved. Our work shows how valuable combined micro-level economic and environmental data are. Such data enable us to gain a better insight into the relationship between these two dimensions of sustainability. Such insight is a pre-requisite if we wish to improve sustainability. In order to gain a holistic understanding of the farm-level link between economic and environmental performance, our future studies will focus on the analysis of the link between (i) economic performance and local environmental performance and (ii) local and global environmental performance.

Analysis of inconsistencies between Product Category Rules in the same supply chain – a case study of food PCRs

ABSTRACT

According to ISO 14025, Product Category Rules (PCRs) are developed as the basis for environmental declarations. The PCRs define the requirements for the underlying life cycle assessment and the format for reporting in an Environmental Product Declaration (EPD) for a given product category. Because PCRs are developed separately by the interested stakeholders, one risk of this approach is that similar methodological aspects could be treated differently in different but related PCRs. The International EPD System has developed a network approach for food PCRs to avoid inconsistencies by 1) creating one document identifying issues common to all food PCRs; and 2) simplifying the development of new PCRs by permitting inclusion by reference of aspects treated in other PCRs. It may be appropriate to extend this network methodology also to other product groups and sectors, and to extend the co-ordination across program operators.

Keywords: Product Category Rules, Food, Environmental Product Declaration, PCRs management, ISO 14025

1. Introduction

Product Category Rules (PCR) define the requirements for the underlying life cycle assessment and the format for reporting in an environmental declaration type III for a given product category. PCR documents are developed within a program for environmental declarations type III according to ISO 14025 (ISO, 2006).

Although the details regarding the process might differ somewhat between programs, PCRs in the same program are normally drafted by the stakeholders interested in the product group. Because PCRs may have scopes covering intermediate or final products, different PCRs may include the same life cycle stages and associated methodological guidance. There is thus a risk that similar methodological aspects are treated in different ways in related PCRs. An example could be wheat that is used an ingredient for many food products such as pasta and bakery products. If the calculation rules for the wheat cultivation process are described separately in the PCR for pasta and the PCR for bakery products, some key methodological aspects shared by the two product systems may be managed in different ways.

The International EPD System is a program for type III environmental declarations with a broad scope in terms of product categories and geographical area covered. As of April 2014, there are 108 PCRs registered within the program, whereof 27 belong to the category “Food and agricultural products” (International EPD System, 2014). The PCRs within this category have been developed in a time period of several years and by different stakeholders. All PCRs fulfill the program instructions of the International EPD System but within the PCRs, in some cases, different approaches have been taken, leading up to inconsistencies. To avoid anticipated inconsistencies between related PCRs, a pilot project called the “Network of PCRs for Food” was initiated in 2013 with the scope of agricultural and food products (International EPD System, 2013b).

2. Methods

This paper identifies and analyses the methodological inconsistencies between PCRs within the International EPD System and how they have been treated in the first year of the network of PCRs for food pilot project. The method chosen is a qualitative identification of the key methodological questions and a comparison of the different guidance given in the PCRs before and after the alignment. The main LCA methodological aspects that are normally covered by PCRs include (International EPD System, 2013):

- Functional unit
- System boundary
- Allocation procedure
- Data quality requirements

– Cut-off rules
– Data collection and calculation procedures
– Impact assessment categories
– Scenario assumptions

The analysis focuses on these methodological aspects and on seven linked PCRs available within the food and agricultural products category of the International EPD System; see Table 1. PCRs and related guidance documents from other programs and initiatives were not included in the scope of the analysis.

Table 1. Food and agricultural PCRs in the International EPD System included in the analysis.

Name [a]	PCR registration number	Version
Arable crops	2013:05	1.01
Raw milk	2013:16	1.01
Processed liquid milk and cream	2013:17	1.01
Yoghurt, butter and cheese	2013:18	1.01
Meat of mammals	2012:11	2.0
Grain mill products	2013:04	1.02
Uncooked pasta	2010:01	2.0

The identified connections between the different PCRs are illustrated in Figure 1. There are three levels of the PCRs, with the ones earlier in the supply chain function as the upstream system for the following two levels. The PCR for arable crops (including wheat) is part of the shared upstream supply chain for all the other analyzed PCRs, including milk, meat and grain mill products. The PCR for raw milk relates to the animal husbandry, which is the same technical system as is described in the PCR meat of mammals. From an LCA perspective, beef and raw milk are two co-products from the same process, which results in an allocation problem to be handled in the PCR. The different dairy products are covered by two different PCRs, which share a similar allocation problem between different co-products from the dairy plant.

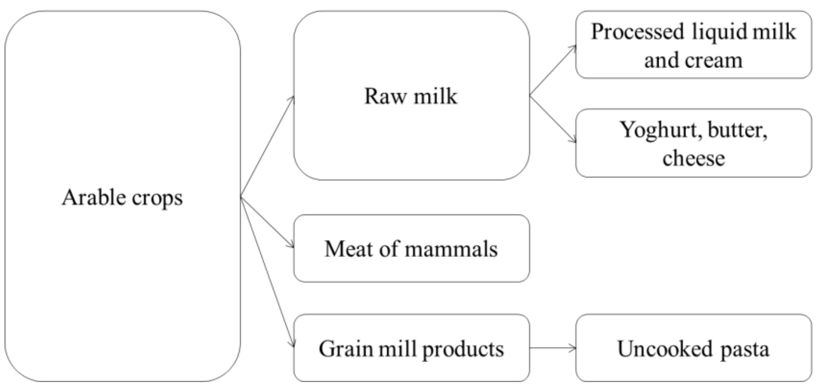

Figure 1. Identified supply-chain connections between the analyzed PCRs.

3. Results

3.1. Identified inconsistencies

The qualitative assessment identified that potential methodological aspects were those normally specified in a PCR: system boundaries, data quality requirements, allocation procedures and allocation factors. Aspects such as the choice of systems approach (e.g. attributional or consequential LCA) and environmental impact categories were less relevant in the analyzed PCRs because the basic requirements for these aspects are set up in the General Program Instructions and thus shared between all PCRs (International EPD System, 2013a). The main methodological aspects with potential inconsistencies that could alter the results among the analyzed PCRs were identified as:

– factors used for the estimation of emissions from fertilizer use (EF),
– allocation between agricultural co-products (AG),
– allocation between milk and meat (MM),

– allocation among co-products at the mill (MI),
– allocation among co-products at dairy plant (DP).

Table 2 lists all the PCRs in which the analyzed factors were treated. Some of the aspects (EF and AG), were treated in all the analyzed PCRs, while other were only treated in some of the analyzed PCRs.

Table 2. Main methodological aspects and PCRs where they were treated – before the network of PCRs.

	Arable crops	**Raw milk**	**Processed liquid milk and cream**	**Yoghurt, butter, cheese**	**Meat of mammals**	**Grain mill products**	**Uncooked pasta**
EF	X	X	X	X	X	X	X
AG	X	X	X	X	X	X	X
MM	-	X	X	X	X	-	-
MI	-	-	-	-	-	X	X
DP	-	-	X	X	-	-	-

These methodological aspects may greatly affect the environmental impact of a product. As an example the results for climate change (calculated with Global Warming Potential, 100 years) of wheat grain and straw as a function of different methods of allocation was calculated (Figure 2). While the results may vary greatly between different cases and methodological aspects, the example shows that the results have the potential to vary significantly (here: -45% for mass allocation compared to the case where straw is considered as waste).

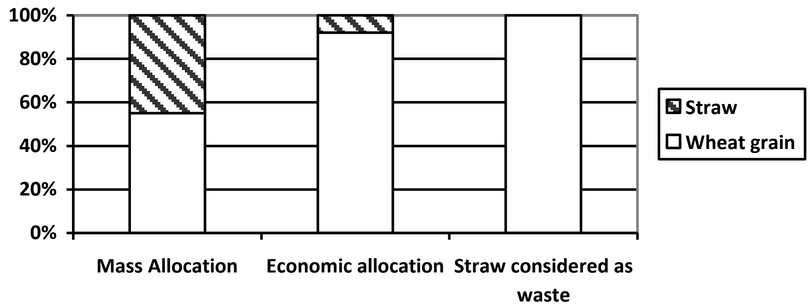

Figure 2. Normalized example results for the climate change indicator results (calculated with GWP, 100 years) of wheat grain and straw as a function of different methods of allocation. The result of straw considered as waste has been set to 100%.

An EPD in the International EPD System uses as a default life cycle inventory (LCI) indicators for resources use and four environmental impact categories (International EPD System, 2013a). Table 3 shows which methodological aspects affect which indicator results and environmental impact categories.

Table 3. Main methodological aspects and potentially affected indicator results and environmental impact categories.

Factor	**Resource use (LCI)**	**Climate change**	**Acidification**	**Eutrophication**	**Photochemical oxidant formation**
EF	-	X	X	X	-
AG	X	X	X	X	X
MM	X	X	X	X	X
MI	X	X	X	X	X
DP	X	X	X	X	X

Four of the five analyzed factors (AG, MM, MI and DP) have an influence of all the indicator results declared in an EPD, since different methods of allocation lead to different life cycle inventories and resulting environmental burdens attributed to the product object of the EPD. The other factor, EF, influences mainly the impact categories Climate change, Eutrophication and Acidification.

To avoid inconsistencies within the network it was decided to treat each of the methodological aspects in a single PCR and make reference to that in the other PCR documents (see Table 4). An example of this approach is that in the PCRs for arable crops rules for EF and AG are given. In the other PCRs in the upstream phase, the guidance on these methodological aspects is replaced by references to the PCR for arable crops.

Table 4. Main methodological aspects and in which PCRs they were treated – after the network of PCRs.

Factor	Arable crops	Raw milk	Processed liquid milk and cream	Yoghurt, butter, cheese	Meat of mammals	Grain mill products	Uncooked pasta
EF	X	-	-	-	-	-	-
AG	X	-	-	-	-	-	-
MM	-	X	-	-	X	-	-
MI	-	-	-	-	-	X	-
DP	-	-	X	X	-	-	-

In some cases, such as those of MM and DP, it was not possible to treat an aspect in only one PCR document, because some the PCRs involved (in this case Processed liquid milk and cream and Yoghurt, butter and cheese) are “parallel”, that means that they are at the same level of the supply chain and describe two different co-products from the same process. In such cases the coordination of the network ensured that these aspects are treated in the same way in both PCRs. The motivation to keep two different PCRs is that there is still a need for separate guidance for aspects such as the functional unit of the two different products.

3.2. Alignment of inconsistencies

Another issue was how to treat the aspects, since different approaches were possible and were already used in some PCRs. In Table 5 the analyzed and the chosen approaches are reported.

Table 5. Approaches used in the PCRs before the network, and the chosen approaches after the implementation of the network.

Factor	Approaches used before the network of PCRs	Chosen approach
EF	1. Data from literature (global) 2. Data from literature (regional) 3. Primary data	Data from literature (global) in absence of primary data.
AG	1. Economic allocation 2. Physical allocation (mass) 3. By-products considered as waste	Economic allocation
MM	1. Economic allocation, 2. Physical allocation (mass)	Economic allocation
MI	1. Economic allocation, 2. Physical allocation (mass) 3. By-products considered as waste	By-products considered as waste
DP	1. Economic allocation 2. Physical allocation (wet mass, dry mass, mass of protein and fat) 3. By-products considered as waste	Physical allocation (mass of protein and fat)

The approaches to be used were chosen after an open consultation with the interested stakeholders when each PCR was updated. The choice of the approaches was made according to the main literature and to the experience of the involved experts.

4. Discussion

The International EPD System’s food PCRs network is the first known example of increased coordination of PCRs in an ISO 14025 program. The results of the present study demonstrate that without coordination there would be many inconsistencies, which would make an objective evaluation of different products environmental performances impossible.

The problem of LCI modelling inconsistencies is not only relevant within the same program. Different ISO 14025 programs have chosen different methodological bases and product group classification systems that may or may not be compatible. There are also many initiatives to develop PCRs in programs similar to, but not based on, ISO 14025, such as the European Commission Product Environmental Footprint.

To put a similar coordination in place among different ISO 14025 programs is a big challenge but it certainly should be a target for which to aim.

5. Conclusion

The International EPD System's Network of PCRs has two main positive effects: avoiding methodological inconsistencies between PCR documents (by treating issues common to different PCRs in only one PCR document) and simplifying the development of new PCRs (by allowing incorporation by reference to the relevant PCR document). These benefits also translate to positive effects in the development of environmental declarations: the comparability is strengthened and the time needed to develop the first declaration in a product category is reduced.

For these reasons it may be appropriate to extend the methodology of the network to other product groups and sectors, for example construction products, wood and paper products or textile products, and to extend the co-ordination across ISO 14025 program operators and incorporated into initiatives independent from ISO 14025 such as the European Commission Product Environmental Footprint (EC, 2013). The insights gained on the need for alignment of PCRs in the same supply chain could also be relevant for guidance documents and international standards related to PCRs, such as the Guidance for Product Category Rule Development (Ingwersen and Subramanian, 2013).

ONE TWO WE – Life cycle management in canteens together with suppliers, customers and guests

Niels Jungbluth*, Regula Keller, Alex König, Geneviève Doublet

ESU-services Ltd., Zurich;

ABSTRACT

The environmental impacts of all food purchases of the Swiss canteen operator SV Group were analysed within an LCA study. Improvement potentials were identified, which include measures in the canteen operation (e.g. reduction of food waste), measures in the supply chain (e.g. a reduction of vegetables grown in heated greenhouses) and dietary measures such as a reduction of the average amount of meat per meal. The results have been used to initiate the programme "ONE TWO WE" together with WWF Switzerland. It assists the customers (companies who commission the SV Group with the operation of canteens in their premises) to reach improved levels of environmental performance e.g. a 20% cut on GHG emissions in the supply chain.

Keywords: canteen, diet, gastronomy, life cycle management, supply chain, organisational environmental footprint

1. Introduction

Nutrition causes about 12% of total energy demand and 18% of greenhouse gas emissions due to Swiss consumption patterns (Figure 1). There are many other environmental impacts that should be accounted for in an LCA. Here we use the Swiss ecological scarcity method 2006 which weights different environmental indicators according to the political targets in Switzerland (Frischknecht et al. 2009). Environmental impacts are quantified as eco-points (UBP for Umweltbelastungspunkte). If all types of environmental impacts are included in the analysis with this method this share rises to about 30% (Jungbluth et al. 2011; Jungbluth et al. 2013). This is due to specific environmental impacts caused by agricultural practice such as pesticide use, heavy metal emissions from fertilizers, land and water use as well as problems caused by acidification and nutrification.

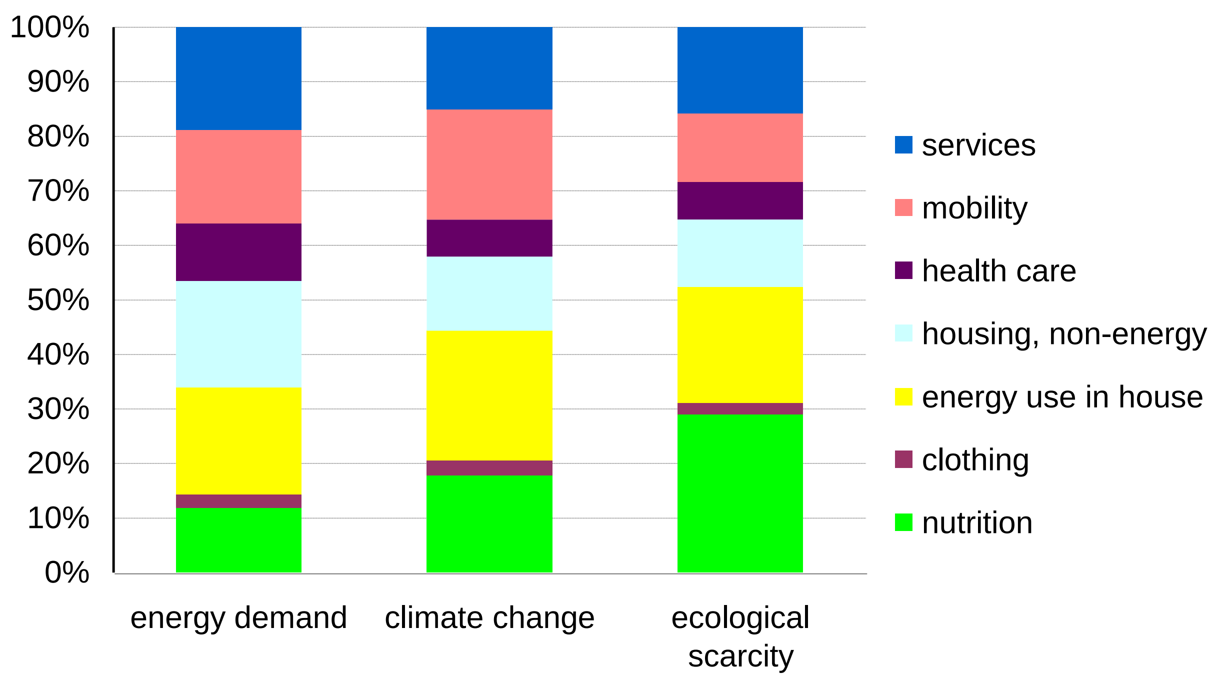

Figure 1. Importance of nutrition in total consumption (Jungbluth et al. 2011; Jungbluth et al. 2013)

The main part of the environmental impact arises from the agricultural production of meat and fish (Figure 2).

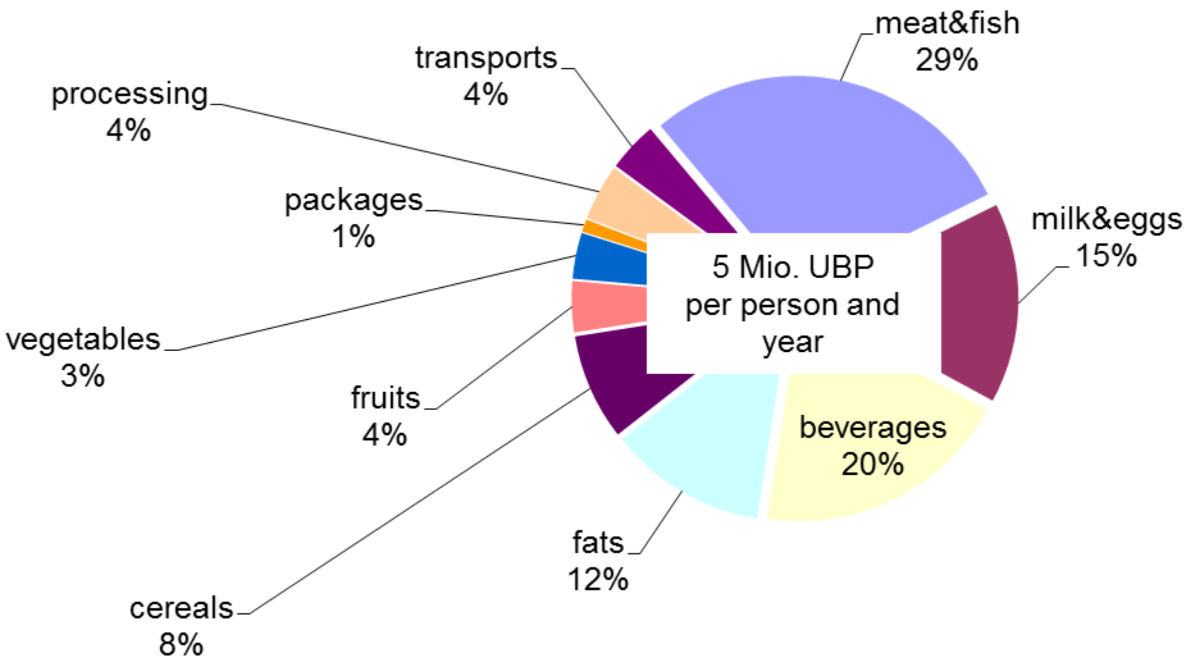

Figure 2. Importance of product groups in total impacts of nutrition. The total impact is 5 million eco-points (UBP – Umweltbelastungspunkte) per year

Environmental awareness is increasing in the gastronomy sector. The Swiss canteen operator SV Group commissioned ESU-services Ltd. to make an LCA of its full food and non-food purchases in order to identify improvement potentials. The LCA results are the basis of the program "ONE TWO WE", which aims to assist the customers of SV Group with the reduction of their GHG emissions by 20 %. The customers are companies that commission the SV Group with the operation of their canteen in their premises. The program is elaborated in close collaboration with WWF Switzerland and ewz Zürich (public electricity supply in the Swiss city of Zurich).

2. Methods

The environmental impacts of all food purchases in 240 canteens of the SV Group were analysed within an LCA study for the operation in the year 2011. In this year 19.2 million meals were prepared and sold. About 820 grams of food items, 2.2 dl (deciliter) of beverages and 40 grams of other materials such as serviettes were used per meal (Table 1).

Table 1. Composition of the average meal in canteens of the SV Group

	Weight in average meal (grams per meal)
meat/poultry	108
fresh vegetables	21
bread	310
dairy products	108
eggs	135
fish	5
sweets	137
convenience	32
beverages	225
non-food	42

The SV group provided a detailed list of their food purchases including weight and costs of the purchased items. In the next step, LCI data for 160 different food items available within the ESU food database (Jungbluth et al. 2014) were linked to the purchased amounts. Therefore also rough assumptions on packaging and transportation have been made for the different food items. This followed the idea of a modular LCA as developed in a previous research work (Jungbluth 2000).

The objectives of this project were twofold. In a first step, the most important ingredients were identified and the impacts of the food supply were compared with the direct global warming impacts of the canteen operation. Impacts of canteen operation (e.g. electricity and water use) were evaluated in previous years within the environmental reporting of the company (SV (Schweiz) AG 2010, 2008). The total impacts have been divided by the number of meals sold as a functional unit. Food waste was already monitored as part of this environmental reporting. Impacts due to its disposal are included in the assessment. The production of the wasted food is included in the figures on total food supply.

In the second stage of the project, improvement potentials were identified in the supply chain and the operation of the canteen. The results in this study are analysed across a representative range of impact categories with the ecological scarcity method (Frischknecht et al. 2009) and with Global Warming Potential (GWP) (Solomon et al. 2007).

3. Results

3.1. Global warming potential of average meal

The food purchases of the canteen operator were summarized for the categories of meat, fish, dairy products, eggs, vegetables, fruits, bread, sweets, beverages and convenience products. Within the group of convenience products a range of different types of food can be found. The contribution of each life cycle stage to the GWP of all food purchases is shown in Figure 3. The GWP is expressed per meal, which means that the GWP of all food purchases were divided by the total amount of meals delivered per year. The life cycle includes the production, the processing, the packaging, the transport of food items to the canteen and the operation (meal preparation at the canteen).

An average meal served in a canteen operated by the SV group has an average GWP of 4.1 kg CO2-eq. The agricultural production step is responsible for 60% of the emissions, the processing 8%, the packaging 2%, the transport 5% and the operation of the canteens (cooling, cooking, etc.) 25%. The overall GWP of the food supply is dominated by the meat and poultry products (35%), the dairy products (15%), the fresh vegetables (14%) and convenience products (14%).

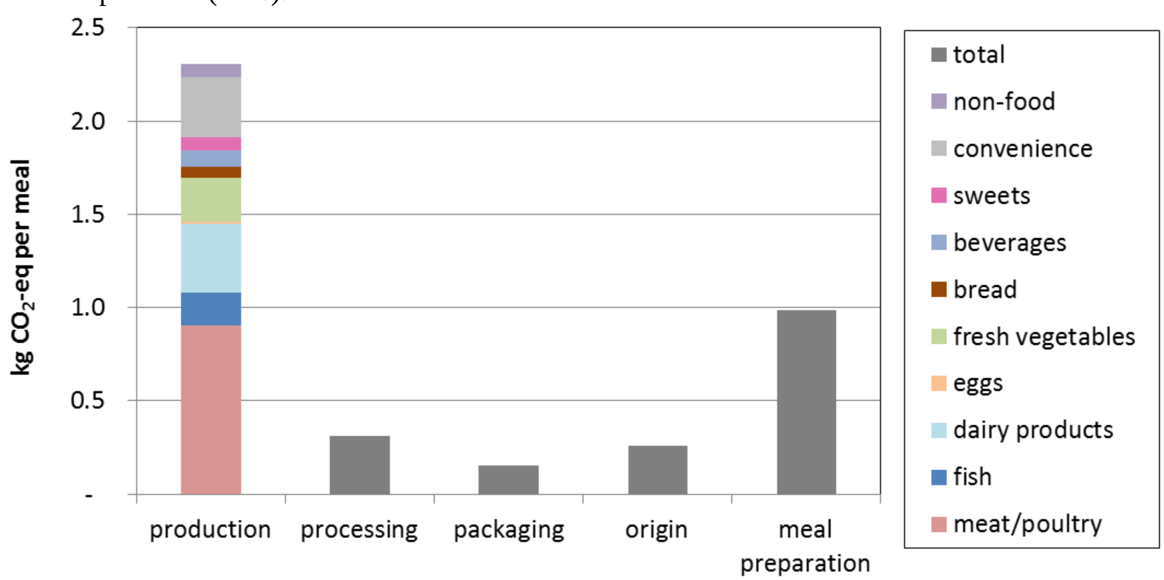

Figure 3. Global warming potential per meal of food purchases and canteen operation

3.2. Environmental impacts of average meal

The importance of the production of food products gets even more pronounced when total environmental impacts are evaluated according to the ecological scarcity method 2006 (Frischknecht et al. 2009). With this about 71% of total impacts are due to production of food products. The impacts per canteen meal are about 9'300 eco-points.

The environmental impacts of this meal can be compared with the average impacts due to nutrition in Switzerland. About 15'300 eco-points are caused due to the purchase of food products, but not including the consumption of food in canteens and restaurants nor including the delivery of food products to the home (Jungbluth et al. 2012). Thus, the canteen meal has quite some relevance which can also be partly explained by the higher share of meat (37%) than in the average daily consumption basket shown in Figure 4.

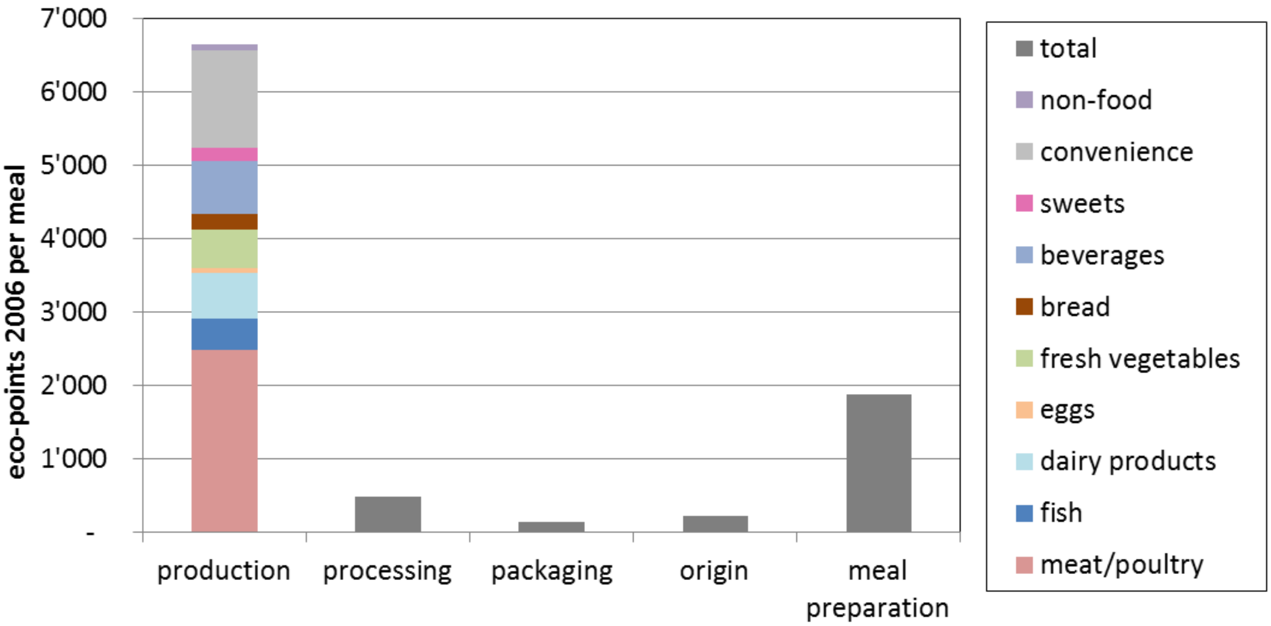

Figure 4. Eco-points according to ecological scarcity 2006 of food purchases per meal

The share of different types of environmental impacts for the different food categories is evaluated in Figure 5. The use of plant protection products, eutrophication, human health impacts due to ammonia emissions are important environmental aspects while evaluating the total food purchases of the canteen operator.

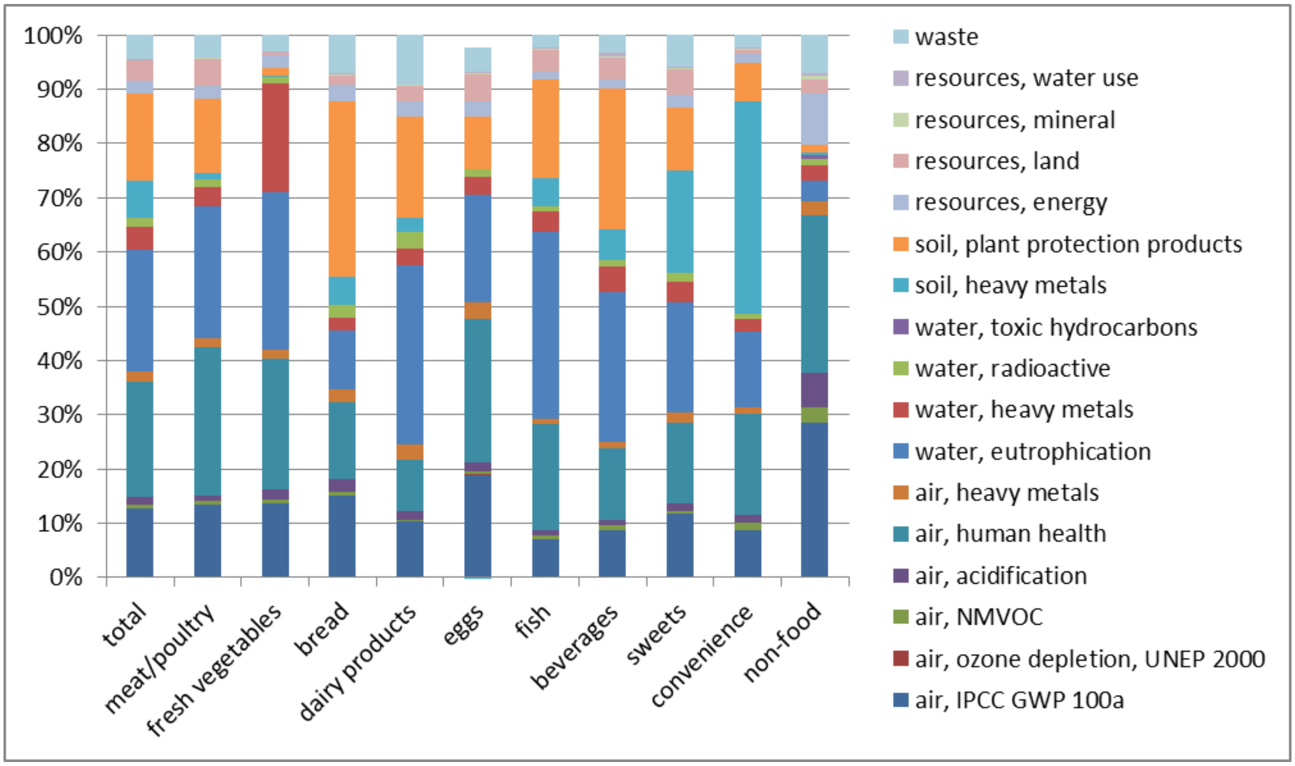

Figure 5. Share of category indicators according to ecological scarcity 2006 per meal of food purchases

3.3. Seasonal calendar to assist supply chain management

Based on the detailed assessment of the total environmental impacts, several improvement options for the supply chain have been discussed with the canteen operator. The detailed analysis of vegetable and fruit purchases has shown that an important part of impacts is due to the heating of greenhouse with fossil fuels when products are bought outside the Swiss season. Also transports by airplane can than play an important role. Therefore one option is the optimized purchase of fruits and vegetables.

The environmental impacts of vegetable and fruit purchases depend on the production period, the origin and the means of transport. For a given fruit or vegetable, all monthly supply routes were assessed in a seasonal calendar in order to provide better guidance for purchases. Two examples are illustrated in Figure 6.

For example, fresh broccoli is supplied from Switzerland, Spain and Italy. The fresh broccoli from Switzerland is only supplied from May to October and its GWP is 0.6 kg CO2-eq per kg. From January to May and from November to December, fresh broccoli is transported in truck from Spain and Italy. According to the supplier of the canteens, the fresh broccoli is produced in fossil heated greenhouses and its GWP is 7.2 kg CO2-eq per kg in January, February and December. The production of fresh broccoli that is deep-frozen in order to maintain a supply during the off-season generates a GWP of about 0.7 kg CO2-eq per kg. This increases with the time of storage after harvesting and is thus highest in April. Deep-frozen vegetables are an interesting alternative to fresh vegetables cultivated in heated greenhouses. The information concerning heating does not necessarily match with information found in literature about this type of vegetables (e.g. Milà i Canals et al. 2008).

Another relevant example is the supply of green asparagus. From July to February, green asparagus cultivated in Peru and transported by air cause a GWP of 12.8 kg CO2-eq per kg. Green asparagus cultivated in Switzerland or Spain and supplied from April to June have an average GWP of 1.6 kg CO2-eq per kg.

The cooperation with the wholesale dealer for vegetables shows that so far they often do not know in detail about the origin and way of production. A system to better monitor the important factors such as type and amount of heating for greenhouses for a given vegetable in a given months shall be build up in future.

kg CO2-eq per kg good		Jan	Feb	March	April	May	June	July	Aug	Sept	Oct	Nov	Dec

4. Discussion and follow up

The programme "ONE TWO WE" was elaborated based on the results of the LCA and further collaborations. It consists of a set of improvement options in five fields namely the logistic, the canteen operation, the food supply and the food range (see Figure 7). Therefore targets on certain key performance indicators have been set.

The environmental performance of the logistic shall be improved by reducing the share of air-freight. The optimisation at the canteen includes for example the amount of food waste and energy efficiency (cooling, lighting, cooking and ventilation). The mitigation of the environmental impacts of the food supply relies on the reduction of fruit and vegetables cultivated in heated greenhouses based on a seasonable table which calculated the carbon footprint per month of different products. Another important measure is the reduction of the average quantity of meat per meal by offering attractive vegetarian meals and meals with a lower amount of meat per serving. Therefore an education program has been initiated in order to teach the cooks attractive ideas for vegetarian meals that can be prepared for canteens.

A good communication with the guest and customers should explain the background of this programme while at the same time allowing the guest to choose from attractive recipes. The program "ONE TWO WE" aims for a reduction of 20% on greenhouse gas emissions in canteens which follow all suggestions for improvements. The achieved reductions are documented transparently. Therefore a simplified Excel tool has been elaborated which allows a simplified calculation of greenhouse gas emissions per meal passed on some key environmental performance indicators to be entered by the canteen operator.

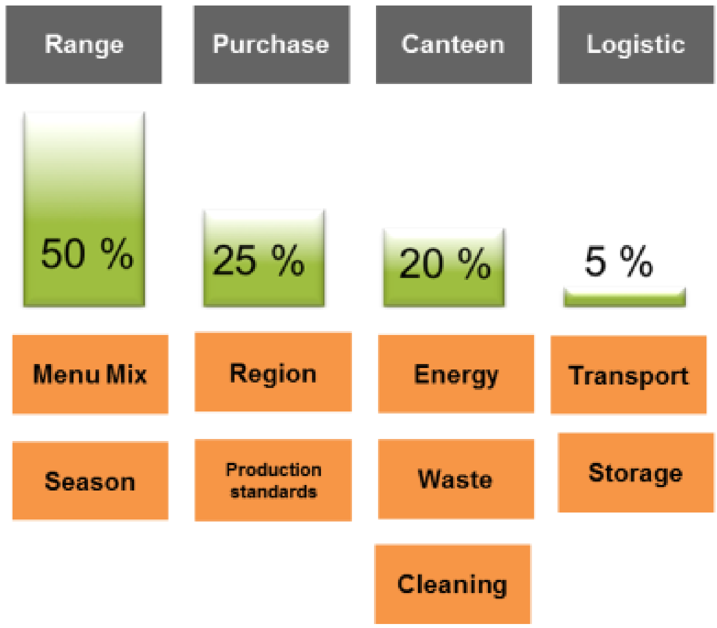

Figure 7: The program “ONE TWO WE” is structured in different steps

5. Conclusions

The programme “ONE TWO WE” started successfully with many customers positively convinced by the proposed changes in the provision of canteen meals. The program was launched in October 2012 in Zürich and is being implemented in 70 restaurants until the end of 2013. In 2013 the initiative " ONE TWO WE" has been awarded with the Zurich Climate Prize 2013. The future will show whether also the guest in the canteens support the changes.

ABSTRACT

Demand for sustainable meat with balance between environmental, economic and social (EES) aspects has increased recently. Brazil has promoted production of a wider variety of beef products and European Union is one of the target markets for Brazilian organic beef. This study aims to evaluate the EES performance of conventional and organic beef production. Accordingly, global warming, land occupation, energy consumption, operating profit and animal welfare were evaluated for different systems. Relevant indicators were measured using different methods, such as life cycle assessment, operating profit analysis, price volatility analysis, and qualitative scoring. Results confirmed a higher impact of organic beef production on global warming and land use due to animals' longer grazing period. Animal welfare, however, scored slightly higher for the organic beef production systems. Organic beef showed a slightly higher profitability, but its economic sustainability is constrained by technical barriers and higher transaction costs.

Keywords: Organic, conventional, mixed crop-beef, life cycle assessment

1. Introduction

The last decade has witnessed an increasing demand for meat that has been produced in a sustainable way, i.e., meat that provides a better balance between environmental, economic, and social (EES) aspects. The sustainability needs improving agricultural production systems which requires the promotion of farm practices that provide high-quality, affordable food in sufficient quantity while ensuring appropriate economic returns and minimizing negative environmental effects (Pelletier et al. 2008). Some countries, such as Brazil, have promoted the production of a wider variety of beef products to give consumers more choices. Essentially Brazil is producing two types of beef, i.e., organic and conventional. Conventional beef is produced either in specialized beef farm or mixed[1] crop-beef farm. Mixed crop-beef farming is an agricultural system in which a farmer conducts crops and livestock farming practice together. Mixed crop-beef developers can greatly improve the productivity of a beef system by improving carrying capacity and providing higher quality pasture.Organic beef is a type of farming in which it is not allowed to use synthetic inputs such as medicines, fertilizers, and genetically modified organisms (Chander et al. 2011). The aim of beef organic farming is to establish a method for avoiding environmental problems and promoting the quality and safety of beef (Nardone et al. 2004). Although currently mixed crop-beef and organic system cover a small share of the total beef production in Brazil, experts in beef production perceive these two systems as potential for future beef production in Brazil. However, there is limited knowledge regarding sustainability performance of the different beef production systems. A number of studies evaluated environmental aspects of beef production (Beauchemin et al. 2010; Casey and Holden 2006; Cederberg and Stadig 2003; Dick et al. 2014; Nguyen et al. 2010; Ogino et al. 2007; Pelletier et al. 2010; Röös et al. 2013; Roy et al. 2012; Stewart et al. 2009). Nevertheless, none of these studies focused on the three dimensions of sustainability simultaneously. Hence, an assessment of the EES performance of conventional and organic beef systems in Brazil should give insight into the sustainability consequences of these two production systems. Therefore, the objective of this study is to evaluate the EES performance of the conventional (based on specialized and mixed crop-beef farming) and organic beef production systems in Brazil.

2. Methods

2.1. Description of the systems

EES issues relevant for soybean production systems were listed in a study that performed by Pashaei Kamali et al. (2014). We limited the evaluation to some key EES issues for beef production due to data restriction,

[1] In this study mixed farm refers to On-farm mixing which enables the recycling of resources generated on a single farm.

methodological feasibility, and geographical relevancy of issues. Four EES issues were selected: Global warming, land occupation, primary energy use, profitability and animal welfare. Data for the conventional production systems were derived from Embrapa[2] cooperative data base which is aggregated farm data for two biomes in Brazil (Cerrado and Pampa) and represent average contemporary Brazilian conditions in these biomes. Comparable, broadly representative data were not available for mixed crop-beef and organic system in Brazil. Hypothetical mixed crop-beef and organic models were therefore designed to capable comparability with the conventional systems while reflecting key similarities and differences from conventional production technologies. The scenario model for the mixed crop-beef and organic beef were defined based on Brazilian expert opinion and broad trends identified through a literature review of comparative inputs in conventional (specialized and mixed crop-beef) and organic beef production systems. The simulated production unit used in this study for all systems consisted of a herd starting with originally 608 cows, 36 bulls.

2.1.1. Specialized beef system

The normal production system in Brazil is to produce animals under pasture condition. A small amount of animals (6.7% of slaughtered animals), in 2008 were fed in feedlots for a short period (Ferraz and Felício 2010; Somwaru and Valdes 2004). Therefore, in this study EES performance were calculated on a whole-herd basis in one year for grass-finishing systems, where the animals are able to continuously graze on the natural pasture throughout the year with little or no supplementation. Housing is not utilized in Brazilian beef production system, hence all manure is assumed to be deposited directly to pasture. The description of specialized beef system was based on representative beef production system in two biomes (Cerrado and Pampa). Main characteristics of specialized beef system are presented in (Table 1).

2.1.2. Scenario 1: Mixed crop-beef system

In the mixed crop-beef systems, livestock and crops are produced within a coordinated framework. In this system cattle graze in pasture-crop land, thus contributing to the relatively short beef production period. Crop–livestock systems that are spatially and temporally mixed can occur through various combinations of the following: (i) rotations of grain crops with perennial pastures; (ii) short rotations of grain crops with annual or short-season pastures; and (iii) utilization of grain crop residues for livestock grazing (Sulc and Tracy 2007). The mixed crop-beef model in this study was the third one. The crop was considered to be sold and assumed to be leguminous crops which increase the nitrogen of the soil and helps pasture improvement as well as reduce farm costs. The sold legumes were not included in this analysis, but the quantity of resources used for producing the crops were corrected in the computations. The herd evolution was performed using a method similar to that in the specialized beef system; with a starting point of same number of cattle. Main assumptions of mixed crop-beef system are presented in Table 1.

2.1.3. Scenario 2: Organic beef system

Organic animal husbandry is defined as a system of livestock production that promotes the use of organic and biodegradable inputs from the ecosystem in terms of animal nutrition, animal health, animal housing and breeding. It deliberately avoids the use of synthetic inputs such as drugs, feed additives and genetically engineered breeding inputs. In general, organic beef in Brazil comes from cattle raised in pastures for the majority of their lives. Unlike traditional or conventional systems of production, organic production systems are governed by a set of standards that must be strictly followed by producers. Main assumption and characteristics of organic system was presented in Table 1. There seem to be no fundamental differences between the specialized and organic cattle nutrition in Brazil since both of them are pasture base.

2.2. Environmental performance

2.2.1. Global warming

The environmental impact of beef production systems was evaluated by life cycle assessment (LCA). LCA is a method that evaluates the environmental impacts along the entire life cycle of a product (Guinée 2002). LCA relates the environmental impacts of the defined production system to the functional unit (FU) (Guinée et al., 2002), which is the main product of the analyzed system in quantitative terms, and defined here as one kilogram of live weight. The system boundary is cradle-to-farm gate (Figure 1). The animal population of systems was estimated from the simulation of herd evolution as recommended by (IPCC et al. 2006). The LCA began when the initial animals were weaned, continued through the meat production cycles, and ended when the initial cows and bulls were fully replaced (Dick et al. 2014). To estimate greenhouse gases (GHGs) in beef production in different systems, the following GHGs sources were included: (1) on-farm methane (CH_4) emissions from cattle and manure, (2) on-farm nitrous oxide (N_2O) emissions from manure and soils, (3) off-farm N_2O emissions from Nitrogen (N) leaching, run-off and volatilization (indirect N_2O emissions), (4) carbon dioxide (CO_2) emissions from on-Farm energy use (e.g., fuel and electricity). Animal housing is not common in Brazilian cattle system, so the energy use related to housing was not considered. Emission related to production of medicines and vaccines were excluded in this study due to lack of data.

To assess the impact of a production system on global warming (GW), we quantified emissions of CO_2, CH_4 and N_2O. Emission of CO_2, CH4, and N_2O were summed based on their equivalence factors in terms of CO_2-equivalents (100-year time horizon): 1 for CO_2, 25 for CH_4, and 298 for N_2O (IPCC et al. 2006). Emissions were subsequently summed based on their equivalence factor in terms of CO_2. For this study, impacts were calculated on a whole-herd basis for each class of cattle separately and per kg of live weight (LW) produced in each system. For the cow–calf system and grass-finishing systems modelled, housing is not utilized hence all manure is assumed to be deposited directly to pasture.

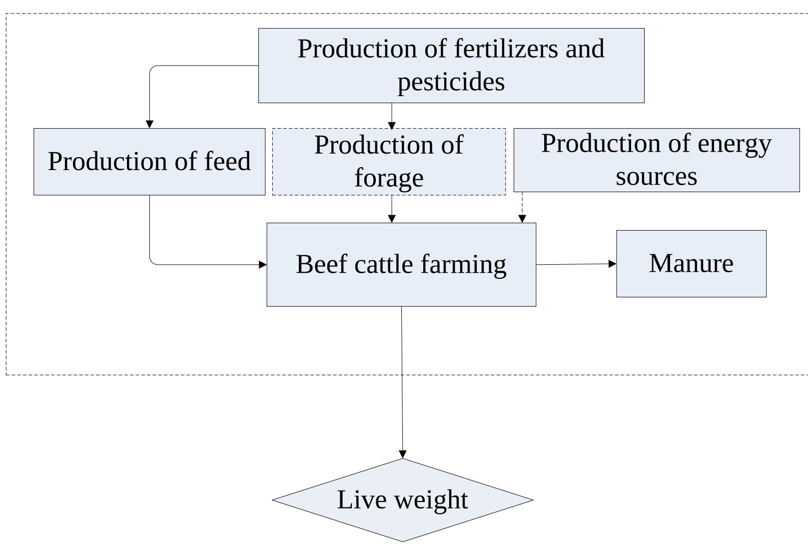

Figure 1: System boundary

Tier II method were applied for calculating enteric methane emissions due to the sensitivity of emissions to diet composition and the relative importance of CH_4 emissions to total GHG emissions in beef production (Pelletier et al. 2010). The enteric methane fermentation was quantified based on gross energy intake (GEI) of the cattle, which was calculated based on animal requirements and feed energy values. Daily net energy requirements for cattle in each stage of production were estimated from energy expenditures for maintenance, activity, growth, pregnancy, lactation and work as appropriate. The gross energy (GE) intake required to meet energy requirements was then estimated taking into account the energy density of the diet (Dick et al. 2014). Enteric CH4 emission was calculated from gross energy intake using the CH4 conversion factors (Ym) for each diet. Methane emissions from manure management were calculated following IPCC (2006) Tiers I. Tier I method was applied for manure management given the trivial methane emissions associated with solid manure management, which is common to all systems modelled (Pelletier et al. 2010). Nitrogen excretion estimates were used to calculate direct N_2O emission, ammonia and N_2O emissions from manure management and indirect N_2O emissions from nitrate leaching following (IPCC et al. 2006) emission factors.

The physical occupation of land areas was measured as the area (m^2. yr^{-1}) used for production of one kg of beef during one year. In calculations related to land occupation it was considered. For this study, we considered land for animal grazing (pasture). Primary energy use for producing beef was estimated based on total energy consumption in each phase. The energy required to produce beef included the energy used to produce farm inputs including transports (i.e., seed, fertilizers and agrochemicals) and energy use for field operation (fuel and electricity to operate agricultural field equipment). The energy required for buildings and agricultural machinery was ignored due to the lack of data and its small contribution to the total emissions (Pradhan et al. 2008). The primary energy use was calculated as the mass (kg) of material multiplied by its energy (MJ/kg).

2.2.2. Economic performance

To explore economic performance, profitability was evaluated. Operating profit was selected as an indicator for profitability, and was quantified as total revenue minus operating costs minus depreciation (Hillier et al. 2010). Operating costs are costs related to vaccination, medicines such as fertilizers, antibiotics, ear tags, fuel, electricity, repair, maintenance, operating interest, insurance, hired labor and transportation. Operating profit was quantified by revenue minus operating cost minus depreciation. Total operating costs is an indicator of the relative success of operations in terms of their ability to meet short-term financial obligations (McBride and Greene 2009).

2.2.3. Social performance

Animal Welfare focuses on beef cattle production including on-farm management of beef cattle. Animal welfare was evaluated based on main principles of welfare quality (assessment protocol for cattle). Four main principles are identified by this protocol: (P_1) good feeding, (P_2) good housing, (P_3) good health, and (P_4) appropriate behavior. The last one is out of the scope of this study due to lack of data. Regarding principle (1), (2), and (3), a number of welfare criteria were defined based on the aforementioned protocol for farm, transportation, and slaughtering. We defined eight welfare criteria for the farm level: (C_1) absence of prolonged hunger, (C_2) absence of prolonged thirst, (C_3) comfort around resting, (C_4) thermal comfort, (C_5) ease of movement, (C_6) absence of injuries, (C_7) absence of disease, and (C_8) absence of pain induced by management procedures (Welfare Quality 2009). The survey was carried out from April 2013 to January 2014 in Brazil. An invitation to complete an online questionnaire was distributed by email to the personal networks of SALSA[3] members. The questions were structured as closed-end questions and referred to eight welfare criteria for beef cattle farms. Respondents were asked to assign importance to each issue, using a five-point Likert scale, where 1 represented the "worst" or the poorest situation, 2 represented "worse" situation 3 represented "neutral" situation (neither bad nor good), 4 represented "good" situation and 5 represented the "best" situation (no more improvement is needed). Finally, an overall performance score is computed as the average over all indicators scores.

3. Results and discussion

Results from previous beef production studies showed large variability in terms of sustainability performance. The methods applied in these studies (e.g., system definition and characterization factors) were

[3] Knowledge-based Sustainable vAlue-added food chains: innovative tooLs for monitoring ethical, environmental and Socio-economic impActs and implementing EU-Latin America shared strategies.

different, which likely contributed to the variability in the results. However, the results of environmental evaluation of beef production obtained in this study fall within the range of values from previous studies. Total emission was low for specialized and mixed crop beef production compared to the organic and specialized beef production (Table 2). This conclusion is consistent with previous research, which has shown that higher quality diets and increased growth rates, reduce cattle CH_4 and manure N2O emissions, both of which are key contributors to life cycle emissions (Dick et al. 2014). Short days at grass and high productivity of the mixed crop-beef system are the main reasons for low emission. In the mixed crop beef production, crop residues (fibrous by-products) resulting from the cultivation of cereals and oil plants were the major source of nutrients for beef cattle and caused higher yields and better quality of the beef. The difference between the different beef production is due to the lower quality of the forage consumed by the animals in the specialized and organic compared with the mixed crop-beef and is based on the differences in dry matter (DM) intake/animal/day, the Ym, the digestibility, and the pasture use efficiency related to the time required to produce 1 kg live weight (Dick et al. 2014; Pelletier et al. 2010). Legumes in mixed crop-beef farms act as cover crops and green manures preventing soil degradation (Dick et al. 2014). Another benefit for incorporating legumes crops into pasture is the significant amount of available N added to the farm through dinitrogen fixation (Sulc and Tracy 2007).

Beef production in Brazil does not differ dramatically between organic and conventional systems. A few differences between these two systems were distinguished, for instance using antibiotics and medicines in conventional beef system which is not allowed in organic system. In this study organic beef had the highest GHGs emission since in this system cattle have the longest days at grass, lowest stocking rate, highest mortality rate and lightest animals sold for slaughtering. The aforementioned factors in organic system cause slightly higher GHGs emission compared to conventional system. Although this result has contradiction with other studies (Casey and Holden 2006), however, the difference easily can be explained by differences in feedlot or grain based finishing versus pasture based finishing (this study). Organic beef usually produced for quality rather than weight (Casey and Holden 2006), therefore the moderately high GHGs emission arises because of the lower weight per animal.

The land occupation for organic farm was higher (53.1) compared to conventional system (Table 2). Higher land occupation in organic system can be explained by a lower total production of slaughtered cattle (due to high mortality rate and high grazing period). Organic beef production system is commonly associated with lower productivity in comparison with conventional production system (Casey and Holden 2006; Nardone et al. 2004). This study also confirmed that there is difference between organic and conventional beef system productivity. Therefore, the main challenge for organic production system to improve overall sustainability is to increase productivity without negative impact on the environment (Nardone et al. 2004). A number of research experiments have shown that under carefully controlled management and better performance conditions organic production system has the potential to achieve comparable output with those in conventional one. The lowest land occupation was in mixed crop-beef farm (38.6) due to high productivity in this farming practice (Dick et al. 2014). Regarding energy specialized and organic beef use less energy compared to specialized crop-beef beef production (Table 2). The result of land occupation in this study is in similar to the studies performed by Pelletier et al. (2010) for intensive pasture finishing beef cattle. For specialized and organic beef production there was not any energy related to feed production, fertilizer production and transportation of feed and fertilizers. However, for mixed crop-beef system due to having crop production in the farm part of energy use was allocated to beef production system. Indeed energy use in this study is much less than the other studies which had feedlot or grain based finishing system (Nguyen et al. 2010; Pelletier et al. 2010). Hence, we could compare this study only with limited number of studies which had pasture based systems (Cederberg et al. 2009).

Despite the interest in organic beef production due to some environmental and human safety reasons, there is a little information concerning the relative costs and returns of organic beef production. Although our study showed that organic production has higher production cost compared to the conventional beef production, however, the operating profit per kg live weight was highest for organic beef, followed by mixed crop beef, and specialized beef. Without organic price premiums, the average annual profits of the conventional production system were higher than the organic production system. (Azadi and Ho 2010; Fernandez and Woodward 1999). Higher cost of organic beef is related to veterinary cost, certification cost, long staying of animal in farm and low productivity. Mixed crop-beef systems is resulted in higher livestock carrying capacity and more consistent farm profitability compared with conventional system (Sulc and Tracy 2007). Lowering input levels increase productivity, and maintaining or increasing profitability. Crop residues represent a vast feed resource available to livestock producers that can effectively reduce feed costs. According to (Sulc and Tracy 2007) in southern Brazil, research and experiences on commercial farms have demonstrated that mixed crop–livestock grazing systems can improve net returns eightfold over the traditional extensive stocker grazing systems and 1.5-fold over soybean grain production systems. Grazing winter cover crops (such as soybean) did not reduce subsequent grain yield when animal stocking was managed (Sulc and Tracy 2007). Animal welfare score of the organic system was slightly higher (4.5) than the score of the other farms. Animal welfare is a basic principle of organic production, and organic beef cattle farmers and managers have a more explicit responsibility for the health, welfare, and treatment of the animals. Organic farms are obliged to obey certifications and standards, which are proposed for organic beef production. The mixed crop beef system had a slightly lower average score (4.2) than the organic farm. The specialized beef system had the lowest animal welfare score (3.98).

Table 2: Environmental and economic performance of beef cattle production in different farming practice

Impact	Unit	Conventional beef	Mixed crop-cattle beef	Organic beef
Global Warming potential	kg CO2 eq.	16	14.2	15.7
Primary energy use	MJ eq.	13	12	13.7
Land occupation	m^2 x year	41.4	38.6	53.1
Operating profit	US $	2.91	3.1	4.3

The management of small ruminant organic farming is fundamentally based on the choice of an appropriate forage system and on good knowledge of climatic and animal production system. Furthermore, prices of organic beef might have great variability, immature nature of the organic market (McBride and Greene 2009). Organic beef cattle productivity are is subject to disease, weather and other factors, which mean that the output stay rather volatile also in the future and may present particular risks and ways of managing risks (Van Bueren et al. 2002). Additional risks of producing organic beef, such as production, marketing and policy risks may cause differences in farmers' risk attitudes. For a risk-neutral farmer it is optimal to produce organic beef; however, for a risk-averse farmer it is only optimal to produce organic products if policy incentives are applied, or if the market for the organic beef becomes more stable.

4. Conclusion

The potential environment impacts of 1 kg live weigh beef produced in different beef production systems in Brazil were shown to differ considerably. (Hanson et al. 2004). Different features of systems contribute to EES performance of each system. The production period of the beef and the quality and production of the pastures determine the GWP, land occupation, energy use and profitability. Concerning product quality, there is little evidence for a system-related effect on product quality due to the production method. It is concluded that the benefits of the basic standards are primarily related to environmentally friendly production and to the animal welfare issue while the issues of animal health and product quality are more influenced by the specific farm management than by the production method. There is evidence to support the assumption that organic livestock farming creates stronger demands on the qualification of the farm management, including the higher risk of failure. As a consequence, quality assurance programs should be established to ensure that the high demands of the consumers are fulfilled. (Sundrum 2001). Alterations in diet composition and animal husbandry practices in mixed crop-beef and organic systems have been proposed as a means of reducing negative environmental impacts and improving economic performance of beef farms (Beauchemin et al. 2008; Eckard et al. 2010; Johnson and Johnson 1995; Martin et al. 2010). We hypothesize such systems will be economically competitive and less environmentally harmful than the specialized beef system. However, for this to become reality it needs to invest in research and training for establishment of management systems adapted to environment and sociological context. Moreover, crop–beef farming systems by producing of different products can provide additional marketing opportunities beyond the conventional commodity markets

ABSTRACT
Life cycle assessments (LCAs) of crop production systems and food products commonly report results using functional units of mass. While these functional units appear to facilitate comparison between different products, they fail to account for substantial differences in a multitude of benefits humans derive from food products, especially nutritional value. This study explores the effects of using different functional units, including mass, serving size, energy content, protein content and a composite nutrient score, on four food's life cycle global warming potential (GWP). Process-based LCA models of almonds, processed tomatoes (diced and paste), and rice, all produced in California, are used to calculate GWP. The results show that rice has the highest GWP except for the energy-content based functional unit, and almonds the lowest GWP except for the mass-based functional unit, and the performance of all the products are significantly affected by the choice of functional unit. The composite nutrient score functional unit appears to magnify the differences among the foods because it accentuates nutrient density, and thus foods like almonds perform better and foods like rice perform worse. Transparency in reporting and reporting multiple functional units is recommended for future studies.

Keywords: carbon footprint, nutrition, rice, almond, tomato

1. Introduction

Life cycle assessments (LCAs) of crop production systems and food products commonly report results using functional units (FUs) of mass of the harvested crop or food product. While these FUs appear to facilitate comparison between products, they fail to account for substantial differences in how various food products are actually used by consumers and the types of benefits consumers derive from these foods, especially nutritional value (Heller et al. 2013). Though meal- and diet-based FUs address this shortcoming (Carlsson-Kanyama 1998), they include functions beyond nutrition, such as those derived from culture. In many cases these additional functions improve the quality and interpretation of analysis and provide important context for decision-making; however, meal and diet-based LCAs may limit generalizability and comparability of results. This study explores a variety of FUs for diverse food products, including mass, serving size, energy content, protein, and a composite nutrient score, and examines the implications for how these products are perceived in terms of their greenhouse gas (GHG) footprints as calculated using LCA methods.

1.1. Previous work

The issue of FU selection in food LCAs has been the subject of discussion in diet-level assessments, meal-based assessments, comparison of organic and conventional production methods, and comparisons across food products or product categories, for example Camillis et al. (2012), Carlsson-Kanyama (1998), Davis and Sonneson (2008), Davis et al. (2010), Dutilh and Kramer (2000), Heller et al. (2013), Notarnicola et al. (2012), Saarinen (2012), and Van Kernebeek et al. (2013), to name but a few. The primary issue is selecting functional units that reflect both the goal of a study and the role of a particular food product in a diet.

While many comparative studies reject mass-based functional units, the European Food Sustainable Consumption and Production Round Table Working Group 1 recommends that business to consumer reporting use a functional unit of 100 g or ml (Camillis et al. 2012), illustrating the continued debate and ambiguity in the appropriate FU for food LCA studies. Complicating the issue of mass-based (or volume based) functional units and nutrition-based functional units is the fact that actual diets are not necessarily healthy, and may over-consume particular nutrients, complicating the selection of a FU when the role of a food or nutrient in a diet or meal is part of the functional unit. For example, Van Kerbeck et al. (2013) examined composite nutritional indices for use as FUs. They found that nutritional indices based on diets with and without protein intake caps arrived at different results. This and other studies highlight the challenge of developing FUs for food LCAs that are both based on scientifically relevant metrics of a food's value to the human diet, and reflect the real-world role of a food in the human diet.

Other issues that affect LCA-based food comparisons are those that are more universal to comparative LCAs and meta-analyses of LCAs, such as incommensurate system boundaries, differing key assumptions and a lack of transparency in reporting that prevents reinterpretation of results for new or alternate functional units.

1.2 Study Approach

This study compares three dissimilar foods produced and consumed in California; almonds, rice, and processed tomatoes. These foods were selected for three reasons: first, LCAs were conducted for these three products by the same research team leading to adequately similar system boundaries, data sources, and modeling approaches; second, because each food has significantly different roles in the human diet, they provided a good test bed for comparing different functional units; third, each of these foods is important globally due to the scale of production and their share of global or national production. California almond production constitutes 83% of global commercial production (USDA Office of Global Analysis 2013), California produces 96% of US processing tomatoes and is the single largest global producer (Economic Research Service 2012), and California is the second largest state in the US for rice production at approximately 2 million metric tons per year, 40% of which is exported to the international market (California Rice Commission 2014).

2. Methods

This study uses process-based LCA models of whole almonds (Kendall et al. 2012), processed tomatoes (Brodt et al. 2013), and rice, all produced in California. Because the rice LCA model was restricted GHG emissions, the only impact assessment category included in this study is GWP_{100} (Intergovernmental Panel on Climate Change 2007). Models were developed to cover all typical California production inputs, equipment operations, and yields on an annual basis, based on University of California Cost of Production studies and consultation with crop experts. Similar methods and system boundaries were used for all three products. In order to preclude confounding the results with different packaging options for different products, all results were calculated for the final products, to the food processing facility gate, without including any packaging. The almond study reports results for raw brown skin almonds. The processing tomato study evaluates two processed tomato products, canned tomato paste and canned diced tomatoes. The rice study reports a weighted average of white rice (90%) and brown rice (10%) based on their estimated production rates because these two products require different levels of milling.

The GWP results for these products are reported here in units of kg CO_2-equivalent per kg food product (kg CO_2e/kg):

- Whole almonds: 0.51 kg CO_2e/kg almond
- Tomato paste: 0.85 kg CO_2e/kg tomato paste
- Diced tomatoes: 0.17 kg CO2e/kg diced tomatoes
- Rice: 1.7 kg CO_2e/kg rice (90% white, 10% brown)

The functional units considered in this study include mass, serving size, calories, protein content, and a composite nutrient score. The recommended serving size of each product is based on common manufacturers' nutrition facts labels on commercially available products and industry standards (Almond Board of California). The following serving sizes are used in this study: rice, 45 g; almonds, 28g; tomato paste, 33 g; and diced tomatoes, 122 g.

The calorie content and protein content estimates for each food product are based on the U.S. Department of Agriculture's most recent database on nutrients in food (U.S. Department of Agriculture Agricultural Research Service 2013). Table 1 report the nutrient values assigned to each food product.

The composite nutrient score used in this analysis is drawn from Arsenault et al. (2012). Arsenault et al. used a regression analysis on real U.S. diets relative to a "Healthy Eating Index," or HEI. By doing so, the authors identified eight nutrient characteristics that were significant in determining the nutritional value of foods. Five of these characteristics contribute positively to nutrition; protein, fiber, calcium, unsaturated fat, and vitamin C. Three characteristics contribute negatively; saturated fat, added sugar, and sodium. Table 1 includes these eight nutrients for the food products considered in this study, as determined by the U.S. Department of Agriculture's Agricultural Research Service (2013).

The regression analysis results in the following algorithm for determining a weighted nutrient density score (WNDS):

$$WNDS = 100 \times (1.4 \times \mathrm{g}\frac{\mathrm{protein}}{50} + 3.3 \times \mathrm{g}\frac{\mathrm{fiber}}{25} + \mu\mathrm{g\ calcium} + 2.51 \times \mathrm{g\ unsaturated}\frac{\mathrm{fat}}{44} + 0.37 \times \mathrm{mg\ vitamin}\frac{\mathrm{C}}{60} - 2.95 \times \mathrm{g\ saturated}\frac{\mathrm{fat}}{20} - 0.52 \times \mathrm{g\ added}\frac{\mathrm{sugar}}{50} - 1.34 \times \mathrm{mg}\frac{\mathrm{sodium}}{2400}) \qquad \text{Eq. 1}$$

Table 1. Food product nutritional characteristics.

Characteristic	Unit	white medium and short grain rice, un-cooked	brown rice medium & short grain, un-cooked	Weighted average of 90% white, 10% brown rice	tomato paste	tomatoes, crushed canned	almonds, raw
g protein	per 100 grams	6.5	7.5	6.6	4.3	1.6	21
g fiber		2.8	3.4	2.9	4.1	1.9	13
mg calcium		3.0	33	6.0	36	34	270
g unsaturated fat		0.20	1.9	0.37	0.23	0.16	44
mg vitamin C		0	0	0	22	9.2	0
g saturated fat		0.14	0.54	0.18	0.1	0.040	3.8
g added sugar		0	0	0	0	0	0
mg sodium		1.0	4.0	1.3	59	19	1.0
kcal (food calorie)		360	360	360	82	32	580
g product	per 100 kcal	28	28	28	120	310	17
g protein		1.8	2.1	1.8	5.3	5.1	3.7
WNDS	na	15	19	15	94	86	75

3. Results

Greenhouse gas emissions, reported in units of kg CO_2e, vary widely for the four different food products, and also vary substantially within each food product depending on which functional unit is used (Figure 1). The WNDS-based functional unit is calculated using Equation 1 based on the mass of product needed for 100 kcal.

In four of the five FU cases rice performs worst, raw almonds perform best in all cases except the mass-based functional unit, and canned tomatoes perform best on a mass-basis and second best in all other cases.

	Per kg	Per Serving (×10)	Per 1000 kcal	Per 100 g protein	Per point of WNDS in 100 kcal
Rice (uncooked)	1.7	0.78	0.48	2.6	3.2
Raw almonds	0.51	0.14	0.086	0.24	0.12
Canned tomato paste	0.85	0.28	1.04	2	1.1
Canned diced tomatoes	0.17	0.21	0.54	1.06	0.64

Figure 1. GWP_{100} for four California food products using five functional units; mass, serving size, energy content, protein content, and a composite nutrient score.

4. Discussion

Results demonstrate how widely environmental impacts can vary, depending on the nutritional characteristic of interest. Due to high methane emissions from flooded field production, rice tends to have higher GHG emissions than the other three foods for all functional units, except for kilocalories. With its high carbohydrate content, rice delivers many more kilocalories than vegetables in any form, even the highly concentrated tomato paste, and therefore the environmental impacts are spread across more kilocalories. However, since white rice tends to be low in other nutrients, its impact on the basis of the WNDS is much higher compared to the other foods. Almonds perform better than rice on the basis of kilocalories, due to their high fat content. They also have an order of magnitude lower impact when assessed on the basis of protein, and even lower impacts when assessed according to their WNDS because of their high nutrient density.

Tomato paste offers an interesting case due to energy-intensive processing required to produce this concentrated product. While the intensive processing results in a relatively high emissions profile on a mass basis, it also serves to concentrate nutrients, balancing the higher emissions with a higher nutritional profile. For this reason, its GHG emissions profile per point of WNDS, while still higher than that for diced tomatoes and almonds, is not as distant from those two products compared to its profile on a mass, kilocalorie or protein basis. This analysis using the WNDS suggests that diets that are more heavily dependent on low-nutrient foods, such as rice, for functional nutrition, might incur higher environmental costs (as well as overconsumption of carbohydrates) than those that rely more on nutritionally-dense foods, assuming maintenance of a similar total nutrient content across diets.

Another observation that may be drawn from Figure 1 is that the WNDS seems to magnify differences among the products. In particular, the impact from rice looks significantly worse, while that from almonds looks much smaller, compared to the other foods. This is mostly due to differences in nutrient density of the two foods, but highlights the importance of transparent reporting when a composite nutrient score is used as the functional unit. Moreover, the WNDS, in this analysis, serves primarily as a mechanism for representing the composite nutritional density of a food based on a limited number of beneficial nutrients. Since all four of the food products are unprocessed or minimally processed foods that are generally considered healthy components of a diet, their WNDS are not highly affected by subtractions (in Equation 1) due to unhealthy factors, namely saturated fat, added sugar, and sodium. Evaluating the impact of these four foods when incorporated as ingredients in more processed products (e.g. almonds in a candy bar or tomato paste on a pizza) that have more of these unhealthy components, would present a more nuanced and complex use of the WNDS, and would more likely reflect the majority of actual consumption of these foods, than in the analysis here. In addition, changing science, subjective or culturally mediated notions of health, and the role of a particular food in a 'balanced' diet (meaning that almonds and rice are not likely to be substitutable in a diet), means that composite indicators such as the WNDS are likely to change over time.

It should be noted that the relative rankings of the four foods are also highly influenced by the environmental impact being assessed, which in this case is GHG emissions. This impact puts rice at a large disadvantage due to the peculiarities of its production system and its high methane emissions. If assessed on other impacts, such as other pollutant emissions or wildlife habitat provision, rice might perform as well as, or better than, the other foods, even with its lower vitamin and protein content. This is a well-understood shortcoming of carbon footprints, or any environmental assessment that focuses on a single impact category.

While researchers may be able to interpret or reinterpret FUs in a way that is meaningful to them, selecting a FU for LCAs targeting consumers is more challenging. A per-serving FU may make the most intuitive sense to a consumer, assuming the serving size reflects typical consumption. However, serving size does not capture the whole-diet or whole-meal perspective which may be important if environmental and dietary decisions are to be linked in a meaningful way in consumer labels. One lesson from our analysis is that presenting results using more than one FU might be desirable, in order to accurately convey the costs of different dietary values that might be of interest to different consumers. However, this approach also risks confusing consumers, if too many FUs show too many conflicting results.

5. Conclusion

Environmental and nutritional policies tend to be formulated in isolation from one another, sometimes resulting in sub-optimal recommendations, such as the advice to consume more fish from fisheries on the verge of ecological collapse. By combining LCA with nutritionally focused functional units, we can begin to bridge this gap between nutritional and environmental sciences and understand the true environmental costs of different nutritional profiles.

Though a recommendation on the FU for any particular study may be driven by a study's goal, audience, scientific developments (particularly with regard to nutrition and diet), or cultural or regional dietary differences, one recommendation applicable to all studies can be made: all LCAs of food products should report results in such a way that alternative functional units can be calculated by other researchers. Thus, a study using a FU based on a composite nutrient indicator should also provide results based on a reference flow such as mass as well as information on nutrient characteristics of the food. As indicated in the discussion section, determining the appropriate FU for consumer-oriented studies is more challenging. There may be ways for interested consumers to use diet calculators, or link shopping lists to LCA information to better understand their diet's impact on the environment. However, the choice of a FU for a consumer-oriented labeling scheme is still unresolved.

ABSTRACT

A farm-gate-to-customer-gate life cycle assessment was conducted to evaluate the environmental and ecological impacts associated with US cheddar and mozzarella cheese manufacturing. Data collected from 16 cheese processing plants (ten cheddar plants and six mozzarella plants) were used to construct a life cycle inventory model, from raw milk delivery to the plant's refrigerated storage silo through delivery of packaged cheese and whey to the first customer. Our baseline allocation approach for energy and other resource use was the facility-supplied fractional estimation of co-products. Where specific information was not provided, revenue-based allocation was used for remaining inputs and emissions. The major environmental impact contributors to climate change were electricity usage (28.3% of total) followed by cheese transport and natural gas use representing 22.5% and 17.3%, respectively. Accumulated reductions in electricity consumption across the life cycle will have significant sustainability benefits. Additional metrics and normalization of the results are discussed in the document.

Keywords: Life cycle assessment, environmental impact, greenhouse gas (GHG) emission, energy use, cheese manufacturing

1. Introduction

Cheese is one of the highly recommended dairy products to consume as part of a healthy and balanced diet. However, cheese manufacturing is a complex process where a myriad of operations take place which are energy intensive. Therefore, it is necessary to estimate the environmental consequences associated with cheese manufacturing to make improvements that promote sustainability (Berlin 2002). In 2009, about 4.6 million tons of cheese products at more than 450 processing plants were produced in the United States, and there has been a trend toward increasing consumption of cheese with an average annual growth rate of 2.5% over the last decade (IDFA 2010). The production of cheese requires numerous resource inputs and outputs that contribute to environmental and ecological risks including greenhouse gas (GHG) emissions. This study provides information that will help the cheese industry to engage more sustainable practices, and reduce environmental consequences, while validating those reductions through science-based analysis. This work will also assist the cheese industry in positioning its products in the market place in terms of their sustainable attributes and be proactive with their own environmental initiatives and toward consumer concerns.

The study reported here was a part of larger effort to evaluate the cradle-to-grave life cycle assessment (LCA) of the environmental impacts associated with cheese consumption in the United States (Kim et al. 2013). This paper presents a farm-gate-to-customer-gate environmental impact analysis of cheddar and mozzarella cheese processing plants. This study focused on quantifying emissions to air, water and soil, cumulative energy demand, consumption of water and other natural resources, and assessing the impacts of inventory exchanges on climate change, resource depletion, human and ecosystem health. In particular, nine environmental impact categories associated with processing, packaging, and distribution in the production and delivery of a ton of packaged cheddar and mozzarella cheese were investigated. Cheddar and mozzarella cheese were chosen on the basis that they represent about 64% of all natural cheese produced and 80% of sales basis in the United States (IDFA 2010). The overarching goal of this work was to equip cheese industry stakeholders with timely, science-based information to further allow incorporation of environmental performance into decision-making and drive innovation.

2. Methods

2.1. Goal and scope

The main goal was to perform an analysis of potential environmental impacts associated with manufacturing of cheddar and mozzarella cheese and to provide cheese manufacturers with information to benchmark their performance against a 2009 industry average in the United States. The identification of the operations which have a major environmental impact will make possible to establish improvement actions and to quantify the impact reductions achieved. The scope of this work was a farm-gate-to-customer-gate impact assessment of a typical cheese processing plant. In particular, the specific operations included transport of raw milk to the plant, cheese and whey manufacture, and delivery of cheese and whey products to the first customer. The first customer can be a retailer for cheese and whey products, animal farm for whey as a feed, or other facility and country for further processing (Some whey is exported to China). This analysis was performed in compliance with ISO 14040 and 14044 standards for life cycle assessment (ISO 2006a; ISO 2006b).

2.2. Functional unit and system boundaries

The functional unit was defined as one ton (1,000 kg, dry-weight basis) of packaged cheddar and mozzarella cheese delivered to the plant's first customers. The system boundaries begin with the raw milk loaded into truck at the farm and end with delivery of packaged cheese and whey to the first customer via the plant's distribution truck. Landfill disposal of packaging is included in the model. In determining whether to expend project resources to collect data for the inclusion of specific inputs, a cut off criterion was established as 1% threshold for mass and energy. Exceptions to this exclusion were made in cases where significant environmental impact is associated with a small mass input. Also, if the data was readily available the elementary flow was not excluded simply because it was small. Even though the study is intended to be comprehensive in consideration of impacts resulting from cheese production, it is not a detailed engineering analysis of specific unit operations within each manufacturing facility. Thus, for example, we did not assign a specific energy requirement for the cheese making vat, cleaning-in-place (CIP), or starter culture operations; rather we used the information available at the manufacturing plant-scale, coupled with allocation of burdens to multiple plant products, to define the burden assigned to primary cheese, other cheese, dry whey, wet whey and other co-products. For this reason, it is important to state that all operations, as well as facility overhead (heating, lights, computers, etc.) are accounted in this study.

2.3. Gate-to-gate inventory data

Data collected specifically for this project were primarily derived from a survey created for cheese manufacturing plants. During 2010, processing companies that participated voluntarily were asked to complete a spreadsheet-based data entry template. Ten cheddar manufacturing facilities (0.55 million tons of cumulative production; 38% of US annual production), six mozzarella manufacturing facilities (0.35 million tons of cumulative production; 24% of US annual production) and one whey manufacturing facility responded. Collected data were based on calendar year 2009. A variety of plant sizes are represented with production ranging from 14 million kilograms per year to around 140 million kilograms per year. The average production of the 10 cheddar and 6 mozzarella plants from the survey was just less than 54 million kilograms per year of cheese, for both cheese varieties. The survey requested facility level data regarding purchases (energy, materials, chemicals, water, and truck fleet fuel), production (cheese and other products), and emissions (solid and liquid waste streams). The information was at the most refined level known by plant managers; however, in many cases only whole facility-level data were available. For example, most plants only reported a single annual electrical energy use. Plants were requested to provide an estimate for separate material and/or energy exchanges (inputs and outputs) associated solely for either cheese or whey products; this information was used to refine the allocation of material and energy exchanges between the co-products of cheese and whey on an individual flow basis. Whey processing can require more thermal energy and resource intensity per ton of finished product than cheese, depending on the degree of solids concentration. Additionally, since facilities produced other cheeses (not cheddar or mozzarella), wet whey, dry whey, other co-products (cream, butter, permeate, lactose, etc.), or a combination of these products, the delineation of the multiple co-products is important in the methodology. For the functional units chosen in this study, packaging is a re-sealable low-density polyethylene plastic bag. In addition to the primary product packaging, we collected survey information regarding secondary packaging (e.g., corrugated cardboard boxes, stretch wrap, paper bags, slip sheets and pallets). The survey also included information for transportation of raw milk to the processor, as well as distribution of final products to storage and first customer. The baseline vehicle was considered to be an insulated tanker truck for raw milk transport and a refrigerated truck for cheese or other co-products distribution. Empty return miles were also accounted. SimaPro© 7.3 (PRé Consultants, The Netherlands 2012) was used as the primary modeling software; the ecoinvent database, modified to account for US electricity (use of the average US grid excludes the variation in the results by region, EarthShift 2012), provided information on the 'upstream' burdens associated with materials like primary fuels and plant chemicals.

2.4. Life cycle impact assessment

We adopted the ReCiPe (Goedkoop et al. 2009) and the USEtox (Rosenbaum et al. 2008) methods with an additional inventory category, cumulative energy demand (Hischier et al. 2010). The two inventory categories, non-renewable fossil fuel (cumulative energy demand) and water depletion (ReCiPe inventory indicator), and the seven impact categories: climate change (IPCC GWP 100a), freshwater and marine eutrophication (ReCiPe midpoint), photochemical oxidant formation (ReCiPe midpoint), ecosystems (ReCiPe endpoint), human health (USEtox), and ecotoxicity (USEtox) are presented quantitatively. ISO 14044 standards do not permit combining multiple metrics into a single score, therefore the results of this study were reported as individual metrics for each of the impact categories.

2.5. Allocation

There are five potential co-products in this work. Because a variety of whey handling technologies are commonly used in the industry, allocation decisions are critically important. Some plants have virtually no processing of the whey after it is removed from the cheese vat, other plants have major processing of the whey making various protein concentrations or dried powders. Data is most commonly available only at the whole plant level. Therefore, to properly account for the energy and impacts that should be allocated to multiple products, a careful accounting of the differences in whey processing is included.

Some of the unit processes are unique to individual products and others are common to all other co-products. For all processes that can be clearly defined as being associated with a single product was assigned to that product. In the survey of manufacturing facilities, we asked for engineering estimates of the allocation of common inputs and emissions to internal facility operations and co-products. In addition, we collected the distribution of gross revenue generated by all the co-products from the facility. For inputs and emissions, these estimated allocation fractions were used as our principal source of information. For energy and other resource use in the plant, we used the plant-supplied engineering allocation. If the plant did not provide engineering estimated allocation fraction, we used an allocation based on the reported fraction of plant revenue assigned to that product. The burdens from milk production and transport were allocated based on the distribution of milk solids using the Van Slyke equation (van Slyke and Price 1979) which estimates the theoretical yield of cheese and whey products based on the incoming raw milk fat and protein content.

3. Results

3.1. Environmental impact assessment results

The inventory information collected from the surveys was converted into lifecycle inventory datasets, coupled with ecoinvent datasets and analyzed using SimaPro 7.3 software. Because the units of measure for each impact category are dissimilar, we report results as a contribution analysis by production inputs. Processing-related operation impacts were grouped into six categories: electricity, natural gas, fuel oil, chemicals, water and wastewater treatment. Packaging-related impacts were grouped into five categories: corrugated board, plastics, pallet, plywood and disposal. Distribution-related impacts were grouped into three categories: cheese transport, raw milk transport and other transport. Other transport here includes the transport of purchased chemicals, packaging materials, cream, and ingredients such as starter media, salt and rennet, etc. On cheddar cheese analysis, electricity usage contributes the largest impacts to climate change with 46.6% on processing stage followed by natural gas and chemical usage with 28.4% and 10.8 %, respectively. Packaging stage does not have significant environmental impacts representing only 7.7% contribution overall to climate change. On distribution stage, cheese transport stands for the largest contributor across all nine impact categories making up about 71.5% contribution followed by raw milk transport, 19.4% contribution to climate change. On overall interpretation from farm-gate-to-customer-gate, electricity usage contributes the largest impacts to climate change with 28.3% followed by cheese transport and natural gas use with 22.5% and 17.3 %, respectively. Similar results as climate change are observed on cumulative energy demand, thus these are not explained here. The freshwater depletion is dominated by processing stage, due to process water usage mostly for cleaning-in-place (CIP), representing 90.8%. The eutrophication impacts are affected by on-site wastewater treatment (WWT). The unit process for whey digestion was adapted from the ecoinvent dataset. This unit process is based on modern technology from Switzerland, and should be generally applicable in the US; however, the incineration of sludge is included in the original dataset, and this is not a common practice in the US. Thus, exchanges in the dataset which were identified as deriving from sludge incineration were removed. In addition, the assumed phosphorus loading to the treatment facility, for Swiss conditions, was 250 mg/L. Based on the survey and literature (Danalewich et al. 1998) reports, we reduced the WWT influent total phosphorus to 70 mg/L. The survey data were highly variable with some reporting post-treatment concentrations. Furthermore, not all plants reported P loadings so the average estimated load was used for all facilities. Freshwater eutrophication is driven by phosphorus loading, and for the impact assessment framework chosen for this study, there was no differentiation between phosphorus emitted directly into receiving waters and phosphorus applied to land with sludge. For marine eutrophication, which is driven by nitrogen emissions, we did not have any information in the survey, and therefore adopted the ecoinvent WWT dataset influent loading and emissions profile. Nitrogen compounds which are emitted are generally in a soluble form, and due to the prevalence of phosphorus limitations in freshwater, an assumption that all N emitted ultimately reaches marine waters is made in the impact methodologies. Because the WWT process is the dominant source of eutrophication, and the uncertainties associated with the inventory and impact methodologies, further evaluation of the damages actually resulting from WWT is needed. This analysis shows that there is a potential impact associated with these emissions, but does not demonstrate the fact of this damage to the environment. The photochemical oxidant formation impact is dominated by distribution stage representing 65.5% followed by processing stage which makes up 28.8% of overall. The primary driver to this impact is observed to be nitrogen oxides (NOx) emissions which are stem from truck tailpipe. Volatile organic compounds emissions from combustion associated with transport and manufacturing are also noticeable drivers. The ecosystems damage is also affected most by processing stage with 55.8% of overall. The primary driver to this impact is carbon dioxide emissions associated with electricity generation and heating fuel combustion followed by forestry for corrugated board packaging. The human toxicity and ecotoxicity impacts show similar result pattern dominated by processing stage which represents 77.1% and 66.0% of overall, respectively. The largest contributor to these impacts is heavy metal emissions to both air and water primarily driven from coal mining tailings and coal ash disposal in the electricity supply chain. However, these results should be interpreted with care because USEtox characterization factors for metals are highly uncertain according to Rosenbaum et al. (2008). A discussion of major contributors to each impact category is provided in Table 1 which is applicable for both cheddar and mozzarella cheese.

Table 1. Gate-to-gate drivers across environmental impact categories for both cheddar and mozzarella cheese.

Damage category	Major gate-to-gate impact drivers
Climate change	CO_2-equivalent emissions from fossil fuels combustion related to electricity generation, on-site heating fuels usage and diesel usage
Cumulative energy demand	Energy demand by electricity generation, natural gas usage and diesel fuel usage
Freshwater depletion	Process water usage
Marine eutrophication	Nitrogen compounds released into water from wastewater treatment; likely associated with nitric acid used in CIP operations
Photochemical oxidant formation	NOx and VOCs emissions from combustion associated with transport and manufacturing
Freshwater eutrophication	Phosphorus emissions associated with wastewater treatment with smaller impacts associated with manufacturing from coal mining for electricity generation. Phosphorus is likely emitted during CIP operations where milk protein residues are removed from piping and equipment
Ecosystems	Majority from CO_2 emissions associated with electricity generation, heating fuel and transport combustion; secondary from forestry for corrugated board packaging.
Human toxicity	Arsenic emission to water and heavy metals emissions to both air and water primarily from coal mining tailings and coal ash disposal in the electricity supply chain
Ecotoxicity	Chromium emission to water and heavy metals emissions to both air and water primarily from coal mining tailings and coal ash disposal in the electricity supply chain

3.2. Cleaning-in-place (CIP)

The cheese manufacturing industry has been active for many years in addressing the important issues associated with CIP technologies and chemical usage. As described in the previous section, CIP is a contributor to several impact categories. However, one of the limitations of the data available for this study was that only whole-plant information and therefore detailed analysis of the CIP was not possible. Specifically, not all chemical purchases, or energy consumption at the whole plant level could be attributed to CIP, thus the emphasis of manufacturers on managing CIP impacts remains important. Sustainability will be achieved through continual incremental improvement, and these improvements across many plants will cumulatively have a significant and measurable impact at the sector level. The granularity of data in this study highlights the need for further investigation at the plant level.

3.3. Normalization

We conducted a normalization test using the Impact 2002+ US midpoint assessment framework which was published by Lautier et al. (2010). The result for cheddar indicates that aquatic ecotoxicity is the largest relative impact in the US context. The primary driver of the aquatic ecotoxicity is aluminum emissions associated with digestion of wastewater from whey processing and treatment for an effluent containing spilled milk or milk residue removed by CIP. Aluminum in the WWT procedure is used as a coagulant to remove phosphorus via chemical precipitation. The ecotoxicity impact associated with cheese manufacturing represents approximately 0.47 percent of the annual US ecotoxicity impact. It reaches about 0.89% combining cheddar and mozzarella. Because nearly identical result was observed with mozzarella, normalization result on mozzarella is not included here. Terrestrial ecotoxicity and aquatic eutrophication are the next important categories to focus improvement activities. From a manufacturing perspective, these can be mitigated through energy conservation and water conservation/treatment activities.

3.4. Uncertainty analysis

The uncertainty in the results was evaluated using Monte Carlo simulation, available in SimaPro 7.3 software. The ecoinvent pedigree matrix approach was applied to each exchange generated from primary data and then the resultant inventory uncertainty is calculated. These results which are based on a dry solid basis can be used to approximate the impacts on as-sold moisture basis (63.2% solids for cheddar, 51.4% solids for mozzarella). GHG emissions are of notable interest, and on dry-weight basis, the GHG emissions of cheddar and mozzarella are approximately 1.29 and 1.81 tons CO_2e per ton of cheese solids delivered, respectively. The 95% confidence band ranges 0.92 to 1.77 tons CO_2e per ton of cheddar cheese solids delivered, and 1.24 to 2.62 tons of CO_2e per ton of mozzarella cheese solids delivered. For an average moisture content of 36.8% for cheddar as sold at retail, the GHG emission is 0.82 ton CO_2e per ton cheddar delivered with a confidence band of 0.58 to 1.12 tons CO_2e per ton cheddar delivered. Based on an average moisture content of 48.6% for mozzarella as sold at retail, 0.93 ton of CO_2e per ton mozzarella is emitted, with a 95% confidence band of 0.64 to 1.35 tons CO_2e per ton mozzarella delivered. On a dry-weight basis, the freshwater depletion – defined as water removed during the production, but not returned to the same watershed – is 15.7 m^3 per ton of cheddar delivered with 95% confidence band of 12.9 to 19.4 m^3 of water consumed per ton of cheddar delivered. This is equivalent to approximately 9.9 L of water per kilogram of cheddar cheese delivered in the United States. For mozzarella cheese, 13.6 L of water are consumed per kilogram of mozzarella delivered. It should be noted that, even though the same allocation scheme was used for both cheeses, the variability of the co-products for typical cheddar plants and mozzarella plants make direct comparisons of environmental impact results between the two cheese products very difficult and inadvisable.

3.5. Estimated industry scale contribution to US GHG inventory

An estimate of the entire cheese sector impact from farm-gate-to-customer-gate was made through inclusion of the whey and other co-products produced. In reported surveys, mozzarella manufacturing facilities did not produce significant quantities of other cheeses. Cheddar facilities did report some production of Monterey Jack, Swiss, and other natural cheeses. Taking the assumption that all cheeses other than mozzarella had a similar production impact as cheddar manufacturing facilities coupled with whole-plant data, the cheese sector impact was estimated by scaling the study results to national scale. In 2009, about 4.6 million tons of cheese products were produced in the United States (IDFA 2010). The total GHG emissions as sold at retail, including whey and other co-products, are approximately 3.5 million tons CO_2e; cumulative energy demand of 4.7e10 MJ (roughly equivalent to 8.2 million barrels of oil); water consumption of 32 million cubic meters of water.

4. Discussion

From a manufacturing perspective, the study suggests some opportunities to reduce individual plant impacts. First, a focus on plant electricity consumption is explicit since it is the single greatest impact driver. Implementation of energy efficiency best practices should be considered for the refrigeration system, compressed air system, motors, and lighting. Similarly, plant fuel reductions could be realized through improved steam system efficiency and operating practices. Minimizing the amount of water and energy used for CIP can be achieved through using reuse or recovery distribution systems (Baskaran et al. 2003). Finally, careful study of plant specific optimization of the transport distances and the future selection of transport refrigeration systems using low-GWP refrigerants could lead to reduced emissions for the cheese industry.

5. Conclusion

Average impacts in various unit processes (processing, packaging, and distribution) were reported and discussed. For an average moisture content of 36.8% for cheddar as sold at retail, the GHG emission is 0.82 ton CO_2e per ton cheddar delivered with a 95% confidence band of 0.58 to 1.12 tons CO_2e per ton cheddar delivered. Based on an average moisture content of 48.6% for mozzarella as sold at retail, 0.93 ton of CO_2e per ton mozzarella is emitted, with a 95% confidence band of 0.64 to 1.35 tons CO_2e per ton mozzarella delivered.

For the post-farm supply chain, climate change and cumulative energy demand impacts are closely linked with fossil fuel consumption primarily associated with coal mining and combustion. The impacts associated with the electricity supply chain and combustion of other fossil fuels was found to be the most intensive contributor within nearly all impact categories including climate change, cumulative energy demand, ecosystems, human toxicity, and ecotoxicity. Thus conservation efforts to reduce electricity and fuel use will have broad beneficial consequences for environmental sustainability. Truck fleet tailpipe emission is also observed to be a significant impact driver. Thus, seeking the most appropriate transport modes and methods to mitigate the impacts on the environment will deliver financial benefits as well as boost a company's reputation in the minds of consumers.

The regionalized normalization analysis based on an average US citizen's annual cheese production showed that aquatic ecotoxicity stands for the largest relative impact due to aluminum emissions associated with digestion of wastewater from whey processing. Terrestrial ecotoxicity and aquatic eutrophication indicate the next significant impact categories. Therefore, incorporating best practices around heavy metals, phosphorous and nitrogen emissions management can yield good improvements.

Acknowledgement

This study was funded by the Innovation Center for US Dairy's Dairy Research Institute (DRI). The Innovation Center for US Dairy played an instrumental role in the collection of the data and information gathered from the processing facilities. Without the strong industry commitment to collect high quality data across the supply chain, this study would not have been possible. The authors also appreciate three ISO panel reviewers for their constructive comments.

ABSTRACT

The grain legumes pea and faba beans are among the relevant alternatives to imported soybeans for livestock feed for growing in the European agricultural systems, but what is the climate impact of an increased European production of grain legumes such as pea and faba bean? In order to estimate the overall climate impact of producing more grain legumes in Europe, we applied Life Cycle Assessment (LCA). The results showed that carbon footprints per kg protein of pea and faba bean in Europe did not vary much for different regions in Europe. Based on FAO statistics and an expert survey (Reckling et al., 2014), it was assumed that an increased European production of grain legumes will decrease the import of soybean cake and decrease the export of wheat from Europe. Taken that into account, results showed a small climate benefit of producing more grain legumes in Europe compared to importing soybeans to Europe.

Keywords: grain legumes, LCA, carbon footprint, soybeans, pea, faba bean

1. Introduction

Soybeans are number one on the world import list of agricultural products based on value (FAOSTAT, 2013); indicating that it is one of the most important agricultural products traded globally. Europe has a net import of 22 mill t cake of soybean and 15 mill t soybeans, but it is not the only region with a high demand for soybean protein. The demand for soybeans for the globally increasing livestock production has seen a dramatic increase during the last decade with China being by far the largest importer of soybeans globally (FAOSTAT, 2013). China has seen a three-fold increase in the import of soybeans during the last decade, with Brazil being the major supplier. Brazil's own consumption of soybeans for the increasing livestock production has also increased and due to the increasing demand, the producer prices of soybeans in Brazil have seen a three-fold increase during the last decade. The European livestock production is vulnerable to increasing prices of soy protein and combined with environmental concerns related to the production and import of soybeans, alternative and more sustainable protein sources are potentially attractive for the European livestock sector. The production of livestock feed is a major contributor to global greenhouse gas emissions, making mitigation options to reduce these important.

Pea and faba beans are relevant alternatives to soybeans in the European cropping systems and livestock diets, since they can be grown across Europe in the different agro-climatic zones. The aim of the present study is to assess the impact on GHG emissions of an increased European production of grain legumes.

2. Methods

We applied a life cycle assessment (LCA) approach to assess the overall climate impact of producing more grain legumes in Europe. The analysis focused on the greenhouse gas emissions or potential global warming impact.

2.1. Estimating carbon footprints of single crops

Studied crops

The basis for the analysis was the cultivation of pea and faba beans in five different agro-climatic zones in Europe, including Sweden (SE), Scotland (SC), Germany (DE), Romania (RO) and Italy (IT). All sites were rainfed. The analysis was based on an expert survey (Reckling et al., 2014) for representative crop rotations with and without grain legumes in the different zones.

Functional unit and system boundaries

The functional unit is 1 tonne harvested crop (DM). However, the greenhouse gas emissions per t harvested protein and per hectare are also presented. The main system boundaries in the present cradle to farm gate study include two main processes; 1) production of agricultural inputs and 2) the agricultural production system. The temporal system boundaries are one year of crop production based on current practice in the five different agro-climatic zones

Estimation of emissions

The characterization factors for the global warming potential (GWP) were based on the IPCC 2007 standards for greenhouse gas emissions (IPCC, 2007). Production data from Reckling et al. (2014), such as crop DM yields and amount of fertilizer, were used for the analysis. The same field operations were assumed for all the sites, which included one ploughing, one harrowing, one sowing, 2.5 pesticide applications, fertilizer applications according to the survey and one harvesting. The GHG emissions related to the fertilizer production were based on Williams et al. (2006). The diesel consumption was based on the field operations and the diesel consumption per field operation was estimated as described by Dalgaard et al. (2002). GHG emissions related to diesel and energy consumption was based on data from the Ecoinvent database (Ecoinvent Centre, 2009). The direct and indirect emissions of nitrous oxide (N_2O) were estimated according to the IPCC guidelines 2006 (IPCC, 2006). NH_3 emissions were estimated according to EEA (2013). N leaching was estimated in accordance with Reckling et al. (2014), who estimated N balances and N losses using the ROTOR model (Bachinger and Zander, 2007). Soil carbon changes related to grain legume production were assumed to be insignificant. The grain legume production was modeled as an individual crop in the crop rotation (Knudsen et al. 2013) , but the interactions with the following crops in the crop rotation was taken into account in terms of a reduced fertilizer use in the following crop of 10 kg N (Plantedirektoratet, 2011) . Furthermore, an increased yield in the following crop of 0.3 t cereal DM per hectare was anticipated and included in the analysis, based on information from Reckling et al. (2014).

2.2. Overall analysis

If Europe starts producing more grain legumes such as pea and faba bean for the European livestock production, the import of soybeans and soybean cakes will be reduced. At the same time the crops being replaced in Europe by grain legumes, will have to be produced somewhere else. According to Reckling et al. (2014), the grain legumes will mainly replace wheat in the crop rotations.

The overall analysis assumes that the production of one hectare of either pea or faba bean will replace one hectare of wheat, previously grown on that land and in that crop rotation. Europe has a net import of soybeans and soybean cake of approximately 37 mill tonnes and a net export of approximately 30 mill tonnes of wheat (FAOSTAT, 2013). It is assumed that an increased production of grain legumes in Europe will decrease the import of soybean cake and decrease the export of wheat from Europe.

Europe mainly imports soybean cake and soybeans from Brazil, but also from Argentina, USA and Paraguay according to FAOSTAT (2013). Since Brazil supplies approximately half of the imported soybeans to Europe, the values from Brazil are weighted accordingly (50%) in the average values while the values from the remaining countries are weighted by 17% each of them. Since part of the wheat production in Europe will be replaced by production of peas or faba beans, the wheat needs to be produced elsewhere. According to FAOSTAT (2013), USA, Canada and Russia are the main wheat exporters globally, and they will presumably increase their production accordingly.

To analyze the overall climate impact of those changes, the carbon footprint of the imported soybean and the wheat production outside Europe is also needed. The inputs and yields from soybean and wheat production in the countries concerned are based on FAOSTAT (2013) (average over the last five years) and FertiStat (2007) and the emissions are estimated based of IPCC (2006) and EEA (2013). Protein content of pea, faba bean and soybean are based on Burstin et al (2011). Transport steps for the import and export of the grains are included in the study.

3. Results and discussion

The carbon footprint of the European grain legumes and the imported grain legumes (soybeans) to Europe is presented (Figure 1). The emissions are given in CO_2 equivalents per t protein for comparison across different grain legumes.

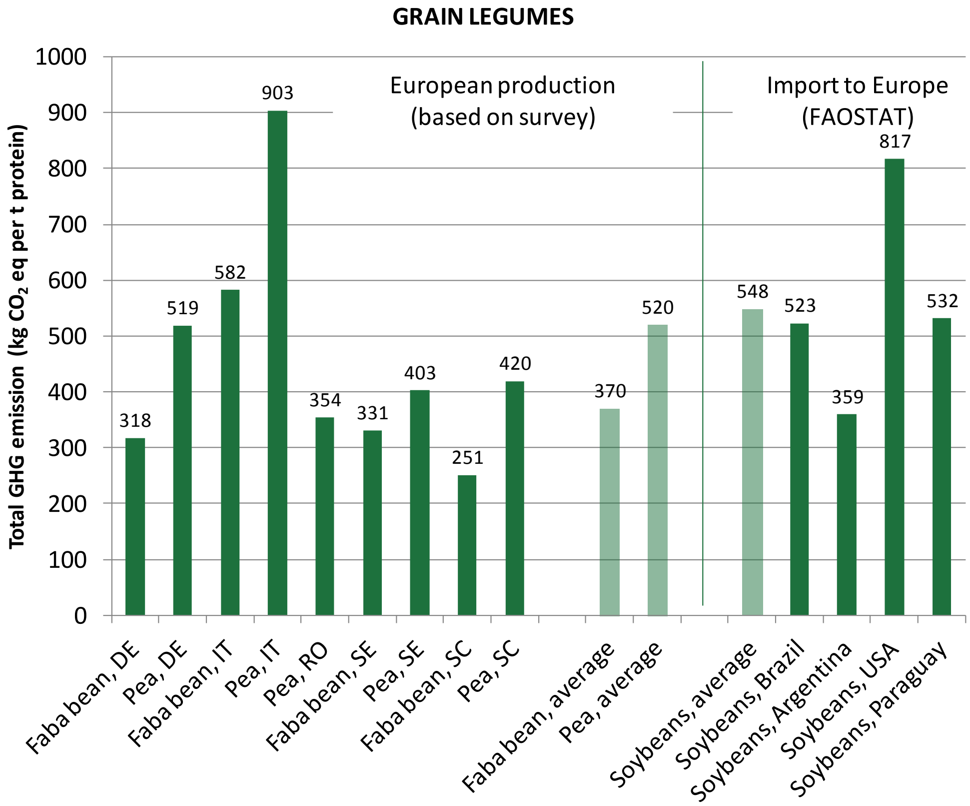

Figure 1. Greenhouse gas emission per t protein for grain legumes produced in five different regions in Europe and soybean imported to Europe. DE, IT, RO, SE and SC refers to the different agro-climatic zones, represented by Germany, Italy, Romania, Sweden and Scotland, respectively.

On average, soybean production outside Europe has a global warming potential of 548 kg CO_2 eq. per t protein. This can be compared to the average for pea and faba bean in our study of 520 and 370 kg CO_2 eq. per t protein, respectively (Figure 1). The higher value for pea is mainly due to lower DM yield and lower protein content in the grains.

The carbon footprint of the wheat produced in Europe (based on Reckling et al., 2014)) can be compared to the carbon footprint of wheat on the world market produced outside Europe (Figure 2). Figure 2 shows that the carbon footprint values are comparable for the wheat production in Europe and outside Europe, despite different yield and input levels. The average values for greenhouse gas emission from wheat production in Europe and outside Europe (Figure 2) are used in the following calculations. Likewise, the values for pea and faba bean production in Europe and for soybean production outside Europe (Figure 2) are used in the overall assessment on the climate impact of producing more grain legumes in Europe.

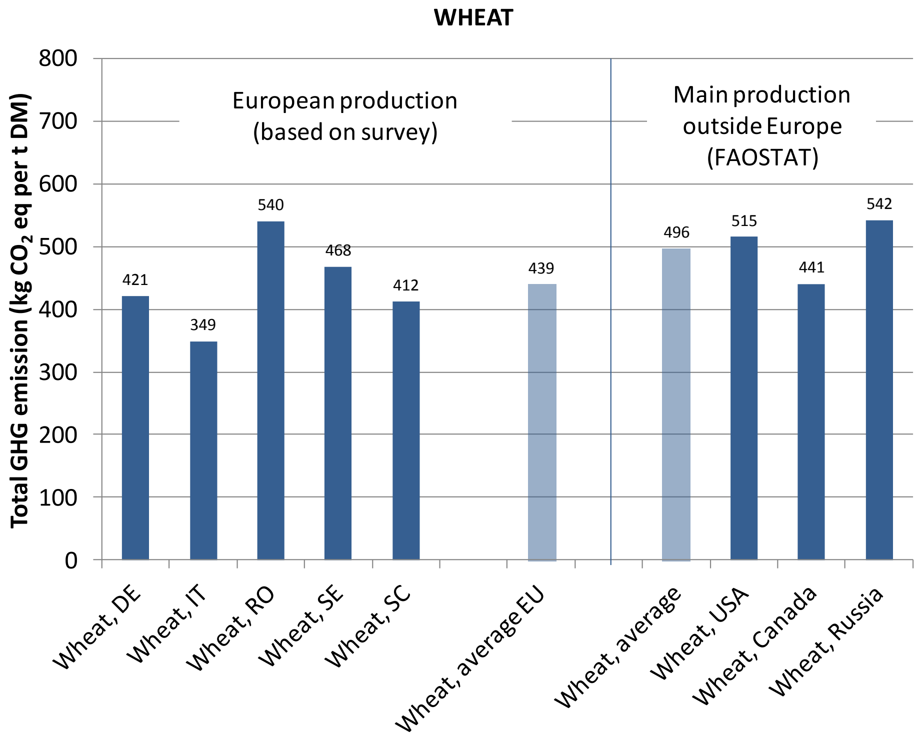

Figure 2. Greenhouse gas emission per t DM for wheat produced in five different locations in Europe and wheat produced by the main wheat exporters outside Europe. DE, IT, RO, SE and SC refers to the different agro-climatic zones, represented by Germany, Italy, Romania, Sweden and Scotland, respectively.

The global flows will be affected when replacing one hectare of wheat in Europe with the production of one hectare of either pea or faba bean in Europe. The wheat formerly produced in Europe will be produced somewhere else. The major global wheat exporters, USA, Canada and Russia are assumed to take over this wheat production. The increased production of grain legumes in Europe, are assumed to replace a corresponding production of protein from soybeans. However, the avoided production soybeans and import of soybean cake to Europe also implies that a certain amount of soybean oil is not produced. The market response to a lower amount of soybean oil on the world market, will, according to Schmidt (2010), be an increase in the production of the marginal vegetable oil, which is palm oil from Malaysia and Indonesia (Schmidt and Weidema, 2008) , and this assumption is used in this work. The division between soybean cake and soybean oil are based on Dalgaard et al. (2008) and the greenhouse gas emissions from palm oil are based on Schmidt (2010).

The overall climate impact of producing more grain legumes in Europe are presented in Table 1 for pea and faba bean.

Table 1. The overall climate impact when replacing one hectare of wheat in Europe with pea or faba bean production, while taking the impact of a reduced soybean import to Europe and an increased wheat production outside Europe into account.

	Kg CO_2 emissions per ha of grain legumes cultivated in Europe	
	PEA	**FABA BEAN**
EMISSIONS		
1 hectare of pea/faba bean production in Europe	296	287
Production of wheat outside Europe	2524	2524
Production of palm oil (to account for less produced soybean oil)	711	1066
TOTAL emissions	3531	3877
AVOIDED EMISSIONS		
1 hectare of wheat production in Europe	-2343	-2343
Soybean production	-329	-493
Soybean, processing to oil and cake[a]	-230	-344
Transport of soybean cake to Europe	-175	-262
Extra carbohydrates in peas/faba beans compared to cake of soybean, avoided cereal production	-733	-610
TOTAL avoided emissions	-3810	-4052
OVERALL climate impact	-279	-175

[a] Dalgaard et al. (2007)

In the assessment it is also taken into account that pea (and faba bean) having the same amount of protein as the cake of soybean that it replaces in the livestock diet, contains more carbohydrates compared to the cake of soybean. This means that it also replaces a certain amount of cereals in the livestock feed – and the production of this cereal can thus be avoided.

The overall impact of producing more grain legumes in Europe showed a small climate benefit compared to importing soybeans to Europe. Approximately 280 kg CO_2 eq. are avoided for each hectare in Europe producing pea instead of wheat. Similarly, 175 CO_2 eq. are avoided for each hectare faba bean produced in Europe instead of wheat.

5. Conclusion

The carbon footprint of pea and faba bean did not vary much over the five different agro-climatic zones in Europe, except from Italy. The carbon footprint of pea cultivated in five different agro-climatic zones in Europe varied from 88-222 kg CO_2 eq. t^{-1} harvested grain DM. On average per kg pea protein, the greenhouse gas emission was 520 kg CO_2 eq. t^{-1} pea protein. For faba bean, the carbon footprint varied from 71 to 165 kg CO_2 eq. t^{-1} harvested grain DM in the different agro-climatic zones in Europe. The greenhouse gas emission per kg protein was on average 370 kg CO_2 eq. t^{-1} faba bean protein.

Based on FAO statistics and Reckling et al. (2014), it was assumed that an increased European production of grain legumes will decrease the import of soybean cake and decrease the export of wheat from Europe. The overall impact of producing more grain legumes in Europe showed a small climate benefit compared to importing soybeans to Europe. Approximately 280 kg CO_2 eq. are avoided for each hectare producing pea instead of wheat in Europe. Similarly, 175 CO_2 eq. are avoided for each hectare faba bean produced instead of wheat in Europe. Thus, the study also illustrates a method for estimating the overall climate effect for a change in production systems.

ABSTRACT

Consumer desire for sustainably sourced goods and services is transforming the way our food is grown and how products are made. Quantifying and assessing the environmental impacts of the inputs and outputs of each life cycle phase in primary agriculture production is a complex and resource-demanding task beyond the capabilities and affordability of individual producers. In collaboration with commodity groups and Alberta Agriculture and Rural Development, Quantis Canada completed four environmental footprints. In compliance with the International Organization for Standardization 14040 and 14044 standards, four primary agriculture life cycle assessments (LCA) were completed for Alberta produced canola, potato, egg, and broiler chickens. Hundreds of producers, through online and paper based data collection, participated in the study. This paper explores the use of an LCA approach to systematically identify opportunities to reduce the environmental impacts of primary agriculture production, and to document and communicate environmental performance to internal and external stakeholders.

Keywords: primary agriculture, life cycle assessment (LCA), beneficial management practices (BMP), sustainability, footprint

1. Introduction

Consumer desire for sustainably sourced goods and services is transforming the way our food is grown and how products are being made. In particular, the environmental sustainability is becoming an increasingly important consideration in consumer purchasing decisions. These consumers are those that are active stewards of the environment and are willing to pay a premium for green and socially responsible products (Ross et al. 2010). Environmentally sustainable production processes are becoming more prevalent in the marketplace due to this public pressure as well as shareholder transparency. But more importantly, there is growing evidence that firms that adopt proactive environmental management strategies become more efficient and competitive (Berry and Rondinelli 1998). Calls for corporate social responsibility are coming from investors, insurers, environmental interest groups, financial institutions, and international trading partners. Ultimately, the organizations with in-depth knowledge of how their business operations interact with the environment will remain competitive. In this context, sustainable sourcing is becoming a means of differentiation and access in the agri-food marketplace.

However, quantifying and assessing the environmental impacts of the inputs and outputs of each life cycle phase of primary agriculture production is a complex and resource-demanding task that cannot be afforded by individual producers. The life cycle assessment (LCA) approach systematically identifies opportunities to reduce the environmental impacts of primary agriculture production, and to document and communicate environmental performance to internal and external stakeholders. The objective of this study was to inform producers of the environmental footprint of their production, as well as identify the potential benefits and mitigation strategies producers and commodity associations could implement. The LCA methodology was chosen for this research, as the most comprehensive approach to analyze environmental footprints. To communicate the LCA results, concise and creative communication pieces were developed to inform producers and consumers. In addition, an environmental footprint calculator was developed for Alberta egg producers to measure the footprint of their farm, run different scenarios, and compare results to the benchmark regional average. The information can then be shared with stakeholders, including those who aim to conduct further LCAs of the commodity. This work is also part of an effort to make LCA information accessible and useful for sustainability decision making by producers and the supply chain.

2. Methods

In order to provide the industry with a better understanding of the environmental profiles of current conventional production in Alberta, Alberta Agriculture and Rural Development (ARD), along with Quantis Canada, completed LCAs for Alberta canola, potato, egg, and broiler chicken (including hatching egg) production. In collaboration with the commodity associations, the studies completed environmental assessments of the 2012 practices within the industry using LCA, a framework defined by the International Organization for Standardization (ISO) 14040 and14044 standards (ISO 2006a; ISO 2006b). On farm data was collected from producers through online and paper surveys. Environmental hotspots (those areas with the highest environmental impacts) for different impact categories were identified in each of the LCAs with Impact 2002+ methodology (Jolliet et al. 2003) and associated management recommendations were made. As one of main purposes of the studies was to communicate the results with internal and external stakeholders including non-LCA audiences, a combination of three end-point indicators (human health, ecosystem quality and resources) and two mid-point indicators (climate change and water consumption) were selected.

2.1. Boundaries and Assumptions

The system boundaries chosen for all four commodities identify the life cycle stages, processes, and flows considered in the LCA. The studies assessed the life cycle of Alberta canola, potato, egg and broiler chicken (including hatching egg) production, from the extraction and processing of all farm inputs, to the energy used to the farm gate. The LCA for egg production also included the two Alberta washing and grading facilities that go beyond the farm gate. Within each of these stages, each LCA considered all identifiable upstream inputs to provide a comprehensive view of the production systems. All inputs may therefore be traced back to the original extraction and processing of raw materials used at the various life cycle stages, which include: crop inputs, transportation, field operations, farm utilities, infrastructure, feed production, hatchery, farm operations, egg washing and grading, and waste management.

The study included the diversity of management practices implemented across the industry, and comparisons were made between combinations of practices to identify trade-offs between the various conditions. The project team worked in close collaboration with industry experts to better understand common farm practices and conventional Alberta production of the four commodities. Once the information was reviewed, appropriate scenarios were established for evaluation.

2.2. Data Collection

The quality of the LCA results depends on the quality of the data used as an input in the model. For this study, every effort was made to implement the most credible and representative information available. The life cycle inventory (LCI) was established based upon different data sources.

On farm data was collected to assess the overall environmental impacts of production in Alberta through online and paper surveys. In some cases, information came directly from provincial commodity association records. Data was collected for the 2012 production year. When possible, data was also collected for an additional two years (2011 and 2013) to allow for data gaps or unexplainable data points in the 2012 data. Survey questions covered the entire primary production practices such as acres planted, crop variety, agronomic practice, yield, flock management (diet, feed, and water consumption), manure management, and energy use. Because on farm data can be of variable quality, data from the farm surveys was verified by an industry specialist and compared to industry standards to insure good representativeness. High and low value points for important parameters were tested in sensitivity scenarios but no quantitative uncertainty assessment was realized. Important field emissions as nitrous oxide and ammonia from fertilizer application were based on local Canadian models (Rochette et al. 2008; Sheppard et al. 2010). As the Canadian models of direct nitrous oxide emissions were used in the study, it appeared that uncertainties in the modelling were likely lower in the study than using IPCC Tier 1 specifications.

When no site-specific data were available or the contributions to known impacts were minimal, LCI databases, mainly ecoinvent v2.2, were adapted or used as is. As a last resort, when assumptions were necessary and activity data was not available, stakeholders and experts were consulted to determine specific values.

SimaPro 7.3.3 was used for LCA modeling; it links the reference flows with the LCI database and computes the complete LCI of the systems. The final LCI result was calculated by combining foreground data (intermediate products and elementary flows) and generic datasets, providing cradle-to-gate background elementary flows to create a complete inventory.

3. Results

The four LCAs were assessed based on the environmental scores of Alberta production through five end-point indicators: human health, ecosystem quality, resources, climate change, and freshwater consumption, as well as water stress for potato production. Mid-point indicators of Impact 2002+ were also analyzed. It is important to note that LCA estimates relative, potential impacts rather than direct measurements of real impacts, and that results and conclusions should be considered applicable only within the scope of the study. The ecosystem quality indicator expresses the composite score of eight midpoint categories which measure toxicity effects of pesticides.

3.1. Alberta Canola Production

Crop inputs are responsible for the greatest proportion of impacts for all categories. The efficiency of the farm input use (e.g. fertilizers, pesticides, seeds) and land use is directly proportional to canola production yields. Electricity and gas consumption on farm varied significantly from one producer to the next showing potential room for improvement.

3.2. Alberta Potato Production

Crop inputs are responsible for the greatest share of environmental impacts for all indicators, except water stress, where irrigation is the main contributor. The production and emissions associated with synthetic fertilizers are significant contributors to impacts for climate change, human health, and resources. The proper management of synthetic fertilizers is therefore crucial to achieve considerable environmental impact reductions. The most variable parameters between farms are electricity consumption for potato storage and irrigation requirements. This is partly explained by the fact that not all producers store their potatoes and by the different efficiencies of storage facilities between producers.

3.3. Alberta Egg Production

Feed production was identified as the largest contributor to all environmental impacts, followed by farm operations. Fertilizer production and application, and land occupation are major causes of high environmental impact in feed production, while on farm energy use and manure management are responsible for most of the environmental impacts for the farm operations. Preliminary results of the enriched cage system indicate equivalent feed efficiency of the birds and globally slightly lower environmental impacts.

3.4. Alberta Hatching Egg and Broiler Chicken Production

The feed production stage is the main contributor to all impact categories, except climate change. The main impacts for climate change come from farm operations, specifically the energy used for heating the barn. Coal heated barns, which consume more fuel per functional unit compared to other energy sources, are responsible for causing a higher impact in this category. Hatching egg production is the third most important contributor to the life cycle impact of broiler production.

4. Discussion

LCA methodologies and background databases are becoming more accurate by depicting impacts at a regional level through environmental modeling. At the same time, agricultural technologies are evolving and becoming increasingly precise and efficient. As such, the four Alberta agri-food LCAs establish a benchmark, allowing industry to be prepared for market demands and reflect the new technological changes in the industry. With a credible baseline in hand, representing provincial average production systems, specific attention was given towards management recommendations. The LCA model was used to evaluate the environmental benefit of implementing beneficial management practices (BMP), focusing on parameters that producers have the ability to influence and/or that the LCA identified as a hotspot. A summary of the commodity-specific LCA results and associated BMP recommendations are provided below in Table 1.

Table 1. Environmental footprint results and BMP recommendations by commodity

Commodity	**Life cycle stage with largest footprint (descending order)**	**Primary BMP recommendations**
Canola	Crop inputs Farm utilities and infrastructure Field operations Waste management Transportation	• Adoption of 4R Nutrient Stewardship to manage nutrient sources • Soil carbon sequestration from conservation tillage
Chicken	Farm operations Feed production Hatching egg Hatchery Transportation	• Phasing out coal barn heating for natural gas or biomass heated barns • Encouraging use of the industry's efficient feed conversion ratio
Egg	Feed production Farm operations Hatchery Transportation Washing and grading	• Implementing on farm energy efficiency measures such as well-designed ventilation systems • Soil carbon sequestration from conservation tillage
Potato	Crop inputs Farm utilities and infrastructure Irrigation Field operations Waste management	• Adoption of 4R Nutrient Stewardship to manage nutrient sources • Ongoing improvement of irrigation infrastructure and delivery equipment, such as a variable rate irrigation system

4.1. Alberta Canola Production

The yield per acre improvement constitutes an important lever for producers considering that the efficiency of the farm input use and land use is directly proportional to canola production yields. The synthetic fertilizer production and emissions drive farm input impacts for all categories except ecosystem quality; therefore, improving fertilizer use efficiency is crucial to the reduction of environmental impacts through BMPs such as the 4Rs nutrient stewardship system - using the right fertilizer, right rate, right time and right place.

On-farm energy efficiency measures can be a significant potential mitigation area to reduce the environmental impacts of canola production. Reducing the number of passes and opting for operations that are less fuel intensive could reduce the impacts of field operations. It is important for industry to give priority to the high impact areas (i.e. hotspots indicating significant contribution to the total footprint) to ensure that targeted investments in BMPs yield significant environmental paybacks. Fertilizer management and tillage management BMPs are another potential mitigation strategy for reduction of environmental impacts. BMPs related to better fertilizer management are based on the "4R" nutrient stewardship principles. Potential greenhouse gas (GHG) emissions reductions ranged from 2% to 23% for fertilizer management. Depending on the tillage system, a potential reduction of impacts can be achieved by adopting conservation management practices such as no-till/zero-till and minimum/reduced systems. It can therefore be concluded that Alberta canola producers can manage their environmental impacts and footprint to a certain extent by continuing to adopt BMPs.

4.2. Alberta Potato Production

On-farm energy efficiency measures for potato storage and water pumping are important levers for growers, with significant potential for reducing the environmental impacts of potato production. Reducing the number of passes and opting for new measures, technologies, tools, or machinery that increase fuel efficiency could significantly reduce the impacts of field operations. Continued work on reducing water loss from sprinkler systems with variable rate irrigation and low pressure distribution systems at the farm would lower freshwater consumption. The "4Rs" of fertilizer management—the right product, right rate, right time and right place—could significantly reduce GHG emissions as well.

The potato growers have been adopting a number of BMPs related to fertilizer management, tillage management, irrigation management, and on-farm management. Over the past decade, Alberta potato growers have made steady progress in adopting many of the BMPs identified to reduce the environmental footprint of potato production. BMPs related to better fertilizer management were based on the 4R Nutrient Stewardship system. Potential impact reductions ranged from 1% to 25% for climate change and 11% and 13% for freshwater consumption. It can therefore be concluded that Alberta potato growers have opportunities to reduce the environmental footprint of their production through continuous improvement and adoption of BMPs.

4.3. Alberta Egg Production

Considering that the feed production stage is the main contributor to all impact categories, optimizing feed efficiency is a key lever to reducing the egg footprint. Furthermore, feed is one of the major contributors to the cost of production. Nonetheless, collected surveys indicate that feed efficiency can vary significantly between farms. The next step for industry should be to focus on working with nutritionists and published literature to produce appropriate recommendations to producers. Another significant impact is the production of feed, therefore promoting BMPs back to the feed producers could lower the egg footprint (lower impact of producing the feed will lead to a lower impact of the egg).

Due to the importance of energy consumption in the farm operations stage, energy reduction measures were investigated. Energy efficiency measures at farm could save up to 21% on electricity consumption. Implementation of renewable energy in the electricity grid mix or at farm could be also be beneficial, but to a lesser extent. The difference in the results between the baseline scenario and the use of 30% of renewable energy in the grid mix did not exceed 3%. Feed transport is the major contributor to transportation impacts. Therefore, increased proportion of farm-grown and locally grown feeds should be used for feed formulation to avoid the transportation of feed crops from the United States and other provinces.

4.4. Alberta Hatching Egg and Broiler Chicken Production

Optimizing feed efficiency is a key factor to reducing the environmental footprint of broiler production. Feed is one of the major contributors to the cost of production. Similar to egg production, collected surveys for this project indicate that feed efficiency can vary significantly between farms. As suggested previously with regard to eggs, a next step could be to focus on working with nutritionists and published literature to produce appropriate recommendations for producers. Hence, broiler producers would benefit from being informed regarding the research on feed efficiency in order to align all factors to favor a better feed conversion ratio (FCR).

Promoting beneficial practices to feed producers could significantly lower the broiler footprint (lower impact of producing the feed will lead to a lower impact for the broiler). In particular, an increased understanding and the adoption of BMPs for fertilizer use in feed production could be further investigated. Also, prioritizing on farm energy efficiency measures for space heating, phasing out of coal furnaces to natural gas powered furnaces, or implementing biomass or litter capable furnaces, would be beneficial to lower GHG emissions.

Being very similar to its broiler counterpart, hatching egg production can orient its priorities accordingly, particularly by reducing the FCR and using feed with a lesser impact. One important aspect to work on is hatchability, as only 79% of fertilized eggs are sold as broiler chicks. Reducing the loss rate would greatly improve the impact of this stage.

The key impact findings of this study can be addressed by adoption of BMPs related to feed, energy, and operational changes. GHG emission reductions can result in 1% to 5% for feed, and 1% to 33% for energy related BMPs. Hence, broiler chicken producers have considerable leverage over their environmental impacts by implementing certain BMPs.

5. Conclusion

Alberta Agriculture and Rural Development (ARD) commissioned the LCA of four commodities in order to better understand and quantify the environmental impacts of the province's agri-food industry. ARD is dedicated to ensuring that Alberta's agricultural producers remain competitive, adaptive, and responsive in the marketplace. With the studies completed, highlights and key findings have been documented for easy-to-communicate two-pager factsheets that will be distributed to industry associations and producers in an effort to raise awareness and highlight opportunities to reduce environmental impacts, especially GHG emissions and freshwater consumption. In addition, a calculator for producers to assess the footprint of their farm is available to all Alberta Egg Farmers online. This will enable the egg producers of Alberta to benchmark their farms and identify farm specific reduction opportunities. Later, stewardship initiatives to help producers implement environmentally, technically, and economically sound BMPs on their farms may be launched.

This holistic and systematic environmental assessment helps to identify environmental hotspots of primary production in Alberta and propose potential mitigation strategies that could improve environmental performance of the systems. Indeed, an opportunity to reduce GHGs and the shift by certain European jurisdictions toward a multi-criteria environmental food product labeling system has led to the creation of sustainability-based markets.

This study provides industry with a better understanding of the environmental profiles of conventional production in Alberta. The study also aimed to set out a scientifically robust and transparent environmental assessment of current practices of the industry. This Alberta benchmark will provide a way to measure improvements and focus on identifying opportunities to enhance the environmental performance of Alberta's agri-food industry. In addition to providing a benchmark, the work established a protocol for data collection and an approach for continuous improvement throughout the industry. The initiative will also serve as a model for the analysis of other local and international agricultural commodities.

ABSTRACT

Life cycle assessment was used to quantify the environmental impacts and identify supply chain hotspots for high oleic soybean oil (HOSO), conventional soybean oil (CCO), hydrogenated soybean oil (HSO), high oleic canola oil (HOCO), and conventional canola oil (CCO) for use in US restaurant fryers. On a cradle-to-grave basis, environmental impacts for fryer oil are a function of oil use rate, manufacturing burdens, and restaurant management behavior. Results identify 30%-45% reductions of impacts for high oleic oils relative to their conventional counterparts for the relevant impact categories evaluated. Impacts are similar for HOSO and HSO based on similar use-phase performance. The LCA highlights the importance of oil performance in use, nitrogen fixation of soybeans, allocation assumptions, and waste disposal considerations of the oil after use. Using LCA demonstrates that HOSO not only offers nutritional and functional benefits but allows restaurants to improve the environmental footprint of their oil ingredients.

Keywords: Soybean Oil, High Oleic Soybean Oil, Canola Oil, High Oleic Canola Oil

1. Introduction

Many markets are experiencing a trend towards sustainability. The fryer market is no exception as consumers demand healthier options, causing restaurants to respond in kind, but without wanting to sacrifice cost, taste, or quality. For more than 50 years hydrogenated oils have been the main stay in the fryer oil market, providing increased stability, long fry life, and low cost relative to conventional oils (AHA, 2010). However, health concerns about trans-fats have caused regional bans on their use including bans in New York, Philadelphia, and California (Tavarnise, 2013). Top chefs and restaurant chains are looking for alternative oils that are just as stable and cost effective but without trans-fat and lower saturated fat content. Recently, the FDA announced a preliminary decision to remove partially hydrogenated oils from the 'Generally Recognized As Safe' (GRAS) list which will continue to boost the need for alternative highly stable oils. To stay in the market, oil suppliers are met with the task of supplying drop-in replacement products which can meet the nutritional demands without increasing costs. A switch to conventional oils may meet nutritional requirements, but they do so at the expense of fry-life. High oleic soybean oil is now available in the U.S. market which provides both the desired functionally (fry-life & taste) in addition to eliminating trans-fats and reducing saturated fat content. To complement the nutritional and performance benefits of high oleic frying oils, this study takes a holistic approach, using life cycle analysis, to quantify the environmental impacts of high oleic frying oils in restaurant fryer applications relative to those for conventional and hydrogenated oils. The goal of the study is three fold:

- Quantify the importance of functionality and oil performance in the use-phase
- Identify hotspots within the fryer oil supply chain;
- Understand the importance and sensitivity of the assumptions used in the LCA

2. Methods

Attributional life cycle methodology is used to evaluate the environmental impacts associated with frying oil use in restaurants for conventional soybean oil (CSO), high oleic soybean oil (HOSO), hydrogenated soybean oil (HSO), conventional canola oil (CCO), and high oleic canola oil (HOCO). The study focuses on U.S. restaurant fryer oil applications. Oil availability, consumer demands, restaurant practices, oil transportation, and, of course, seed agronomics may all vary with geography. No comparative assertions are intended. Comparisons among different seeds are made to highlight hotspots within the supply chains for the US market.

2.1. Functional Unit

The functional unit for this system is based on days of fryer oil use in a restaurant. As restaurants have many variations in terms of food throughput, the types of foods fried, and hours of operation, more than one scenario is required. A base case, Scenario 1, assumes two days of fryer use and a 4% loss rate of oil to the food per day. An alternate case, Scenario 2, assumes six days of fryer use and a 10% loss rate of oil to the food. Both cases follow fry-life test results where high oleic oils and hydrogenated oils have increased stability, allowing twice the fry-life of conventional oils based on polar compound generation rates (see Section 2.4.4). For each scenario, high oleic and hydrogenated oils are charged once, while conventional oils require two charges. Top-off is assumed to occur each day if the oil has not been changed. All cases assume four (4) 22.7 kg (50 lb) fryers are used at the restaurant. These two scenarios are not all-inclusive, but provide perception into the impacts of food absorption rates and fry-life. Extended fry-life increases the number of times oil must be topped-off while higher absorption rates increase the amount of top-off oil required. Since high-oleic and hydrogenated oils require half as many charges, one less day's top off quantity is required in each scenario for these oils relative to conventional oil. Table 1 summarizes the oil use rates and wash cycles for each type of oil for each scenario.

Table 1. Fryer Oil Use Scenarios; Scenario 1: Two Days Fryer Use, 4%/day Oil Loss Rate; Scenario 2: Six Days Fryer Use, 10%/day Oil Loss Rate

		Scenario 1		**Scenario 2**	
		Conventional	**High Oleic / Hydrogenated**	**Conventional**	**High Oleic / Hydrogenated**
Oil, Charged	kg	181.4	90.7	181.4	90.7
Oil, Top-off	kg	0	3.6	36.3	45.4
Oil, Total	kg	181.4	94.3	217.7	136.1
Oil, Spent	kg	174.2	87.1	163.3	81.6
Wash Cycles	-	2	1	2	1

2.2. System Boundaries

The system boundaries for this study are illustrated in Figure 1. They include agricultural inputs, farming operations, seed processing, soybean and canola oil refining (and hydrogenation when required), transport along the supply chain as well as transport for the refined oil to a warehouse local to the restaurant, oil use in the restaurant, washing of the fryers, and spent oil disposal. Key exclusions from the system boundary are as follows:

- Health impacts (Scope of the study is on environmental impacts)
- Electricity to operate the fryers at the restaurant (equivalent in all cases)
- Conversion of spent oil at EOL to alternative products such as biodiesel, animal feed, or boiler fuel (This study uses a restaurant perspective – see section 5)
- Transportation from the warehouse to the restaurant (deemed negligible)
- Oil packaging (would increase with increased total oil use – i.e. higher for conventional oils)
- Indirect effects such as indirect land use change (attributional modeling employed; would increase with increased total oil use – i.e. higher for conventional oils)
- Infrastructure
- Sequestered carbon in oil (Study assumes all biogenic carbon sequestered in the oil is released via digestion (absorbed oil), combustion (spent oil), or biodegradation (spent oil).)

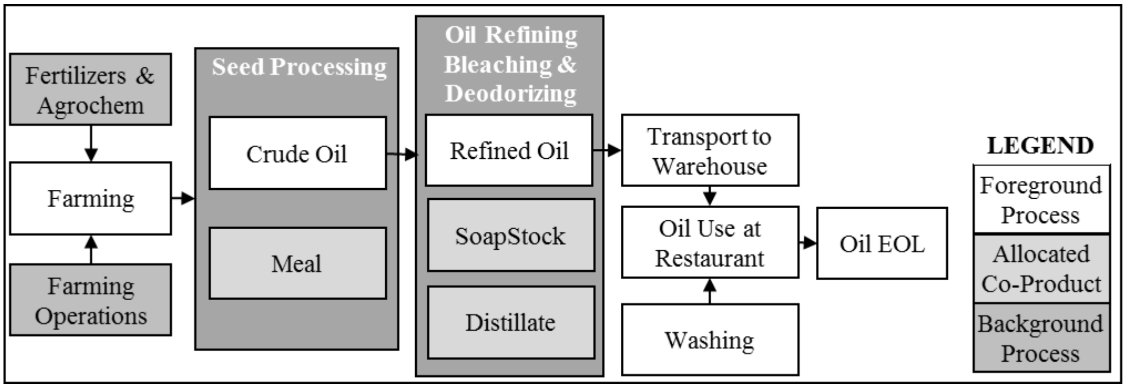

Figure 1. System Boundaries for Soybean Oil or Canola Oil.

2.3. Impact Categories

Based on the agricultural processes involved, the following impact categories were identified as relevant and included in this study: Climate Change Potential (CCP), Eutrophication Potential (EP), Acidification Potential (AP), Land Use, and Non-Renewable Energy Demand (NRE). The TRACI 2.0 impact assessment method is used for CCP, EP, and AP based on the U.S. focus for the study. NRE is calculated using the Cumulative Energy Demand (CED) Impact method. The CED model available in SimaPro™ software has been corrected to quantify all energy flows on a higher heating value (HHV) basis. Land Use is included and modeled using the impact category available in the ReCiPe Midpoint (Heuristic) model. Water use is both relevant and of interest, but is outside the scope of this study as this would require more regional information to provide meaningful results.

2.4. Process Models

2.4.1. Farming: U.S. Soybeans, Canadian Canola

U.S. soybean supply is virtually all domestically grown. A detailed life cycle analysis from the United Soybean Board (USB) is used as the basis for the soybean farming life cycle model (Omni-Tech, 2010). From 2007-2012, more than 65% of the canola oil supply to the US is imported, with most of that from Canada. A detailed life cycle assessment for the production of canola from the Canola Council of Canada (S&T2, 2010) is used which is deemed representative for the US supply chain and for US canola farming (S&T2, 2010; USDA, 2014). Ammonia air emissions and phosphorus and nitrate water emissions were adjusted or added such that both datasets used the same methodology for calculation (Nemecek & Kagi, 2007). Dinitrogen monoxide, a key field emissions contributing to CCP, has been updated since the original USB report from 0.35g N_2O per kg soybean based on DAYCENT modelling to 0.682 g N_2O per kg soybean based on actual field measurements in Minnesota. No carbon sequestration is included in either seed model as all carbon is assumed to be converted back to carbon dioxide at the end-of-life through digestion, combustion, or degradation.

2.4.2. Seed & Oil Processing

Data from the USB is used to model the burdens associated with soybean processing (Omni-Tech, 2010). Specific canola processing data is not available in the Canola Council of Canada LCA. Detailed and consistent data for a European rapeseed mill is available in the literature (Jungbluth, N., et. al., 2007; Schmidt, 2007). For this study, canola mill yields, solvent use, and energy consumption are taken from the thesis by Schmidt.

Since mill processing results in both oil and meal co-products allocation is required. This study uses economic allocation of the oil and meal for both soybeans and canola. For soybeans, average price and production data of US meal and oil from 2007-2011 per the USDA NASS oil crops yearbook (USDA, 2014) is used. For canola, price and production data are taken from Statistics Canada(StatCan, 2014). Sensitivity analysis for allocation methods is included in this study.

For high oleic oil allocation purposes, pricing for crude high oleic soybean and canola oil is assumed to be \$0.132/kg (i.e. \$0.06/lb) higher than conventional oil. No price differences are included for meal.

Refining, bleaching and deodorizing are required for both soybean oil and canola oil food applications. Both are modeled using the same oil refining process data (Schmidt, 2007). In addition to refined oil (98.7% by mass), soap stock and a distillate co-product are produced. Spot pricing for the co-products is used for economic allocation. The refined oil receives roughly 97% of the allocation.

Hydrogenation was modeled by accounting for energy (100 kg steam, 13 kWh electricity), Hydrogen (72 m3 at STP), refined soybean oil (1010 kg), and nickel catalyst (0.3 kg) required per tonne of hydrogenated soybean oil (Chakrabarty, 2009). Allocation for HSO is not affected by its higher price since hydrogenation occurs after both the milling and refining steps.

2.4.3. Transport: Refined Oil to Warehouse

The transport for refined oil to the restaurant is simplified to capture just the main portion of travel from the refinery to the warehouse local to the restaurant. As a base case, the restaurant is assumed to be in New York City, NY, requiring 900 miles of transport for soybean oil (i.e. distance from Rock Island, IL) and 2200 miles for canola Oil (from Prince Albert, Saskatchewan). Local transport from warehouse to the restaurant and backhaul is ignored. Sensitivity analysis on transport assumptions is included.

2.4.4. Use-Phase: Fry-Life and Washing

DuPont internal fry-life tests were performed for high oleic soybean oil relative to conventional soybean oil. For HOSO, oil stability, as measured by the composition of polar compounds in the oil reaching 25% during prolonged time at frying temperature, was at least twice that of conventional soybean oil. Actual fry-life is a function of restaurant cooking demand and restaurant behavior. This study assumes that the restaurant cooking demand results in either 2 or 6 days of fry life for HOSO and, half of that, 1 or 3 days, for conventional soybean oil. HOCO and CCO fry-life performance is estimated to be consistent with HOSO, and CSO, respectively. HSO is estimated to have the same fry-life as the high oleic oils (Pambau, et.al, 2010).

The washing procedure used in this study is based on Stratas Foods Fryer Tips (Stratus, 2009). Two fryer volumes of water are used for washing including 1 cup of vinegar per five gallons of water. The energy associated with the washing step is based on heating the water from 50°F to 200°F with electric heat. The same washing procedure is assumed for all oils. Washing is assumed to be done every time the oil is changed.

2.4.5. Spent Oil

Spent oil has several potential end-of-life scenarios after use in the restaurant. For instance, the spent oil may be used for animal feed, may be processed and used as fuel in a boiler, or may be processed to yellow grease and used as a feedstock to biodiesel generation. However, the restaurant typically does not control the end use for the oil. As it leaves the restaurant, the spent oil has free fatty acids generated during use and contains water and animal fats as well as other impurities. In the past, restaurants would need to pay for spent oil waste removal. Currently, many restaurants are having the oil collected without charge or credit, while some may receive a small credit. From the restaurant's perspective, an appropriate method to model the spent oil is via economic substitution. For the base case, we assume no burdens and no credits for the spent oil, so no adjustments, additions, or credits to the model are required to address the end-of-life (EOL) for the spent oil. Sensitivity analysis is included for modeling of spent oil.

Of note, no carbon sequestration is assumed in the production of soybeans or canola, so no carbon emissions associated with the spent oil need to be addressed at end-of-life. All carbon in the oil is assumed to return to the atmosphere as carbon dioxide via digestion, combustion, or decomposition.

2.5. Auxiliary Models

Throughout the process models, several background LCA models are required for electricity and fuel supply, minor chemical, fertilizers, farming operations, etc. In general, US-EI 2.0 database models are used. These models are based mainly from ecoinvent 2.2, where all electricity flows have been replaced with a US average electricity mix. Foreground models use region specific electricity.

3. Results

For each impact assessment, the burdens associated with different steps of the supply chain were segregated to identify their contribution to the total burden. The term ‘Farming’ includes the production, transportation, and application of fertilizers, soil emissions, and the on-farm energy. ‘Milling/ Refining’ includes all processing energy and impacts allocated to the oil including milling, solvent extraction, degumming, neutralization, bleaching, and deodorizing. For HSO, impacts associated with the hydrogenation are included as well. ‘Transportation’ refers only to burdens of transporting the refined oil to a warehouse local to the restaurant. ‘Washing’ refers to cleaning the fryers at the restaurant each time the oil is changed. For each oil type, Figures 2a-2e show the breakdown of impacts by these process areas.

The results presented are based on several assumptions and methodologies. Sensitivity analyses are required to understand the importance of these assumptions and to test the robustness of the magnitude of the impacts and the trends identified in the results. These are presented for fry-life and oil absorption, oil transportation from the warehouse, allocation methods, and spent oil allocation.

3.1. Scenario 1; 2 Days Fryer Use, 4% Oil Loss Rate

In general, under the assumptions in this study, environmental impacts follow the functionality of the oil. The increased oil stability due to the high oleic content or hydrogenation uses less oil, results in lower transport requirements and requires fewer washes. HOSO and HOCO achieve these savings at the expense of slightly higher allocation at the mill stage due to a higher valued oil product. HSO requires additional processing following the refining steps. Figures 2a-2e show the impacts broken down by process step for CCP, NRE, AP, EP, and Land Use, respectively. Across all impact categories, the increased oil stability provided by the high oleic oils and HSO result in roughly a 42%-47% reduction in impact relative to conventional oils.

3.1.1. Climate Change Potential

As shown for Scenario 1 in Figure 2a, CCP is dominated by the farming step for each oil type. For soybean oils in scenario 1 (2 days frying, 4% oil loss rate), farming contributes 53%-57% of the total impacts. Field N_2O emissions account for half of the soybean farming CCP burden, while emissions during quicklime production account for 24%, and emissions from fuel consumption at the farm account for 16%. Milling adds another 28%-31% to the overall CCP. HSO has slightly lower climate change impacts than HOSO. For CCP, the increased impacts from economic allocation for the higher priced HOSO are marginally higher than the burdens from hydrogenation for HSO. Although the overall CCP impacts for canola oil are higher than those for soybean oil, two-thirds of the difference is due to oil transport to the warehouse. Canola oil has higher CCP from farming due mainly to increased fertilizer use (particularly N-based fertilizers). Canola oil has 40% lower impacts in the milling process per kg oil relative to soybean oils.

3.1.2. Non-Renewable Energy Demand

Figure 2b shows the NRE impacts for Scenario 1. For soybean oils, milling and refining impacts account for 44%-50% of the total NRE impacts, while farming only accounts for 26-29%. Washing impacts are more important for NRE than for CCP, accounting for 18%-21% of the total NRE. Roughly 50% of the soybean farming NRE comes from on farm energy requirements. The impacts from HSO are 3% higher than those for HOSO. For canola, fuel use at the farm accounts for 45%, while the production of N-based fertilizers accounts for 44% of canola farming NRE impacts. Differences between soybean and canola oils are more pronounced for NRE as compared to CCP, mainly due to the higher fertilizer inputs for canola.

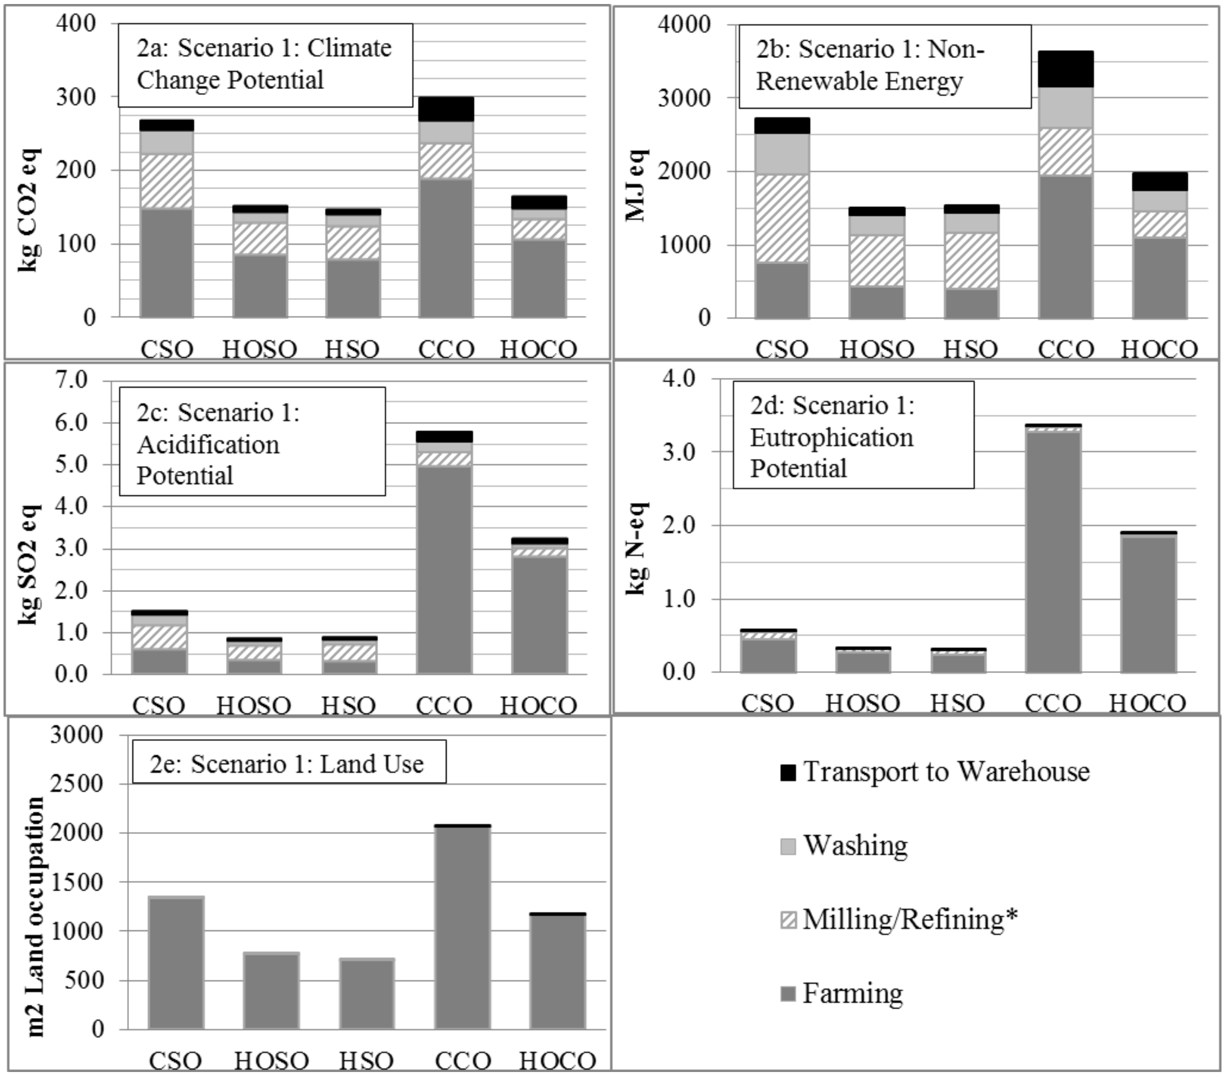

Figure 2a-2e: Impacts by Process Step and Oil type for Scenario 1. Impacts evaluated include Climate Change Potential, Non-Renewable Energy Use, Acidification Potential, and Eutrophication Potential, and Land Use.

3.1.3. Acidification Potential

Ammonia, nitrogen oxide, and sulfur dioxide are the three main emissions affecting acidification. In the frying use supply chain, these are released as field emissions, from fuel combustion throughout the supply chain, and from production of some N-based fertilizers. For soybean oils, where N-fertilizer demand is low because of the N-fixation properties of the legume, the fuel combustion pathway dominates. As shown in Figure 2c for Scenario 1, farming impacts are 38% of the total AP impact for soybean oils, with less than 12% from direct field emissions. For canola oils, field emissions of ammonia drive the AP impacts since fertilizer use is much higher, leading to much higher AP impacts than soybean oils. More than 85% of the AP impacts for canola oils come from farming with over 66% from direct field emissions.

3.1.4. Eutrophication Potential

Eutrophication is driven mainly by releases of nitrates, ammonia, phosphates, and phosphorus in this supply chain. Both soybean and canola farming play the major role for their respective oil co-products. As shown in Figure 2d, for soybean oil, farming accounts for 78%-80% of the total impacts, with nearly 30% from field emissions. The impacts from canola fertilizer requirements are even more pronounced for EP than seen above for AP, as farming accounts for more than 97% of the total EP potential with 72% from direct field emissions.

3.1.5. Land Use

Not surprisingly, agricultural land use is governed by farm yields, oil content, and the amount of soybeans or canola allocated to the respective oils. For CSO, at a yield of 2768 kg soybeans / ha, an oil content of 19.5%, and an economic allocation factor of 39.42%, 1368 kg crude soybean oil are produced per hectare. For CCO, at a yield of 1550 kg canola/ha, 42.6% oil content, and a 75.01% economic allocation factor, 880 kg crude canola oil are produced per hectare. Due to use of economic allocation for the base case, where high oleic oils are priced $0.132/kg higher than conventional oils, a higher allocation rate of seed is applied to HOSO and HOCO per kg of oil used. Therefore, for Scenario 1, although oil use rate drops by 48% due to high oleic oil stability, land use decreases only 43%. Based on economic allocation, canola oils require over 50% more land per 2-day fryer use in Scenario 1. Figure 2e shows the land occupation for each oil type for Scenario 1.

3.2. Sensitivity Analysis: Scenario 2; 6 Days Fryer Use, 10% Oil loss rate

In general, Scenario 2 impacts are higher than those from scenario 1, but with less differentiation between conventional and high oleic oils due to higher oil adsorption rates to the food. The benefits of additional oil stability are not realized for the oil that is absorbed. The importance of washing is diminished for Scenario 2 since washing burdens don't change compared to Scenario 1, but oil use rate increases. For a given oil type, the other relative impacts of farming, milling, refining, and transport are similar to Scenario 1. Impacts for conventional oils increase roughly 17-19% compared to Scenario 1while high oleic impacts increase 40%-42%. HSO impacts increase 37%, slightly less than high oleic oils due to economic allocation.

3.3. Sensitivity Analysis: Transportation Assumptions

Transportation of the oil is clearly a function of location. Selecting cities closer to the refinery would reduce the magnitude of the oil transport to the warehouse. Selecting different cities may also change the relative impacts of canola based oils versus soybean based oils, but would not affect the relative impacts of high oleic and conventional oils. In the base case, transport had the highest impacts on CCP and NRE, but still only account for 5-13% of the total impacts. Impacts for transportation for three other U.S. cities are presented to show the change in magnitude of impact due to distance and the relative impact across seed types. Table 3 shows the CCP impacts for both transportation and for the functional system for Scenario 1 for each city. The relative impacts from transport range from 1%-10% for soybean oils and 5% to 13% for canola oils. For Seattle, where the transport distance is greater for soybean oil than canola, the overall CCP burdens from Scenario 1 for the different seed types become equivalent instead of favoring soybean oil. For NRE, Scenario 1 transport impacts range from 1%-14% for soybean oils and 7%-15% for canola Oils depending on restaurant location. Unlike for CCP, the Seattle location still favors soybean oils over canola oils, but the relative difference is decreased from 30% to 15%. Transport has much less impact for AP, EP, and Land Use and does not result in any significant changes in relative impacts among oil types for any restaurant location evaluated.

Table 3. Transportation Sensitivity: Transportation and Total Impacts for Scenario 1, CCP, at various U.S. Cities

Restaurant Location	Distance, km			CCP, kg CO2 eq.				
	Soybean	Canola		CSO	HOSO	HSO	CCO	HOCO
New York City, NY	1450	3540	Transport	13.1	6.8	6.8	32.1	16.7
			Total	**268**	**151**	**146**	**300**	**165**
Seattle, WA	3080	1820	Transport	27.9	14.5	14.5	16.5	8.6
			Total	**283**	**159**	**154**	**285**	**157**
Los Angeles, CA	2990	4410	Transport	27.1	14.1	14.1	40.0	20.8
			Total	**282**	**158**	**154**	**308**	**169**
Chicago, IL	270	2210	Transport	2.4	1.3	1.3	20.0	10.4
			Total	**257**	**146**	**141**	**288**	**159**

3.4. Allocation Methods

Central to LCA methodology is how to address the burdens associated with co-products. Allocation choices affect both the magnitude of impacts for all oil types and the relative impacts between soybean oils and canola oils since soybeans and canola have significantly different oil and meal compositions. The referenced USB LCA study for soybeans used mass allocation of soybean oil and soybean meal at the mill. However, the two co-products have significantly different value. Further, soybean meal is actually valued on its meal protein content, not just its overall mass since it may be sold with and without the hulls. This study has used economic allocation as the base case to address the difference in value of the two co-products. This prevents favoring soybean oils relative to canola oil based on the higher meal content in soybeans. A downside to economic allocation is price fluctuation. Since oil and meal serve different markets, they do not necessarily vary in the same manner. However, these fluctuations are dampened by averaging across multiple years of production.

For comparison to the base case economic allocation method (ECON), two additional allocation techniques are investigated, including mass allocation (MASS) as used in the USB report, and mass allocation between the meal protein content and the oil content in the seed (MASS-MP). The MASS-MP basis combines the simplicity of mass allocation with the valued aspects of the two co-products. Process subdivision was not credible for the mill stages due to both processing and energy integration.

Meal protein concentrations for soybeans from the United Soybean board and have been averaged across the 2007-2010 time horizon at 44.2% of soybean meal (USB, 2010). Meal protein content for canola meal is reported at 36% (S&T2, 2010). Results for CCP based on scenario 1are shown for each oil type and each allocation method in Figure 3 along with the mill allocation factors for each allocation method. Mass allocation results are 32%-45% lower than economic allocation for CCP. Reductions are higher for soybeans where more meal is produced relative to oil and for high oleic oils where the oil has higher value. While still lower, the MASS-MP results are much closer to economic allocation results since meal is priced on protein content. For each impact category evaluated, using mass allocation or MASS-MP allocation generally reduces the overall impact for fryer oil use, increases the differentiation between soybean oil and canola oil, and results in HSO being consistently higher than HOSO due to the impacts from hydrogenation

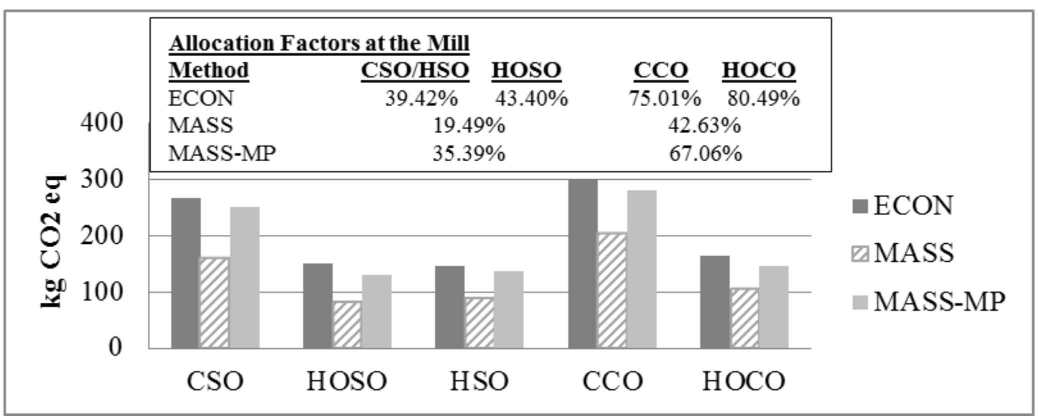

Figure 3: Allocation Sensitivity: CCP Impacts for Scenario 1 using Economic, Mass (Meal/Oil), and Mass-MP (Meal Protein/Oil) Allocation Methods. Allocation factors at the mill are included for reference.

3.5. Spent Oil Sensitivity

As demand for biodiesel increases, the potential outlets for spent oil for the restaurant owner may become more plentiful and profitable. While the current scenario assumes no burdens or credits for the spent oil, this sensitivity analysis assumes the restaurant receives \$0.11/kg (i.e. \$0.05/lb) for the spent oil on a dry basis. It is modelled as an economically equivalent quantity of crude (i.e. extracted) conventional oil that is avoided from the overall burden of the fryer system. In other words, roughly 0.1 kg crude soybean oil is avoided per 1 kg spent soybean oil produced. No packaging materials are considered with respect to spent oil collection.

For scenario 1, overall impacts are reduced 6%-10% for conventional oils depending on the impact category, and 5.5%-8.1% for high oleic oils, with the reduction being 15% more for conventional oils than for high oleic oils for any specific impact category. For scenario 2, overall impacts are reduced 4.5%-5.9% for conventional oils but only 1.7%-2.5% for high oleic and hydrogenated oils. Figure 4 highlights the CCP impacts with and without the spent oil credit for conventional and high oleic soybean oil.

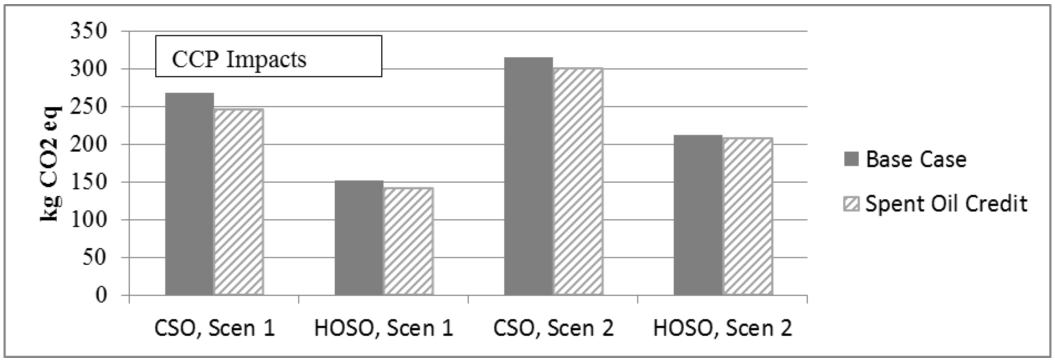

Figure 4: Spent Oil Sensitivity: CCP impacts for CSO and HOSO for both Scenarios 1 and 2 for the base case and assuming a $0.11/kg spent oil credit.

4. Discussion

When comparing among the environmental impacts evaluated in this study of the three soybean oil options, oil performance and restaurant behavior account for the majority of the differences in impacts, while mill co-product allocation, spent oil allocation, and oil processing have more subtle impacts. The increased stability of both the high oleic and the hydrogenated oils allows for lower oil use rates and fewer washes at the restaurant. The amount of food cooked during the day will affect the oil absorption rate, with increased absorption dampening the environmental benefits of the HOSO and HSO since the benefits of increased stability are not realized for absorbed oil. Impacts can be reduced as much as 48% based on the increased stability compared to CSO. As absorption rates increase from 4% to10% the differentiation among CSO and HSO environmental impacts is reduced by 20%. The allocation methodology can have significant impacts to the overall environmental burdens of the soybean oil options. Mass allocation results in impacts as much as 40% lower than economic allocation, but has less importance when differentiating among the oils types. For instance, CCP for HOSO is 44% lower than CSO using economic allocation and 48% lower using mass allocation. The environmental impacts of increased processing required for hydrogenation for HSO counterbalances the higher economic allocation impacts of HOSO, resulting in 4% to 6% lower impacts than HOSO for CCP and EP, but 3%-4% higher impacts for NRE and AP. For MASS and MASS-MP allocation methods, HSO consistently has higher impacts than HOSO. Soybean yields, farming practices, electricity mix assumptions, and oil transport distance do not serve to differentiate among these options since they are the same for each. Similar conclusions can be made when comparing CCO to HOCO.

However, when comparing different types of oils, such as CSO to CCO, or HOSO to HOCO, other facets of the oil supply chain become important. Farming fertilizer use is significantly higher for canola, leading to increased impacts for canola oil, particularly for AP and EP. As legumes, soybeans have N-fixating capabilities which significantly reduce the amount of N-based fertilizer required. This, in turn, reduces CCP, AP, and EP due to reduced fertilizer production impacts and field emissions. Crop yield favors soybeans as canola is shown to require as much as 50% more land under Scenario 1 assumptions. Although modeled with similar emissions per hectare, nitrous oxide field emissions have a substantial impact on the overall climate change and the relative impacts for soybean and canola oils. These emissions will likely differ by region for each crop, local field conditions, farming practice, etc., and have perhaps more than 100% uncertainty based on the USB report where N_2O emissions increased two-fold as they moved from calculated emissions to a site specific measurement (Omni-Tech, 2010). Finally, transport of the oil becomes more important. Although only 1%-13% of the total CCP impact for the cities evaluated, the transport model assumptions can represents more than 60% of the relative difference between soybean and canola oils for CCP. Transport accounts for roughly 30% of the difference between soybean oil and canola oil for NRE with little to no impact on AP, EP, and Land Use.

5. Conclusion

Overall, oil functionality was shown to be a key driver and a new handle on reducing environmental impacts for frying oil applications. Improvements to oil stability facilitated by high oleic seeds reduces oil use requirements and restaurant washing requirements. Increases in economic allocation factors for the high oleic oils do not dampen the impact reductions significantly. Restaurant behavior in terms of food throughput and oil replacement frequency as well as the food's oil absorption rate may significantly influence the extent of benefit. Similar environmental impacts are seen for HSO in comparison to HOSO as they both provide similar increased oil stability, but the hydrogenated oil alternative is compromised with trans-fats and higher saturated fat content. While yield, allocation methodology, transportation assumptions, and spent oil allocation all have the potential to affect the overall magnitude of frying oil environmental impacts, and may influence comparison across oils from different seeds, they have limited impact when comparing high oleic and conventional oils from the same feedstock. In addition to having nutritional benefits, high oleic soybean oil has been shown to reduce all environmental impacts evaluated in this study relative to conventional soybean oil for fryer use in the U.S.

Creating coherent life cycle databases for ecodesign and product declaration of agroindustrial products: how to deal with contradictory methodological requirements

Jens Lansche *, Patrik Mouron, Thomas Nemecek, Gérard Gaillard

Life Cycle Assessment Group, Institute for Sustainability Sciences, Agroscope, Zurich, Switzerland

ABSTRACT
Existing guidelines and standards for creating LCI databases provide partly contradictory requirements which lead to initiatives that aim on harmonization. As the harmonization is still ongoing, this challenges current database projects to find a scientifically sound and applicable way to establish coherent datasets. We present a four-step approach to deal with this challenge. Based on our experiences in the two ongoing projects ACYVIA (Analyse de CYcle de Vie dans les Industries Agro-alimentaires) and WFLDB (World Food LCA Database) we draw the following conclusions: it has been shown that by following the proposed approach, most contradictory advices from different guidelines do not appear because the number of relevant guidelines can be reduced. Creating a database that allows different methodological decisions can be achieved by clearly defining and reporting all methodological decisions that are followed. For existing contradictory requirements, decision criteria are presented that can be taken into consideration to decide for one specific requirement.

Keywords: LCI database, agri-food sector, methodological guidelines, harmonization

1. Introduction

Agricultural production systems and the processing of agricultural raw materials to food products contribute significantly to several environmental impacts like global warming, eutrophication and acidification (Pardo and Zufia 2012; Ruviaro et al. 2012; Saarinen et al. 2012). Emissions from agricultural production systems show a high temporal and spatial variability which is a reason for a high variability of environmental impacts of these systems (Mouron et al. 2006; Roy et al. 2009; Nemecek et al. 2012; Rees et al. 2013). These facts together with an increasing public interest enforce the demand for LCI data in the agri-food sector in companies, science and governments in the last years. Various guidelines exist (see Table **1**) with partly contradictory requirements which causes confusion (Finkbeiner 2014). A recent review of such reference methods conclude that flexibility with respect to methodological standards is more common than prescriptive requirements are (Pelletier et al. 2014) In this context, several initiatives and projects deal with the creation on LCI databases that are either focused on the agri-food sector or cross-sectorial including agri-food related content, e.g. ACYVIA (Bosque et al. 2012), Agri-BALYSE® (Koch and Salou 2013), Asian Agri-Food database (Hayashi 2013), Australian LCI Database initiative (ALCAS 2014), Base IMPACTS® (ADEME 2014), Chilean Food and Agriculture LCA database (Emhart et al. 2013), ecoinvent (Weidema et al. 2013), ELCD (JRC 2014), World Food LCA database (Lansche et al. 2013).

This paper wants to start a discussion on the question how one can deal with the situation of existing guidelines and standards with contradictory requirements when creating an LCI database. The focus is on LCI modelling and the ideas presented are not final solutions but aim on being a starting point for further discussions. Basically, three steps are presented:

1) Categorizing the database to select the appropriate standard, guideline or tool for the purpose of the database to avoid contradictions
2) Showing an example for dealing with the requirement that a database should be applicable for different purposes
3) Developing basic principles on how to deal with remaining contradictions

Table 1. Non exhaustive list of existing guidelines and standards.

2. Methods

The following methodological procedure is a proposition on how a coherent database could be created given the various guidelines and methodological recommendations as illustrated in Table **1** above. We suggest a procedure with the following main steps:

- Step 1: Categorizing the database as "general database" or "specific database". For categorizing a database we propose to use specifications for the geography, application, and sector that are addressed given in Table **2**.
- Step 2: Identify the most relevant guidelines (from Table **1**) related to the database.
- Step 3: Identify the methodological options that are crucial for the database. Options for LCI occur e.g. for system boundary choice, direct emission modeling, allocation methods, end-of-life modeling, data source choices and the kind of dataset documentation.
- Step 4: Decide which options to use in order to meet the criteria according to Table **2**.

This four-step procedure is applied to two ongoing database projects that are:

- WFLDB (World Food LCA Database): This project is developing datasets for selected agricultural primary products as well as food and beverage products produced in the most relevant countries that supply the global market.
- ACYVIA (Analyse de CYcle de Vie dans les Industries Agro-alimentaires): This project addresses environmental product declaration of food transformation processes at national-level in France.

Table 2. Categorizing food databases

Criteria	**General database**	**Specific database**
Geographical specification	Global, multi-national	National, regional
Application addressed	Ecodesign and Environmental product declaration (EPD)	Ecodesign or Environmental product declaration (EPD)
Sectorial specification	Agriculture and food industry	Agriculture or food industry

3. Results

Categorizing databases

The two database projects WFLDB and ACYVIA can be clearly categorized with as "General database" and "Specific database", respectively (Table **3**). Table 2 shows also that the two project differ very much in the order of guidelines that are most relevant for each project. For ACYVIA the BPX guidelines are of the highest importance defining methods for LCI modelling, system boundaries, allocation, end-of-live modelling whereas the ILCD entry-level is of importance regarding the method for data quality assessment and the selection of external reviewers. As a consequence, in case of the ACYVIA database practically no methodological options are left since BPX defines them all for EPD in France. In contrast, for WFLDB due to the wide range of geographical, sectorial applications a number of methodological decisions according to ISO 14044/ 44 have to be taken. In practice this means that for each methodological issue one option has to be chosen. Such choices need to be described in the documentation of the database. But whatever option is chosen, it might be that for a certain database user and for certain applications this methodological option is not the one that suits well. Therefore we model a methodological option in a reversible way, that means, the user will have the opportunity to calculate backwards and to apply another methodological option that fits to the desired application. This is e.g. the case when economic allocation is applied.

In the following we will illustrate for the case of modelling "heavy metal uptake by crops" what is meant by reverse modelling:

Table 3. Categorizing WFLDB and ACYVIA database and associated relevant guidelines

	WFLDB **General database**	**ACYVIA** **Specific database**
Geographical specification	Global	National
Application addressed	Ecodesign and EPD	EPD
Sectorial specification	Agriculture and food industry	Food industry
Guidelines (order of importance)	1. ISO 14040/ 44 2. ILCD handbook 3. ENVIFOOD 4. Others	1. BPX 30-323-0 2. ILCD entry-level 3. ISO 14040/ 44 4. Others

Reverse modelling of heavy metal uptake by crops

In crop production heavy metals (e.g. Cadmium) will be imported to the field by inputs such as mineral fertilizers. On the field the plant is taking up nutrients but also heavy metals that will be exported from the field with the harvested crop. In case the whole life cycle (i.e. from cradle to grave) is assessed the amount of heavy metal exported by the crop is of interest since this might cause toxicological problems at another place (e.g. waste water treatment after consumption and digestion). But if the LCA addresses only the crop production on the field (i.e. cradle to gate) the uptake of heavy metal could lead to unrealistic “credits” and therefore want to be excluded from the assessment. We suggest to model heavy metal in that way that the uptake to the plant can be set to zero, if needed.

4. Discussion

We proposed a first approach how one can deal with the situation of guidelines and standards with contradictory requirements when creating an LCI database. The three criteria (geography, application, economic sector) for categorizing databases have been sufficient for the two projects WFLDB and ACYVIA but its sufficiency and applicability need to be proved in practice with other databases.

If contradictions remain, we propose to develop a hierarchy of basic principles that support to make appropriate methodological decisions in respect to LCI modelling. Such criteria can be:

- scientific nature of the requirement
- internal consistency of the database
- acceptance by stakeholders

The ideas presented have to be further developed and tested more comprehensively in practice.

5. Conclusion

By categorizing databases, relevant guidelines can be selected. This helps to identify the relevant methodological options. By following this approach, most contradictory advices from different guidelines do not appear because the number of relevant guidelines can be reduced for each individual database.

ABSTRACT

In this paper, GHG emissions of biogas systems based on food industries residues are analysed according to the method described in the ISO-standard for life cycle assessment. Furthermore, two perspectives are included, one where the residues are not utilised for other purposes today and one where the residues are utilised as animal feed, here presented as systems expansion. The results show that all residues studied are well suited for biogas production if there is no demand for them as animal feed today. Otherwise, it is often more efficient to grow dedicated biogas crops directly.

Keywords: biogas, food industry residues, feed, LCA

1. Introduction

Production of food results in various kinds of food industry residues that can be utilized in different ways depending on their individual features and demand from other market sectors. Often, such residues are used as feed but in some regions this demand decreases due to changes in livestock production. Also, there is a growing market for biofuels where such feedstock could be utilized as well. Recently, the use of industrial residues for the production of biogas as transportation fuel has also attracted a great deal of interest since such production does not compete directly with the use of agricultural land. However, only a limited number of studies quantifying greenhouse gas (GHG) emissions from such biogas systems have been performed. For comparison, the environmental performance of other biofuels such as ethanol and biodiesel as well as biogas from waste and dedicated energy crops has been investigated in several studies (see e.g. Börjesson and Tufvesson, 2011, JRC, 2007, Kendell and Chang, 2009 and Reijnders and Huijbregts, 2008). Also, if the demand for feed remains and such feedstock are used for biogas production, they must be replaced by other animal feed. This may shift the environmental burden from one system to another and needs to be included in a system analysis.

In this paper, which is mainly based on the findings presented in Tufvesson et al. (2013), GHG emissions from different biogas system, where biogas is utilized as a vehicle fuel produced from industrial residues, are analyzed and compared from a life-cycle perspective including different utilization pathways for the residues. Residues included are distiller's waste, rapeseed cake, whey permeate, fodder milk and bakery residues. Also, calculated GHG emissions from biogas systems based on food industry residues are compared to corresponding emissions from biogas systems based on dedicated energy crops.

2. Methods

The analysis is based on the principles described in the ISO standard 140 44 (ISO, 2006). The functional unit is 1 MJ of upgraded and compressed biogas at the biogas plant. Included life cycle emissions of GHG are carbon dioxide (CO_2) of fossil origin, methane (CH_4) and nitrous oxide (N_2O). Characterization factors are set to 1, 25 and 298 g CO_2-ekq./g CO_2 respectively (IPCC, 2006a).

Data is presented for two scenarios; no allocation and system expansion. In the scenario with no allocation all feedstock are considered as residues and no emissions are allocated to them before entering the biogas system. In addition to the upgraded and compressed biogas, all biogas systems also generate digestate which is applied to arable land as a fertilizer. Thus, GHG emissions could be allocated between biogas and digestate. However, this digestate has no clearly defined value today and due to its low dry matter content, it is not considered to have a heating value either. Thus, all GHG are allocated to the biogas produced (Tufvesson et al., 2013). When system expansion is applied, food industry residues are assumed to be replaced with soymeal and barley as animal feed. Also, in the case with system expansion, the digestate is assumed to replace mineral fertilizer.

Inventory data for biogas production and upgrading are collected to represent average new technology that is commercially available today. Inventory data for generation of electricity used in the biogas system, production of mineral fertilizers and animal feed has been chosen to represent average products used in Sweden today.

2.2. Investigated substrates

The substrates investigated in this paper have different features which affect the production of biogas and digestate as well as the amount of mineral fertilizers and animal feed that can be replaced. Also, the same kind of food industry residue could have different features depending on the original raw material and how it has been processed. The features assumed in this study are presented in Table 1. Further background on assumptions made can be found in Tufvesson et al. (2013).

Table 1. Features of analyzed substrates (Tufvesson et al., 2013).

Substrate	DM[a]	Plant available nutrients (% of DM)			Methane yield	Corresponding feed (kg DM/kg DM substrate)	
	(%)	N	P	K	Nm^3/tonne DM	soy meal	barley
Distiller's waste	8,0	4.0	0.9	1.1	302	0.4	0.6
Rapeseed cake	91	5.0	1.2	0.7	422	0.7	0.3
Whey permeate	5,0	0.5	0.8	2.5	309	0	1.1
Fodder milk	9,0	3.9	0.8	1.0	472	0.4	1.5
Bakery residues	61	3.7	0.2	0.4	304	0	1.0

[a] Dry matter

2.3. Analyzed biogas systems

It is assumed that all food industry residues are transported by truck to a centralized co-digestion plant where biogas is produced, upgraded and compressed. Corresponding to the system boundaries applied by Börjesson *et al.* (2010) further transportation of compressed biogas is not included. The transportation distance is set to 10 km for liquid substrates and 30 km for rape seed cake and bakery residues and the energy input for transportation is set to 1,1 MJ/tonne*km (Börjesson and Berglund, 2006).

Electricity consumption at the biogas plant is set to 30.2 MJ/tonne of substrate in addition to the electricity used for upgrading and compression which is set to 1.6 and 1.3 MJ/Nm^3 of biogas respectively. Emissions are based on average Swedish power production and corresponds to 11 g CO_2-eqv./MJ. Also, it is assumed that the biogas plant use 93.6 MJ of biogas to produce process heat (Lantz et al., 2009; Tufvesson et al., 2013).

The methane leakage is set to 1.5% of the biogas produced including biogas production, upgrading and digestate storage at the plant representing a modern biogas plant. For comparison, the average methane losses from Swedish co-digestion plants and upgrading plants were 1.8% and 1.4% respectively in 2012 (Avfall Sverige, 2012). However, there are also biogas plants with state of the art technology where methane losses could be 0.5% or lower.

The digestate produced is transported 10 km by truck, stored in covered concrete tanks and spread on arable land by tractor. Based on IPCC (2006b) it is assumed that there will be no direct emissions of N_2O from the digestate storages. Emissions of NH_3 from the storage tanks are set to 1 % of the total amount of nitrogen in the digestate which also cause indirect emission of N_2O (IPC, 2006b). The amount of indirect N_2O is calculated based on equation 1.

$$N_2O = N*EF*(44/28) \quad \text{Eq. 1}$$

N_2O = indirect emissions of nitrous oxide
N = emissions of nitrogen as NH_3-N (kg N)
EF = emission factor, which is here set to 0.01 kg N_2O-N/kg NH_3-N

In the system expansion, indirect emissions of N_2O from spreading of the digestate are included as well. These emissions are calculated according to Equation 1 assuming that 5 % of the total amount of ammonium nitrogen in the digestate is lost at NH_3.This assumption requires good spreading techniques as well as appropriate weather conditions (Tufvesson et al., 2013).

The amount of mineral fertilizers that could be replaced by digestate is presented in Table 1. Based on the market situation in Sweden, it is assumed that 30% of the mineral nitrogen is produced with catalytic N_2O reduction resulting in average emissions of 6.7 kg CO_2-eqv./kg N. For P and K, emissions are set to 3.2 and 0.5 g CO_2-eqv./kg respectively (Tufvesson et al., 2013).

In addition to the nutrients presented in Table 1, digestate also contains carbon compounds of which some will form stable humus in the soil. In this analysis it is assumed that 40% of the dry matter in the digestate is carbon and 10% of this carbon is conservatively estimated to form long-term stable soil organic matter. A more comprehensive background for this assumption is presented in Tufvesson et al. (2013).

The assumed amount of crops needed to replace the various substrates as animal feed is presented in Table 1. GHG emissions from production of soybean meal and barley are set to 980 and 450 g CO_2-eqv./kg DM respectively (Flysjö et al., 2008). Emissions are calculated assuming average cultivation conditions, including direct land-use change, but not any indirect land-use change.

3. Results

In Figure 1 the contribution to global warming potential is shown for the biogas systems analyzed. The results vary considerably between the case with no allocation and the case with system expansion. However, for all the systems studied the contribution to global warming was lower than for petrol and diesel. In Table 2 it is clearly seen that the parameters that contribute most to the global warming potential are the replacement of mineral fertilizers and animal feed in the system expansion.

In figure 2, GHG emissions from biogas systems based on food industry residues, including system expansion, are compared to biogas systems based on cultivated crops, dedicated for biogas production. Although all biogas systems reduce GHG emissions compared to petrol and diesel, it is clear that the reduction is higher when dedicated energy crops are utilized.

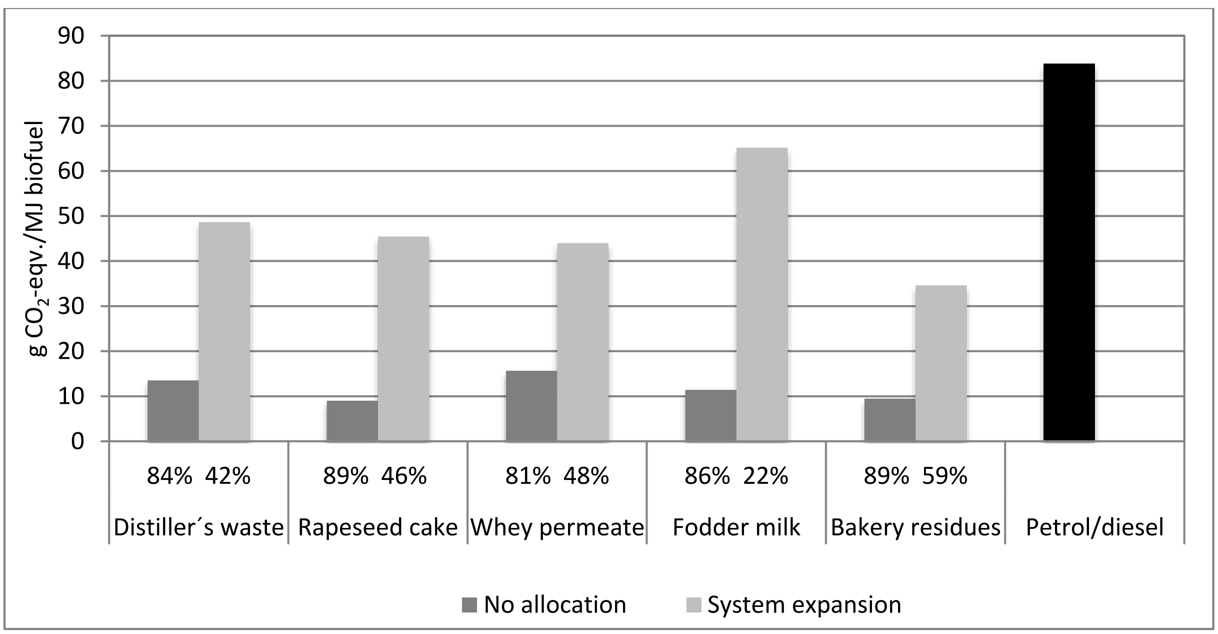

Figure 1. Contribution to global warming potential from biogas based on industrial residues (taken from Tufvesson et al., 2013). The reference for petrol and diesel is set to 83,8 g CO_2-eqv./MJ (European Commission, 2009).

Table 2. The total contribution and most important parameters contributing to global warming potential when no allocation and system expansion is applied (taken from Tufvesson et al., 2013).

Substrate	**Global warming potential (g CO_2-eqv./MJ biogas)**							
	Transport[a]	**Process energy**	**Methane leakage**	**Digestate**[a]	**Total no allocation**	**Mineral fertilizer**	**Animal feed**	**Total system expansion**
Distiller's waste	1.1	1.5	7.5	3.5	13.6	-23	58	49
Rapeseed cake	0.2	0.9	7.5	0.4	9.0	-19	55	45
Whey permeate	1.5	1.4	7.5	4.9	15.3	-8	38	44

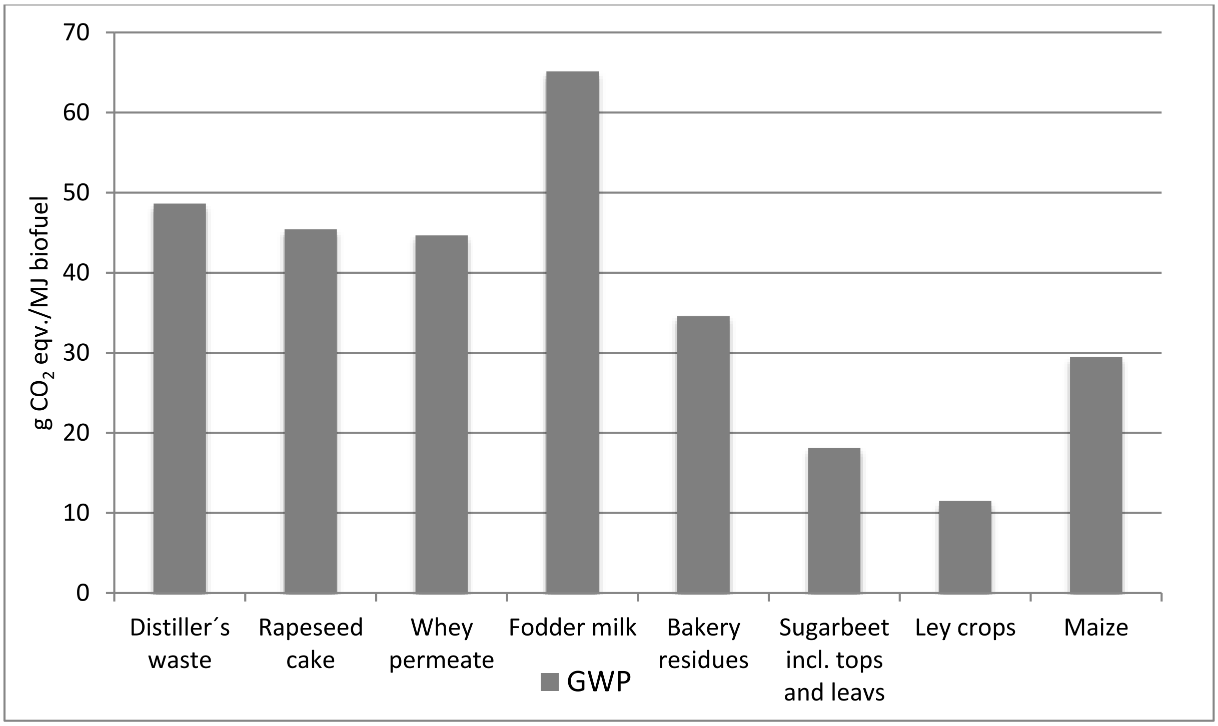

Figure 2. Contribution to global warming potential when system expansion is applied for biogas from industrial residues and dedicated crops (unfertilized grassland as reference land-use) taken from Börjesson et al., (2010).

4. Discussion

Many kinds of food industry residues are well suited for biogas production since they contain organic matter that could relatively easy be degraded in an anaerobic process. The residues are also concentrated to few industrial sites and could easily be transported to a biogas plant in the vicinity of the site or on the site. When the biogas produced is utilized to replace fossil fuels, all analyzed biogas systems also reduce GHG emissions compared to petrol and diesel. This approach is also encouraged by the debate on iLUC factors and the promotion of using residues and waste for biofuel production which e.g. is the case in the EU's Renewable Energy Directive (European Commission, 2009). However, this is a simplified view based on a limited systems perspective since it does not include the potential alternative utilization of the residues. If there is a demand for the residues as feed, their utilization as biogas feedstock will be compensated for by, e.g. new feed crop production. According to the ISO-standard of LCA (ISO, 2006), system expansion should also be applied when possible to cover all relevant indirect effects influencing the result.

As presented in this study, the utilization of food industry residues as feed, if there is such a market, will thus result in the highest reduction of GHG. Food industries considering the best way how to handle their organic residues from a greenhouse gas perspective should thus closely evaluate the possibility to utilize such residues as feed. However, if there is no such market, biogas production is a suitable alternative.

5. Conclusion

Food industry residues analysed in this paper are well suited for biogas production and the reduction of greenhouse gas emissions will be substantial compared with fossil vehicle fuels. One important prerequisite is, however, that the industrial residues cannot be utilized as animal feed. Otherwise, the benefits will be significantly reduced due to additional production of feed crops. If so, it could be more efficient to grow dedicated biogas crops and continue to utilize the industrial residues as animal feed.

ABSTRACT

The use of biowaste compost on land can have beneficial effects on the plant–soil system. While the environmental impacts associated with compost production have been successfully assessed in previous studies, the assessment of the benefits of compost on plant and soil has been only partially included in few published works. In the present study, we reviewed the recent progresses made in the quantification of the effects associated to biowaste compost use on land by using life cycle assessment (LCA). Different research efforts are required for a full assessment of the potential benefits, apart from nutrient supply and carbon sequestration; additional impact categories – dealing with phosphorus resources, biodiversity, soil losses, and water depletion – may be needed for a comprehensive assessment of compost application. Several of the natural mechanisms identified and the LCA procedures discussed in the paper could be extensible to other organic fertilizers and compost from other feedstocks.

Keywords: sustainable agriculture, organic fertilizer, biowaste, soil organic matter, soil quality, biodiversity, carbon sequestration

1. Introduction

There is increasing concern about soil interrelated environmental problems such as soil degradation, desertification, erosion, and loss of fertility (European Commission 2006). These problems are partially consequence of the decline in organic matter content in soils. An estimated 45% of European soils have low soil organic matter (SOM) content, principally in southern regions (European Commission 2006). A parallel concern is the massive generation of organic waste by human activities in urban areas. Composting is one of the best-known and well-established processes to recycle organic waste. Composting allows the stabilization and sanitation of organic waste through accelerated aerobic decomposition under controlled conditions, resulting in a product called compost.

Several studies indicate that the use of compost on land may improve several plant and soil parameters, thereby making compost an interesting option for soil restoration purposes, while taking advantage of its fertilizer properties. On the other hand, the application of compost may also potentially result in environmental and agronomic drawbacks, such as gaseous and leachate emissions, and increase in salt and heavy metals content in soil (Hargreaves et al. 2008). Nevertheless, these issues are in general directly associated with the quality of the final compost and agronomic management.

Life Cycle Assessment (LCA) was promoted in different European directives as a robust quantitative tool and has been widely used for the environmental assessment of waste and agricultural sectors. The negative environmental impacts associated with compost production and transport, particularly in the case of compost produced from municipal solid waste, have been successfully assessed in previous studies (ROU 2007; Boldrin et al. 2009; Martínez-Blanco et al. 2010; Colón et al. 2012). However, assessment of most of the potential environmental benefits of compost on plant and soil has not been carried out yet. Several recent studies address the inclusion of compost benefits in a qualitative manner, recommending that further research should be undertaken on the subject (Boldrin et al. 2009; Favoino and Hogg 2008; Hansen et al. 2006; Martínez-Blanco et al. 2011). Nevertheless, carbon sequestration and nutrient supply are, to date, the only environmental benefits taken into account in these studies. Because of the modeling complexity, ROU (2007) is, to our knowledge, the only study that attempted including most of the abovementioned benefits within LCA of two Australian case studies. The results were however only presented at the inventory stage.

The main goal of this review paper is to quantitatively address LCA modeling of the positive potential effects traditionally associated with land application of biowaste compost produced from organic municipal solid waste and garden waste. Here we have focused only on the implications of compost application to the soil and plant without considering the full life cycle (i.e. production process and transport are not discussed here).

2. Methodology

A comprehensive review of the literature dealing with the potential benefits of compost application and the current situation of the inclusion of each of these benefits in LCA studies was carried out. First, the most relevant benefits of compost on soil properties and plant growth were identified and the inventory data was collected. Subsequently, 90 articles (including both reviews and case studies) published later than 1990 were selected. Although similar environmental and agronomical benefits could be observed in compost produced from other types of feedstock and in other organic fertilizers, in this review field studies considering compost from organic municipal solid waste and green waste (from now on called biowaste) were taken into account when possible. The potential benefits were grouped into nine categories (Table 1). According to the literature review, the benefits were classified into short-term (1 year), mid-term (1–10 years), and long-term (10–100 years), depending on the time perspective of the agronomic effects.

Later on, the potential benefits studied were reviewed, through an LCA perspective, according to: (1) the existing evidences for the effects on soil, plant, environment, farmer or harvest and the main factors affecting the results for each of them; (2) the possibility of quantification of the substituted or saved process (i.e. the availability of data that can be later included in an inventory); and, finally, (3) the current availability of tools for their inclusion in LCA, together with the current status of new assessment methodologies.

3. Results

The following two sections provide an overview of the results. Occurrence of individual benefits is discussed in the first part, while the second part deals with quantification of the benefits in a life cycle perspective.

3.1. Compost potential benefits

An outline of the literature review dealing with the nine potential benefits resulting from compost application is provided in Table 1. The full review is available in Martínez-Blanco et al. (2013) where, for each of the agronomic benefits, a discussion of the main factors affecting the performance of individual benefits, the degree of proof and the range of the benefits measured were included.

Regarding the supply of plant nutrients, carbon sequestration, soil erosion and soil workability, the positive effects of compost application were demonstrated in most of the reviewed studies, and their magnitude was quantifiable. Although we were also able to state the magnitude of the effect, for the following three benefits the share of studies with non-significant results was relevant: crop nutritional quality was not relevantly different for a third of the case studies included; for crop yield, more than 60% of the case studies did not report differences when compost was applied; and finally, non-significant benefits were detected for soil moisture content for low rates of compost. These were also the benefits with higher disparity in the measured effects among the results.

For the benefits pest and disease suppression and crop nutritional quality, although they were proved, it was not feasible to summarize the benefit in a unique data range. These benefits involve several concurring indicators at the same time and the intensity of the effect is different for each of them due to several factors. Regarding weed suppression, this effect was not proved when compost is used as a soil amendment. Finally, data regarding effects of compost application on soil biological properties and biodiversity are scarce and restricted to microorganisms. Table 1 shows the results of the review for three of the most used microbial indicators.

On average, positive effects due to compost application were found for all the potential benefits, except for weed suppression. Benefits in the long-term were only reported for nutrient supply, carbon sequestration, soil biodiversity and soil workability, whereas for the other potential benefits only mid- or short-term data were found. In addition, quantification of the potential benefits yielded broad ranges in most of the cases.

During literature review the variables having the largest influence on the magnitude of compost benefits were identified. The original feedstock material, management of the composting process, compost maturity, and crop management are some of the main factors that determine the occurrence of environmental and agronomic benefits. For instance, Boldrin et al. (2009) reported that the typical contents of nutrients in biowaste compost can vary depending on the initial raw waste material. Susceptibility of these nutrients to mineralization and release might depend on the degree of stability and/or maturity of the compost as well as on the prevailing climatic conditions due to the large influence of temperature and moisture in decomposition and nutrient release (Sikora and Szmidt 2004).

Regarding the impacts of compost on soil moisture, workability and erosion, several authors reported large positive effects with high-rate compost application on soils with initially low SOC content. Compost quality is the most important factor determining the impacts on soil biological properties and biodiversity, together with the dose applied (Hargreaves et al. 2008; Diacono and Montemurro 2010). Increases in crop nutritional quality when compost is employed largely depend on crop management and climate conditions (e.g. better results were observed when a lag of time between compost application and crop existed and nutrient mineralization rates tend to be higher in warm climates).

3.2. Quantification of benefits

Depending on the nutrient content and availability of the compost, the use of mineral fertilizers can be avoided and therefore their industrial production and transport. Final utilization efficiencies for N, P and K are in the order of 20–60% for N, 90–100% for P, and 100% for K (Boldrin et al. 2009). Using the nutrient contents presented in Table 1, the potential amount of inorganic fertilizers replaced may be within the range of 1–13 kg of N, 1–5 kg of P, and 5–14 kg of K per ton of compost applied. A life cycle inventory (LCI) for fertilizer production include use of materials and energy, and emissions to different compartments, which would typically result in potential impacts on Resource Depletion, Global Warming, Human- and Ecotoxicity, and Eutrophication impact categories (Figure 1). Inventory datasets for N-P-K fertilizers are reported in different sources. In addition, the use of a renewable P source rather than inorganic non-renewable supply is of great importance and this reduced raw resource consumption might be quantified during impact quantification.

The amount of C sequestered into soil by compost application, can be translated into saved CO_2 emissions by using a conversion factor of 44/12, based on molar relation, and then entered into the LCI. A time frame of 100 years is considered to be relevant for estimating contributions to Global Warming (Favoino and Hogg 2008). Boldrin et al. (2009) reported that the benefits from C retained in soil 100 years after the addition of biowaste compost is between 2 and 79 kg CO_2-eq. t^{-1}. Higher values, 279 kg CO_2-eq. t^{-1}, were reported by ICF (2005). Most likely, this large variability is due to the synergetic effect of the different environmental and site-specific factors, meaning that estimations should be done on a case-to-case basis.

When the application of compost results in pest suppressive effects, the use of pesticides can be reduced or avoided. However, compost benefits on plant health are so case-specific that it is not possible to provide any general figures for the amount and the type of pesticides saved. The avoided use can be credited to the system as an environmental saving associated to both the avoided production/transportation and to the avoided release of these products to the environment. Inventory data covering emissions modelling, production and transport of pesticides can be found in different databases such as PestLCI, Ecoinvent, and GEMIS. Potential environment impacts from production/transportation and use of pesticides can be assessed using existing impact categories, the most relevant being the Toxicity categories, both Human- and Ecotoxicity (Figure 1).

Increased yield as a consequence of compost application could result in avoided additional agricultural production, and thus all the associated environmental burdens. If arable land is not constrained, the benefit is linked to theoretical avoided use of material and energy needed for the crop production (of the yield increased). In the most likely regime of constrained arable land, the increased yield would have an effect on both intensification and expansion of agricultural production, and ultimately will prevent indirect land use changes (ILUCs), which are for instance a major source of GHG emissions (Thamsiriroj and Murphy 2010). Depending on the specific area and crop, most of the impact categories are influenced when agricultural production is involved (Figure 1).

Table 1. Summary of the potential benefits of compost use-on-land in the short-, mid- and long-term retrieved from the literature review (adapted from Martínez-Blanco et al. 2013).

Benefit	Indicator (Unit)	Short-term (<1 yr)		mid-term (<10yr)		long-term (<100yr)	
		Min.	Max.	Min.	Max.	Min.	Max.
Nutrient supply	N mineralized (% of N applied)	5	22	40	50	20	60
	P mineralized (% of P applied)	35	38	90	100	90	100
	K mineralized (% of K applied)	75	80	100		100	
Carbon sequestration	C sequestered in soil (% of C applied)	40	53		30	2	16
Weed, pest and disease suppression	Weed suppression (-)	ns	ns	-	-	-	-
	Pest and disease suppression (-)	nad	nad	-	-	-	-
Crop yield	Δ Crop yield (% from mineral fertilization) [1]	-138	0	-71	52	-	-
Soil erosion	ΔSoil loss (%)[1]	-	-	-5	-36	-	-
	Δ Soil structural or aggregate stability (%)	29	41	0	63	-	-
Soil moisture content	Δ WHC (%)	0	50	-	-	-	-
	Δ PAW (%)	0	34	-	-	-	-
Soil workability	Δ Soil bulk density (%)[1]	-2.5	-21	-0.7	-23		-20
Soil biological properties and biodiversity[2]	Δ Microbial diversity (%)[1]	-	-	-	-	-2	4
	Δ Microbial biomass (%)	22	116	10	242	3.2	100
	Δ Microbial activity (%)	0	344	-	264	0	43
Crop nutritional quality	Crop nutritional quality (-)	nad	nad	-	-	-	-

Δ, change in the indicator; WHC, water holding capacity; PAW, plant available water; ns, no significant differences; nad, no average data because of complexity of available dataset; “-“, no reported benefits.

[1] Negative value indicates a decrease in the indicator.

[2] The ranges of benefit for three of the more used indicators are presented.

As shown in Table 1, losses of soil could be decreased by 5 to 36% with the application of compost, depending on the time horizon considered. A more precise quantification is possible for specific local conditions taking into account for instance climate, application rate, and type of soil. Avoided soil losses can be modelled within traditional LCA impact categories; here the consequential modelling should identify the agricultural production affected by the losses of arable land. Assuming a constrained agricultural production at a system level, the modelling is then done similarly to "crop yield", meaning that the consequences of intensification and/or land expansion are included in the assessment. Another alternative is to consider soil as a resource, thus either including loss of soil in the inventory as 'resource depletion' (Cowell and Clift 2000) (Figure1).

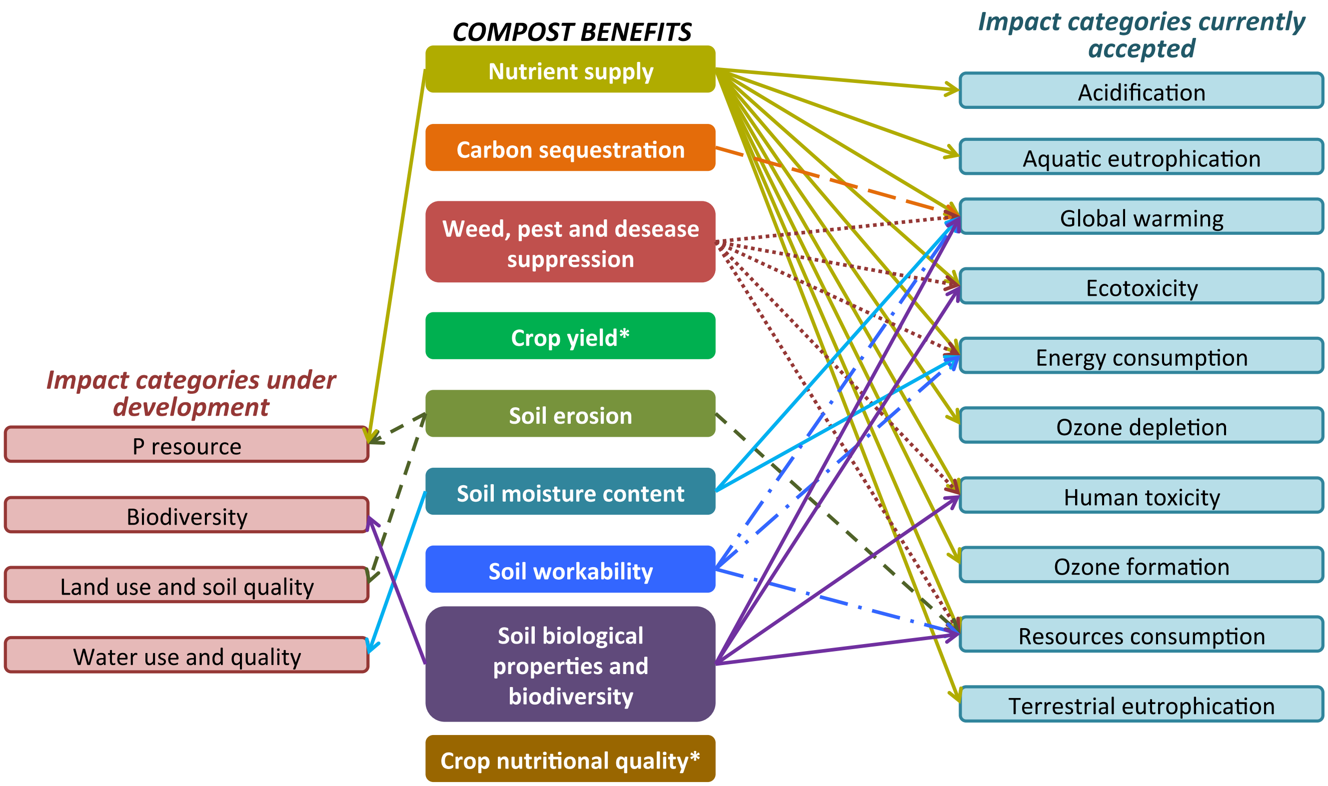

Figure 1. Midpoint LCA impact categories involved in the evaluation of the potential benefits of biowaste compost use-on-land.

* Could be considered as improvement of the function of agricultural processes and included in the functional unit definition.

Compost application might raise the capacity of soil to retain rainfall and irrigation water (green water, i.e. rainwater stored in the soil as soil moisture) allowing the reduction of irrigation water consumption (blue water, i.e. water from surface and groundwater resources). This may result in two distinguished consequences: on one hand, blue water is saved; on the other hand, because more green water is available, crop yield could increase in those areas where irrigation water is scarce. However, there is not a direct relation between the retention capacity and the amount of water saved, as it depends on the water demands of the plants, management practices, and previous moisture content of soils. The theoretical saving of irrigation water could be calculated for a particular case study if all these data are available (ROU 2007). Environmental burdens from irrigation water supply are linked to water extraction, transport, and distribution in the field (electricity, pumps, pipes, etc.), and are found in several inventories, also at a regional level. Potential impacts from these processes are typically those related to energy supply and consumption, thus Global Warming, Acidification, and Eutrophication categories (Figure 1). There is indeed a growing consensus on the fact that water use and consumption should be included in LCA assessing, apart from volumetric amounts, its environmental effects on the three Areas of Protection (Human Health, Natural Environment and Resources) (Núñez et al. 2013).

Improved soil workability can potentially decrease energy requirements for agricultural operations (Favoino and Hogg 2008; ROU 2007). Soil ploughing typically involves large consumption of energy and fuel. In an 8-year long study, McLaughlin et al. (2002) reported that, under a 100 t ha^{-1} application of stockpiled and rotted manure on a corn field, the plough draft was reduced 27–38%, resulting in 13–18% reduction of fuel consumption, due to the improvement in soil quality related to the increase in SOM. No other studies were found linking compost application and fuel consumption for agricultural operations, meaning that more comprehensive data are needed to be able to relate, for example, fuel consumption with soil bulk density. From an LCI point of view, reduced fuel consumptions can be credited to the system as avoided use of diesel. Avoided diesel consumption mainly affects Global Warming impact category, while avoided emissions of nitrogen oxide could also have an influence on Acidification and Eutrophication (Figure 1).

Changes in soil biodiversity after compost addition might influence either positively or negatively the services “delivered” by the ecosystem (i.e. nutrient cycling regulation of soil water and pest incidence), with consequences in terms of impacts associated to the substitution or compensation of those ecosystem services. In LCA terms, alterations in the system service in connection to biodiversity changes could be modelled within the traditional categories if those changes could be quantified in the inventory (Figure 1). If, for example, increased biodiversity can be directly related to increased nutrient cycling and lower need for fertilization, then the benefits from increased biodiversity could be modelled in terms of reduced production of fertilizers. However, data linking compost use, biodiversity and ecosystem services are non-existing, apart from a first attempt of establishing a preliminary relation by Nemecek et al. (2011). In addition, general figures cannot be established in all cases, as the effects of land management practices are highly variable depending on regional and scale dependent factors (Bengtsson et al. 2005). An alternative approach is to consider biodiversity and ecosystem services as independent endpoint categories when assessing the environmental impacts of land management alternatives (Zhang et al. 2010). Some recent initiatives have established baseline diversity indices for different soil organisms and under different soil uses that can be used as a reference to evaluate the impacts of compost on soil biodiversity (Cluzeau et al. 2012).

Different nutrient contents in food products resulting from compost application can have a repercussion on the LCA modelling depending on how the functional unit is defined. When the functional unit includes qualitative aspects (e.g. nutritional and/or economic value), increased nutritional level of a food product may have as a consequence that lower amounts of that specific food product are needed. In general terms, including qualitative aspects in the functional unit, would have an effect on the agricultural production (Martínez-Blanco et al. 2011), which could be modelled similarly to changes in crop yield.

4. Discussion

Regarding the environmental assessment – including quantification and characterization – of the benefits of compost application to soils, four different scenarios were identified: (i) The positive effects of compost application are proved, effects are quantifiable, and there are tools for their consideration with LCA. This includes nutrient supply and carbon sequestration, which are (and should be) included in LCA studies. (ii) The benefits are proved, but their magnitude is too variable as a consequence of the synergetic effect of many factors. Thus, inventory data cannot be unambiguously quantified. Impact categories and characterization factors exist for most of the benefits. (iii) The benefits are proved and quantifiable. However, corresponding characterization factors and/or impact categories are non-existing. (iv) Benefits are not fully proved and thus their inclusion in the modelling is not yet feasible.

Two out of the nine potential benefits initially proposed, are proved and the quantification and assessment are possible, while different research efforts are required for the rest of the effects for a full assessment both regarding improved modelling and characterization. Modeling and quantification issues are related to the fact that LCA models are typically linear steady-state models of physical flows (Guinée et al. 2002) whereas fluxes of nutrients and pollutants after compost application to soil are not linear in most of the cases. This also applies, for instance, to repeated applications of compost: LCA studies typically look at the effects of a single application over 100 years, while the cumulative effects on several applications may not be linear with the amount of compost added. Also, LCA models assume that impacts depend on the compost characteristics while they rarely include environmental parameters as determining factors, which highlights the necessity of coupling LCA and agronomic models to gain a more precise picture. Another methodological issue is derived from the fact that many of the benefits discussed in this paper might be interrelated and therefore their contribution to a specific impact category might be overlapping. This should be clearly identified in order to avoid the overestimation of the benefits.

Finally, for LCA of the agricultural sector, the functional unit is typically defined per area used or product yield. As different functional units can lead to different results for the same product system (Martínez-Blanco et al. 2011), there may be a need for a qualitatively more precise definition when dealing with compost application, especially in those cases where the product quality is affected. Better definitions could, for example, include the economic value or the nutritional content of a product (Schau and Fet, 2008). A more accurate definition dealing with nutritional differences may include a combination of quality (nutritional quality) and quantity (yield). This was for example done in Charles et al. (1998) and Audsley et al. (2003), where the functional unit was defined as "1 equivalent ton grain with 12–13% protein". This involved the use of marginal productions to adjust the overall output of the system under assessment. Finally, the choice of the time horizon of the LCA should be harmonized. The studies reviewed showed in fact that such choice is in many cases very important, as both the foreground and background effects of compost application vary largely depending on the time frame.

In addition to improved quantification and modelling of compost application, the development of new impact categories or modifications of the current ones in the future will allow for a more comprehensive assessment of compost benefits. These should deal with depletion of P resources, biodiversity, loss of arable soil, and consumption of water. Depletion of P as a resource is currently modelled similarly to other natural resources. A revision of the characterization factors is thus needed for the assessment of non-replaceable non-renewable resources such as P. In this respect, the ReCiPe model adds value to resources; it is based on the geological distribution of mineral and fossil resources, and assesses how the use of these resources causes marginal changes in the efforts to extract future ones (Goedkoop et al., 2009).

Although there is no consensus yet on which indicators use in the assessment of land use impacts, there is a common agreement that land use is one of the main drivers of biodiversity loss, and that must be assessed taking into account different taxonomic groups and a spatially explicit approach (De Baan 2013).

Soil loss involves the loss of cultivable land but also the loss of soil organic carbon (SOC), plant nutrients, as well as the associated plant, animal and microbial biodiversity (Cowell and Clift 2000). Loss of soil can thus be included in some of the abovementioned impact categories. However, for a more comprehensive assessment the loss of soil mass could be considered as the loss of a resource and included in the inventory as 'resource depletion' (Núñez et al. 2013). In alternative, soil erosion can be included within the impact category Land Use, whose characterization factors are based on soil quality indicators such as SOM, structure, heavy metals, biodiversity, aesthetic value, etc. (Brentrup 2004; Mattsson et al. 2000).

Depletion of water resources is gradually gaining importance, particularly in certain geographical regions. There is currently only a preliminary scientific consensus about the parameters to consider and the methodology to follow (Núñez et al. 2013). Methodological issues concerning impact assessment methods include the types of water use accounted for, the inclusion of local water scarcity conditions, and the differentiation between watercourses and quality aspects (Berger and Finkbeiner 2010).

5. Conclusion

Most potential environmental benefits of compost are so far not included in LCA studies because of scarcity of data, high variability in the observed effects, or lack of appropriate impact assessment methods. For two of the nine benefits – nutrient supply and carbon sequestration – the literature review showed that both quantification and impact assessment of the effects could be performed, meaning that these two benefits should be regularly included in LCA studies. For four of the nine benefits – increase in crop yield, soil workability, crop nutritional quality, and enhancement of soil biological properties and biodiversity –, quantitative figures could not be provided, either because of complete lack of data or because the effects are both very variable and too depending on specific local conditions. For "soil erosion" and "soil water content" effects could be quantitatively addressed, but available impact assessment methodologies were considered unsuitable to comprehensively evaluate the implication of compost application with regards to these two benefits. Finally, based on the available literature, "suppressive effects of compost on weed, pests, and diseases" could not be generally proved. Efforts at different levels are needed in order to comprehensively evaluate the benefits of compost use, such as the collection of more empirical data to accurately determine the magnitude of some of the effects. Long-term studies are particularly scarce. Further, the comprehensive assessment of compost benefits would also need further improvement of the modeling for the quantification of the benefits, as well as a better understanding of how the local environmental conditions would influence the effects of compost, through the use of agronomic models. Additional impact categories dealing with phosphorus resources, biodiversity, soil losses, and water depletion, may be required.

Implications of alternative greenhouse gas metrics for life cycle assessments of livestock food products

Stewart Ledgard[1], Andy Reisinger[2,*]

ABSTRACT

Life cycle assessments of livestock food products incorporate emissions of different greenhouse gases (GHGs) with very different physical properties. These are commonly aggregated into a single unit, called "CO_2-equivalent", using the 100-year Global Warming Potential. However, an increasing literature emphasizes that many alternative metrics can be justified to compare emissions of different GHGs and would result in a substantially different weighting for methane relative to nitrous oxide and carbon dioxide. We demonstrate that alternative GHG metric choices can materially alter the difference in emissions associated with organic, high-input and conventional dairy farms; and that metrics can substantially shift the differences in GHG footprints of ruminant and non-ruminant meat products. We conclude that the characterization of certain products and farm systems as more or less climate-friendly reflects, in part, implicit choices and value judgments made in the selection of GHG metrics.

Keywords: greenhouse gas metric, Global Warming Potential, livestock, dairy production, organic systems

1. Introduction

Life cycle assessment (LCA) of food products covers various environmental impact categories, including effects on climate. This category needs to incorporate various greenhouse gases (GHGs) with very different physical properties such as differing lifetimes in the atmosphere and contributions to the warming of Earth's atmosphere. To enable comparisons between different food products and production systems, emissions of individual gases are aggregated into a single characterization factor (called 'Global Warming Potential'), using the unit of "CO_2-equivalent" emissions. The 100-year Global Warming Potential (GWP_{100}) is the most commonly used metric to convert emissions of individual gases into CO_2-equivalent emissions; it is employed in reporting and accounting under the United Nations Framework Convention on Climate Change (UNFCCC) and its Kyoto Protocol and in the great majority of LCAs related to climate change.

However, an increasing literature emphasizes that the GWP_{100} is only one of many alternative metrics that can be devised to compare emissions of different GHGs (e.g. Bowerman et al. 2013; Manning and Reisinger 2011; Shine 2009; Smith et al. 2012; Tanaka et al. 2010). The most appropriate choice of metric depends crucially on policy objectives (IPCC 2009; Myhre et al. 2013), and the current use of GWP_{100} for reporting emissions under the UNFCCC is not necessarily consistent with the ultimate objectives of the Convention (Tol et al. 2012). The most recent assessment by the Intergovernmental Panel on Climate Change (IPCC 2013) does not recommend the GWP_{100} as metric of choice, but presents a range of alternative options (Myhre et al. 2013); the metric for a future global climate agreement is being actively debated in the UNFCCC (e.g. UNFCCC 2012).

Alternative climate metrics, reflecting different policy goals and value judgements, would result in different weightings for short-lived GHGs, most notably methane (CH_4). This has potentially significant implications for the LCA of food production, given that CH_4 and nitrous oxide (N_2O) constitute large fractions of the total emissions from livestock-based agriculture. As a result, well-publicised differences in life cycle GHG emissions for different agricultural products and processes could change significantly if a metric other than the GWP_{100} were chosen, since different farm systems typically exhibit different fractions of emissions of CH_4, N_2O and CO_2. Consequently, the relative 'climate-friendliness' of particular farm systems or foods could depend strongly on the choice of emission metric. The importance of alternative climate metric choices for LCA has been discussed in some publications (e.g. Peters et al. 2011), but few studies have explored implications for LCA studies of food production and strategies to reduce agricultural emissions (for one example, see Reisinger and Ledgard 2013).

To advance this discussion, we select in this study a range of published climate metrics and apply them to a range of published food LCA studies. We demonstrate that the choice of alternative metrics indeed has a material impact on the relative climate-friendliness of different farm systems (organic vs conventional and high-input dairy farms) and of different meat products (particularly meat from ruminants or monogastric animals). We demonstrate that the choice of climate metric is at least as important as other methodological and parameter choices that are, in contrast to climate metrics, discussed widely in the LCA literature.

Section 2 presents the metrics used in this study. Section 3 applies those metrics to different dairy production systems and also explores their implications for the climate footprint of various meat products. Section 4 discusses the results and considers their implications for mitigation strategies, product labelling and possible consumer choices geared towards climate-friendly food production, and considers results in the context of food miles. Section 5 concludes, including a short outlook to additional work.

2. Selection of climate metrics and their use in food LCA studies

A recent summary by Tanaka et al. (2013) demonstrates that even if there is agreement to a long-term global climate goal, a large range of choices remains for climate metrics. Scientifically justifiable weighting values for CH_4, relative to CO_2, range from about 4 to more than 70. Furthermore, advances in scientific understanding and changes in atmospheric background concentrations of GHGs result in the best estimates of metric values themselves changing over time (Joos et al. 2013; Myhre et al. 2013; Reisinger et al. 2011). The purpose of this study is not to present the most up-to-date estimates of climate metrics or a comprehensive overview, but rather to test the sensitivity of key conclusions of some food LCA studies to metric choices other than the default GWP_{100}. To this end, we select two alternative metrics and time horizons that have received considerable attention and scrutiny in the scientific literature in addition to GWP_{100}, namely the GWP with a shorter time-horizon of only 20 years (GWP_{20}), and the Global Temperature change Potential with a time horizon of 100 years (GTP_{100}). Scientific justifications and analysis of these metrics, and the calculation of specific metric values, can be found elsewhere (see e.g. Fuglestvedt et al. 2003; IPCC 2009; Shine et al. 2005; Tanaka et al. 2010). Table 1 presents the values for those metrics for CO_2, CH_4 and N_2O as used in the reminder of this study.

Table 1. Metric values for GWP_{100}, GWP_{20}, and GTP_{100} as used in this study. Values are based on Forster et al. (2007) for GWP_{100} and GWP_{20}, and on Fuglestvedt et al. (2010) for GTP_{100}.

Gas	GWP_{100}	GWP_{20}	GTP_{100}
CO_2	1	1	1
CH_4	25	72	4
N_2O	298	289	265

We emphasize that the metrics and values chosen in this study are intended to serve a sensitivity analysis of LCA results; they are not intended to represent the most up-to-date or appropriate choices. Some metric choices, such as GWP_{500}, are not included because the numerical weighting for CH_4 metric would be quite similar to that using GTP_{100} even though the scientific rationale leading to this value is different. We also note that the current best estimate for the 100-year GWP of CH_4 is 28 (Myhre et al. 2013), updated from the previous estimate by the IPCC of 25 in 2007 (Forster et al. 2007) and 21 as used to date under the UNFCCC and the first commitment period of the Kyoto Protocol based on IPCC (1996). In this study, we use the values for GWP_{100} as published in Forster et al. (2007) to facilitate comparability with other LCA studies that have used these values.

Many published LCA studies using GWP do not provide emissions of individual gases in their native units, but the use of GWP_{100} is often ‘hard-wired’ into results. This can make it difficult to separate out the effect of climate metric from the overall conclusions. In this analysis, we use a small number of published studies where we had access to the raw calculation of emissions of individual gases, and hence the implications of alternative metrics can be explored. Similar to the choice of metrics, the selection of studies or food production systems in this analysis is not intended to be comprehensive or representative of the selected issues, but merely to demonstrate the potential sensitivity of LCA-based GHG studies to the choice of climate metrics – but equally to show where conclusions might be robust regardless of the climate metric used. Further work will be required to test the extent to which the conclusions derived from these limited examples can be generalised.

3. Results

We explore the implications of climate metrics in two specific applications: (1) the relative climate-friendliness of organic, conventional and high-input dairy production systems, using a review across different countries and two detailed analyses from New Zealand; and (2) the carbon footprint of different meat products from ruminant and monogastric animals, using a previously published European study as input.

3.1. Carbon footprint of milk from organic, conventional and high-input dairy production

We explored the implications of alternative metrics for the carbon footprints of conventional, organic and other environmentally-friendly milk production systems, based on a review across different countries (de Boer 2003). The original study showed that organic systems had a smaller carbon footprint per kg of fat and protein corrected kg of milk in Sweden, but similar or greater footprint in the Netherlands and Germany, reflecting different production systems as well as potentially different parameter assumptions. More recent studies reported similarly mixed conclusions (Cederberg and Flysjö 2004; Kristensen et al. 2011; Thomassen et al. 2008), with results strongly dependent on the methodology used for land-use change (Flysjö et al. 2012). If GTP_{100} were used in the review by de Boer (2003) to calculate carbon footprints, organic systems would in all three countries show a lower climate footprint than conventional systems, but a consistently greater footprint if GWP_{20} were used. Interestingly, other environmentally friendly/extensive farm systems reviewed in de Boer (2003) show a lower climate footprint for all three climate metrics. This suggests that the choice of metric might be at least as important as country-specific differences in production systems and parameter choices relating to land-use change in determining whether organic systems are more or less climate-friendly than conventional ones.

To further test this conclusion, we examined the sensitivity of the LCA of cradle-to-farm-gate GHG emissions associated with milk production in different farm systems. The first evaluation covers the carbon footprint at the farm gate of milk produced in typical organic, high-input and average (conventional) dairy farms in New Zealand. The organic and high-input (about 25-40% of feed brought-in from off-farm) farm systems were based on survey data from representative groups of 10-20 dairy farms in the North Island of New Zealand (Ledgard et al. 2009). The average dairy farm was based on survey data (animal population, productivity and farm inputs from the DairyBase database; DairyNZ 2014) from over 200 farms from the various dairying regions throughout New Zealand for 2010/2011, weighted for relative milk production (as described in Flysjö et al. 2011). Total GHG emissions were allocated between milk and meat using the IDF (2010) methodology.

The original study showed that organic farms had a lower carbon footprint than conventional farms and significantly lower footprint than high-input farms, if GWP_{100} is used to calculate carbon footprints. Most of this difference comes from off-farm GHG emissions (from fertilizer, brought-in feed, and off-farm grazing), which are minor for organic farms but constitute about 10% for conventional and more than 20% for high-input farms.

However, these conclusions are sensitive to the choice of metric, as summarized in Table 2. Organic farms tend to have a higher percentage of CH_4 emissions per kg of milk solids (fat plus protein) due to the less intensive feeding regime, but a lower percentage of N_2O emissions due to nil use of nitrogen fertilizer (relying on clover N_2-fixation), negligible use of brought-in feed, including associated CO_2 emissions from fossil fuel consumption. Since alternative metrics change the relative weight given to the short-lived gas CH_4 relative to the longer lived gases N_2O and CO_2, the net emissions from different farm systems depend significantly on the choice of metric. Organic farms have 13% lower emissions than conventional farms under GWP_{100}, but 30% lower emissions under GTP_{100} and only 5% lower emissions under GWP_{20}. This is because the latter metric gives much greater weight to the higher CH_4 emissions per kg of product on organic farms. The picture is reversed for high-input dairy farms, which have 11% higher emissions than conventional farms under GTP_{100} but only 2% higher emissions under GWP_{20}, because GTP_{100} gives the greatest relative weight to N_2O emissions which dominate on high-input farms due to the high use of nitrogen fertilizers.

A related shift occurs in the balance between on-farm and off-farm emissions. Off-farm emissions are always a small percentage of total LCA emissions for organic farms, but can range from 41% under GTP_{100} to 13% under GWP_{20} for the high-input farms, and from 20% under GTP_{100} to 6% under GWP_{20} for conventional farms. These different fractions arise because most of the off-farm emissions arise in the form of long-lived gases N_2O and CO_2, which are given much greater weight if GTP_{100} is used as a metric than under GWP_{20}.

Based on this analysis, we conclude that for the specific parameters and input factors used in this study, the milk of organic farms has a lower carbon footprint, and high-input farms a higher carbon footprint than the average conventional dairy farm in New Zealand regardless of the climate metric chosen, but the amount of difference depends significantly on the metric. If only the on-farm component of emissions were considered, different climate metrics would suggest that the climate-benefit of organic farming could range from 18% lower emissions than conventional farms (using GTP_{100}) to almost no difference (only 1% lower emissions using GWP_{20}).

Table 2. On-farm, off-farm and whole-farm system LCA GHG emissions from milk from conventional, organic and high-input New Zealand dairy farms, in kg CO_2-eq per kg of milk solids produced over the cradle-to-farm-gate stages, for GWP_{100}, GTP_{100} and GWP_{20}. Columns in italics show the emissions from organic and high-input systems relative to conventional average of farms.

Scope	**GWP_{100}**			*Org. /*	*High/*	**GTP_{100}**			*Org. /*	*High/*	**GWP_{20}**			*Org. /*	*High/*
	Conv.	Org.	High	*Conv.*	*Conv.*	Conv.	Org.	High	*Conv.*	*Conv.*	Conv.	Org.	High	*Conv.*	*Conv.*
whole farm	10.5	9.1	11.0	*-13%*	*4%*	4.8	3.3	5.3	*-30%*	*11%*	22.7	21.5	23.1	*-5%*	*2%*
on-farm	9.5	8.9	8.5	*-6%*	*-10%*	3.8	3.1	3.1	*-18%*	*-18%*	21.4	21.3	20.1	*-1%*	*-6%*
off-farm	1.1	0.2	2.4	*-80%*	*129%*	1.0	0.2	2.2	*-79%*	*128%*	1.3	0.2	3.0	*-83%*	*133%*
Percentage off-farm	10%	2%	22%			20%	6%	41%			6%	1%	13%		

These conclusions are supported by another dataset, which looked only at the on-farm carbon footprint of a specific set of 23 different conventional and organic dairy farms in New Zealand (Barber 2010). In this study, using GWP_{100}, average on-farm emissions per kg milk solids from organic dairy farms were found to be almost identical to those from conventional farms, but with a considerable variability between farms within each farm system (Figure 1). However, the average organic farm would show 8% lower emissions than the average conventional farm if GTP_{100} were used as the metric, but 4% higher emissions if GWP_{20} were used. These results are consistent with organic farms typically higher CH_4 emissions per kg of milk solids owing to lower milk yield per cow, but lower N_2O and CO_2 emissions mainly due to the lower nitrogen fertilizer use. This higher fraction of CH_4 emissions in organic systems is weighted more strongly by GWP_{20} but less if GTP_{100} is used.

Collectively, these results show that the choice of climate metric could have a significant influence on whether organic farming is considered more or less 'climate-friendly' than average conventional practices. However, these conclusions apply only to the 'average' farm in both systems; regardless of metric, within this sample there is always a conventional farm with a lower GHG footprint than the most efficient organic farm (Barber 2010).

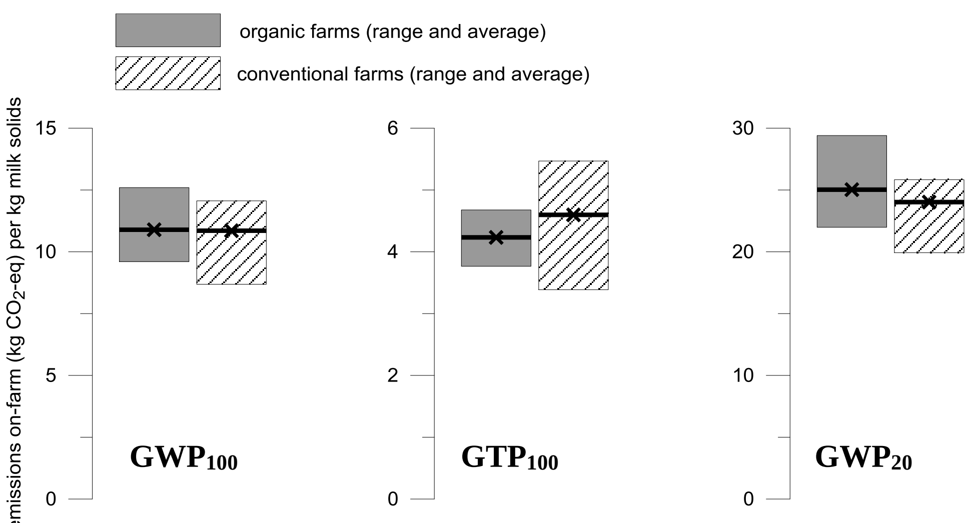

Figure 1. Average, maximum and minimum on-farm GHG emissions from 23 individual organic and conventional dairy farms, for GWP_{100} (left panel), GTP_{100} (center panel), and GWP_{20} (right panel). Note Y-axis has been scaled for each metric to reflect different absolute CO_2-eq emissions for different metrics. The black horizontal bar indicates the average across the surveyed farms for each farm system.

3.2. Climate-footprint of different meat products

LCA can be used to inform policymakers, industry and consumers about whether particular products are, in general, more or less ‘climate-friendly’ than alternative products. A consistent conclusion across many LCA studies is that meat from ruminants (mainly beef, sheep and goat meat) has significantly higher GHG emissions per kg of product at the farm gate than meat from monogastric animals (mainly pork and poultry). This implies that diet switching could be an important part of global strategies to reduce GHG emissions from agriculture (Cederberg et al. 2013; de Boer et al. 2011; Hedenus et al. 2014; Ripple et al. 2014).

We tested the robustness of this conclusion against the choice of different climate metrics, using a comprehensive LCA of livestock production in the European Union (Weiss and Leip 2012). The original study confirmed that farm-gate GHG emissions per kg of meat from ruminants (cattle, sheep and goats) were significantly higher on average across Europe than emissions per kg of monogastric animals (pork and poultry), but the study also showed that emissions per kg of product varied significantly across the 27 member countries. Assumptions around land-use and land-use change emissions for different products and countries were found to have a major impact on the relative ranking of countries in terms of their GHG efficiencies, even though the overall result of ruminant meat being more emissions-intensive on average than monogastric meat was not affected.

We recalculated the average emissions per kg of beef, sheep and goat meat, pork and poultry for the average across the 27 European member states included in the study, for GWP_{100}, GTP_{100} and GWP_{20}. Figure 2 shows CO_2-eq emissions per kg of sheep/goat meat, pork or poultry *relative to* the CO_2-eq emissions per kg of beef, for each of the three different metrics and across the different land-use and land-use change scenarios used in the study. The Figure also shows results if emissions from land-use and land-use change are excluded. The relative ranking of the emissions intensity of different meat products is robust across the three different metrics, with emissions per kg sheep and goat meat comparable to emissions per kg of beef, but pork having consistently lower emissions and poultry the lowest. However, the choice of metric has a large impact on how much lower the GHG emissions from monogastric meat production are compared to those from ruminant meat production. If GWP_{20} is used as climate metric, CO_2-eq emissions per kg of pork are only 20% of the emissions per kg of beef, but almost 50% of beef emissions if GTP_{100} is used. The differences due to alternative metrics choices are comparable to the difference between direct emissions and those from additional land use and land-use change, and considerably larger than the range of results under different land-use and land-use change scenarios.

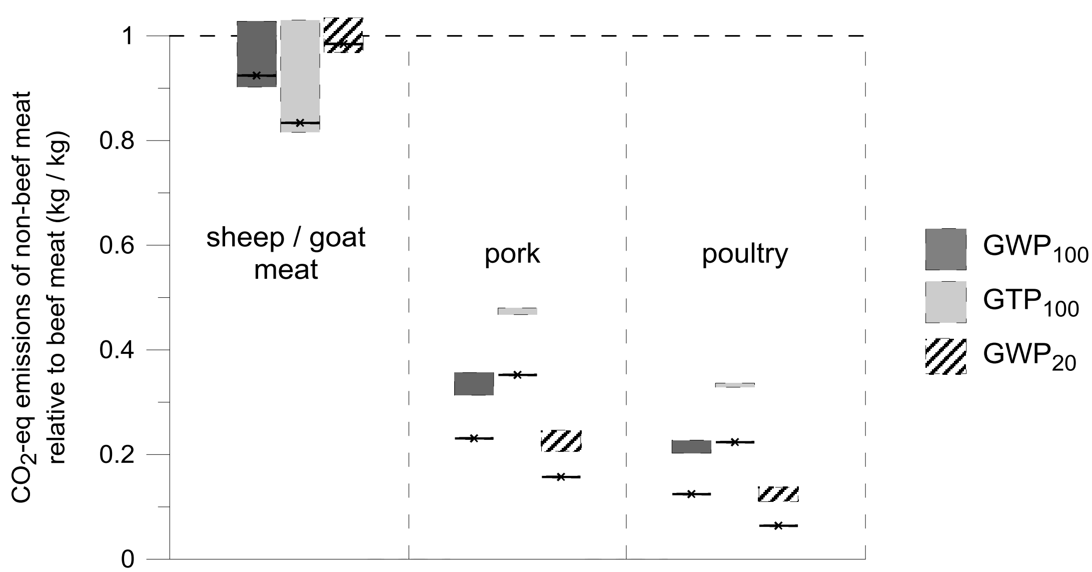

Figure 2. GHG emissions per kg of sheep and goat meat, pork and poultry relative to emissions per kg of beef. Emissions were calculated in CO_2-eq using three different climate metrics, based on data from Weiss and Leip (2012) for the average of 27 EU countries. The vertical bars show, for each metric, the range of results based on different land-use and land-use change scenarios. The black horizontal lines show the emissions per kg of meat relative to beef if contributions from land-use and land-use change are excluded from the calculations.

The emissions of sheep/goat meat relative to beef are much less influenced by alternative metrics and depend more on different land use and land-use change scenarios. These results are plausible, as a significant fraction of emissions for both beef and sheep/goat meat production arises from CH_4 from enteric fermentation.

We also tested the influence of metrics on the ranking of countries within the European Union based on their emissions intensity of meat production. As demonstrated by Weiss and Leip (2012), countries differ significantly in how CH_4 from enteric fermentation, N_2O and CO_2 from both energy use and land use/land-use change contribute to overall GHG emissions of ruminant meat production in individual countries. The use of different metrics, which apply different weights to CH_4 compared to the longer lived gases N_2O and CO_2, can materially change this ranking, as demonstrated for beef in Figure 3 (top panels). For GTP_{100}, the countries with the highest emissions per kg of beef remain largely unchanged, since their ranking is dominated by high CO_2 emissions from land-use/land-use change, which are given even more emphasis under GTP_{100}. Differences arise mainly in the ordering of the lowest and some middle emissions producers, although Austria remains as the country with the lowest emissions. Use of GWP_{20} as metric would result in more significant re-ordering of countries, as some countries with high CH_4 emissions become high emitters per kg of product even though they have low CO_2 emissions from land use/land-use change. At the same time, some countries with low CH_4 emissions become low emitters overall, even if they show more significant land use/land-use change emissions; the Netherlands replaces Austria as the country with the lowest emissions per kg of product. The GWP_{20} values also showed less variation across countries (approximately 2-fold) than for GWP_{100} (3-fold) or GTP_{100} (5-fold), because direct emissions from enteric fermentation (which are emphasized if GWP_{20} is used) are more similar between countries than the additional emissions related to land-use/land-use change.

Such changes in rankings of countries are much less pronounced for emissions per kg of pork (see Figure 3, bottom panels). This is as expected, given that CH_4 constitutes a much smaller fraction of emissions and alternative metrics have a much smaller influence on the weighting of N_2O relative to CO_2.

Figure 3 also demonstrates that the choice of alternative climate metrics influences whether and to what extent the country of origin matters in determining the relative climate-friendliness of pork compared to beef. If GWP_{100} is used, pork mostly has a lower carbon footprint than beef; only two countries with the highest emissions intensities produce pork with a similar carbon footprint (at 15-20 kg CO_2-eq per kg of meat) as the six countries with the lowest emissions intensities for beef. If GTP_{100} is used, the overlap is much stronger: pork from the two countries with the highest emissions intensities now has a carbon footprint (at 14-20 kg CO_2-eq per kg of meat) that is similar to or more than the footprint of beef from more than half of the 27 EU member countries. By contrast, if GWP_{20} is used, pork always has a lower carbon footprint than beef for any country.

4. Discussion

The results from our analysis demonstrate that the choice of alternative climate metrics has a material influence on the question of whether organic dairy farm systems have a lower carbon footprint than conventional or high-input systems, and substantially alters the magnitude of the difference between the carbon footprint of meat from ruminants compared to meat from monogastric animals. Given differences in carbon footprints between different countries for the same meat product, beef from some countries could have a lower carbon footprint than pork from some other countries with relatively high emissions intensity, with the outcome depending strongly on the climate metric chosen to account for GHG emissions. Carbon footprinting is intended to support mitigation strategies, product labelling and possible consumer choices geared towards climate-friendly food production, including choices regarding diet and country of origin. Our results demonstrate that the choice of climate metric has a material effect of whether such choices are robust, but the metric is often not communicated, let alone justified. At the least, a sensitivity analysis illustrating effects of several metrics is desirable. GWP_{100} is but one of many choices that can be justified in some respects using scientific arguments, but its appropriateness for any application depends on the goals and decisions that any specific life cycle assessment intends to support.

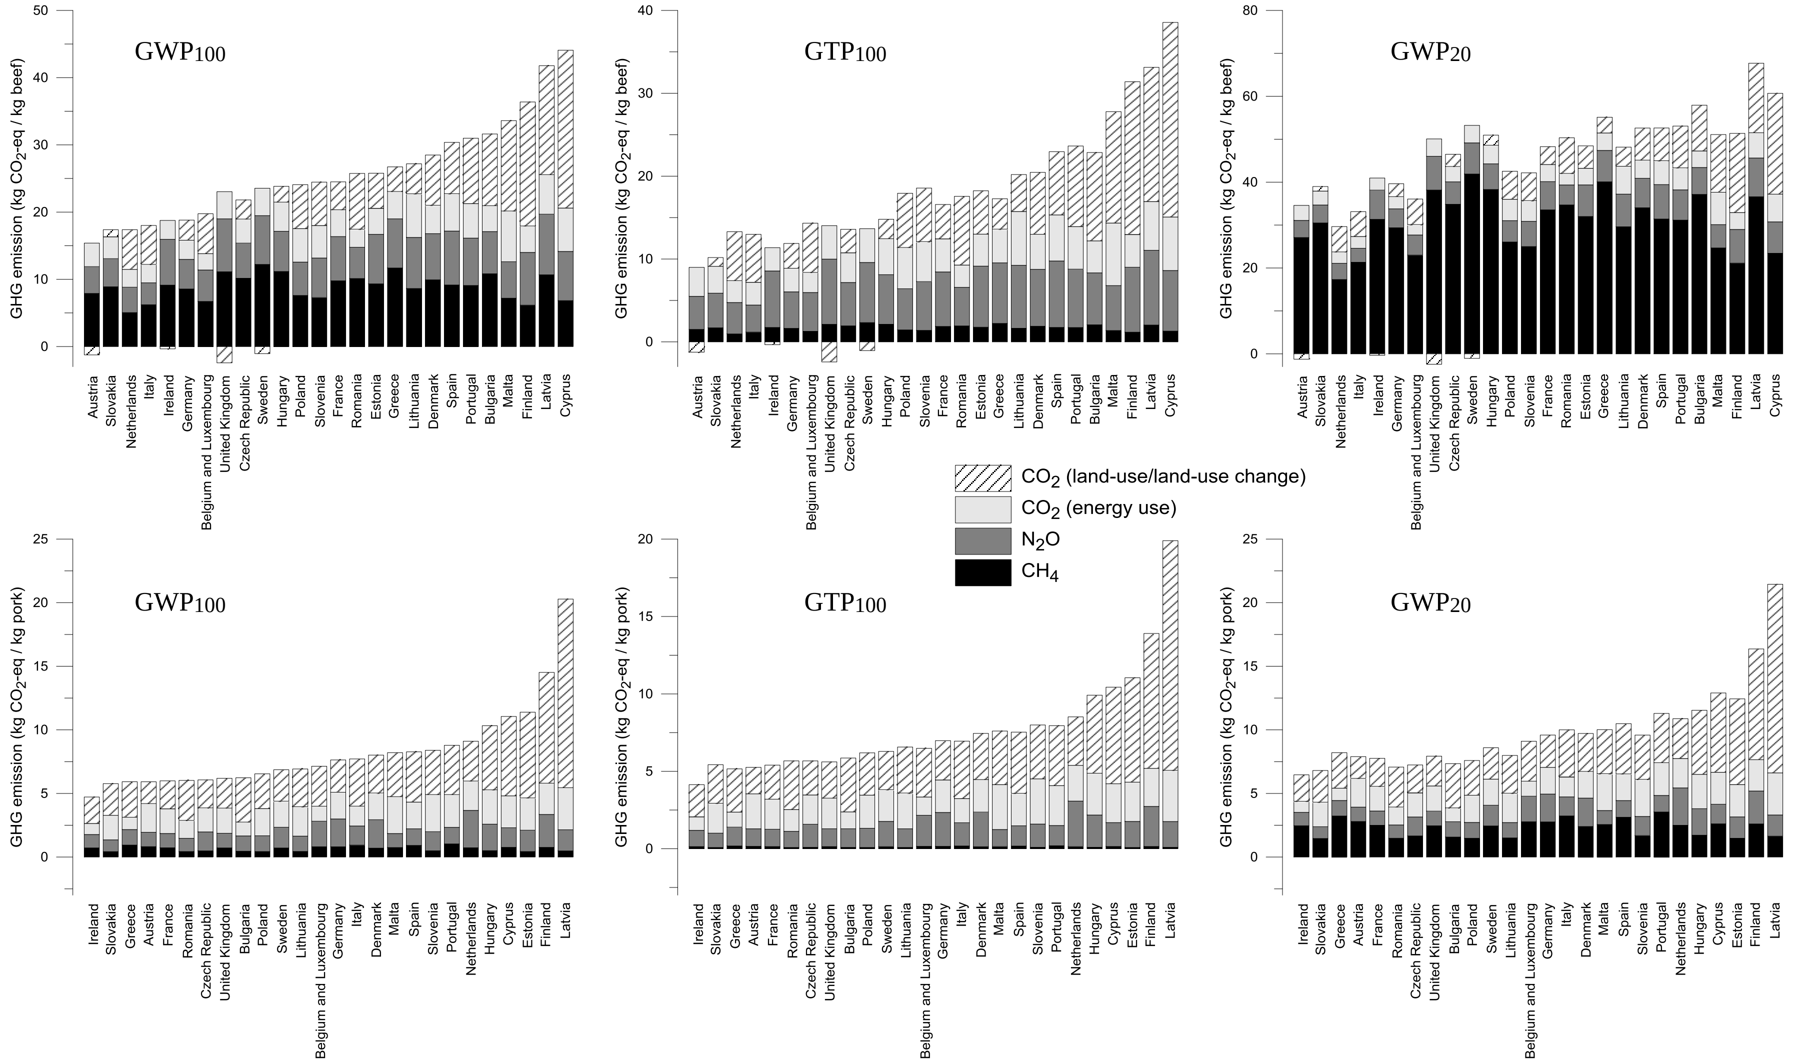

Figure 3. Impact of alternative climate metrics on the ranking of European member countries (EU-27) in terms of their emissions intensity of meat production (kg CO_2-eq / kg meat) for different climate metrics. Raw data are from Weiss and Leip (2012), using scenario II for emissions from land-use and land-use change. The top panels show results for beef, bottom panels for pork. Left panels show countries ranked based on GWP_{100} (using metric values of 21 for CH_4 and 310 for N_2O as in the original study), while middle and right panels show the same order of countries, but with their emissions intensities calculated using GTP_{100} and GWP_{20}, respectively.

Our results also suggest that the importance of food miles, i.e. emissions due to the transport of food to distant markets, can depend strongly on the climate metric. As an example, a study by Flysjö et al. (2011) indicated that the carbon footprint of milk at the farm gate was about a 15% lower on average in New Zealand than in Sweden if GWP_{100} is used. Once emissions arising from the processing of milk and its transport to Europe are taken into account (Hutchings and Ledgard 2009), the total carbon footprint of New Zealand milk sold in Sweden would be some 5% higher than for milk produced and sold in Sweden. However, if GTP_{100} were used, milk production in New Zealand would have 31% lower emissions at the farm gate compared to Swedish milk, given that New Zealand milk has a higher fraction of emissions in the form of enteric fermentation, which is valued less in the GTP_{100} metric (Flysjö et al. 2011). As a result, if GTP_{100} is used, the overall carbon footprint including emissions related to milk processing and transport from New Zealand to Sweden would be almost identical between the two countries. This cursory comparison, and our analysis of the data from Weiss and Leip (2012) within the European Union, indicate that at least for some examples, the choice of metric could have a significant influence on how significant food miles are in comparisons of the overall carbon footprint of products produced in different countries and traded internationally to reach distant markets.

5. Conclusion

Life cycle assessment of the climate impact of different food products and different farm systems requires a metric to convert the emission of different GHGs into a common unit. Even though GWP_{100} is by far the most commonly used metric, many others can be scientifically justified and could be more appropriate, depending on the specific application and decisions that the LCA seeks to support.

We used three alternative metrics, which differ significantly in the weighting for emissions of CH_4 relative to CO_2, to demonstrate that the choice of climate metric materially influences the question whether organic dairy farm systems have a lower carbon footprint than conventional or high-input systems. Depending on the specific study, the choice of metric can flip the result entirely, such that organic systems have lower footprints if GTP_{100} is used but higher footprints if GWP_{20} is used. The carbon footprint of beef from ruminants, based on one comprehensive European study, is higher on average than meat from monogastric animals regardless of the metric choice, but the difference depends substantially on the choice of metric. Given country-country variations, the metric choice could result in beef from some countries having a lower carbon footprint than pork from other countries within the European Union depending on the climate metric chosen to account for GHG emissions.

The choice of metric thus can substantially influence the relative climate-friendliness of different food products and farm systems. The influence is comparable in magnitude to whether and how emission related to land-use and land-use change and emissions related to international transport of food products are accounted for.

We have used only a limited number of readily available studies to test the sensitivity of their results to the choice of climate metric. It would be highly desirable to test our results against a wider range of studies with different assumptions. Given our results, the choice of climate metric deserves much greater attention in LCA studies and transparency when key conclusions about GHG footprints from different farm systems or food products are communicated. To support such transparency, LCA of GHG emissions should strive to retain emissions of individual gases in their ‘native’ units to allow the sensitivity of results to be tested against different metric choices, and results to be updated as metric values change.

6. Acknowledgements

The authors would like to thank Adrian Leip for kindly providing the full dataset underpinning the study by Weiss and Leip (2012), which provides the basis for our analysis of the impact of climate metrics on the carbon footprints of different meat products within the European Union.

ABSTRACT

Methodology and guidelines for quantifying greenhouse gas (GHG) emissions and fossil fuel demand from sheep and goat supply chains covering the system boundary of the cradle-to-primary-processing-gate were developed by an international technical group. Key learnings included the need to recognize and account for 1) the global diversity of small ruminant production and processing systems, 2) the potential for limited data availability, and 3) several main areas of methodology that have potential to change the final results. Two critical areas of Life Cycle Assessment (LCA) based methodology identified were the importance of determining feed requirements by animals and the methods for handling multi-functional processes including allocation. On-farm, biophysical allocation based on relative feed requirements was recommended for allocation between animal species sharing the same feed sources and for allocation between meat, milk and/or fiber. However, sensitivity analysis of different allocation methods should be carried out and results presented to illustrate the effects on results.

Keywords: greenhouse gases, goats, international, methodology, sheep

1. Introduction

Livestock have been identified as being major contributors to resource use and environmental impacts at a global scale (e.g. Gerber et al. 2013; Steinfeld et al. 2006). Small ruminants (e.g. sheep and goats) are a relatively small component of the total livestock sector but are of global importance because they cover a wide diversity of systems across an enormous range of geographical regions that provide a variety of products and functions. In 2011, sheep and goats produced more than 5 million tonnes of meat and 24 million tonnes of milk globally and production has increased by 1.7% and 1.3% per year, respectively, during the past 20 years (FAOSTAT, 2014). This increase was driven mainly by developing countries in Africa and Asia, although Oceania (mainly for meat) and Europe still contribute significantly to production. Production systems can vary from intensive systems, where animals are partially or predominantly housed, to extensive systems which rely on grazing and native forages, and transhumance systems that involve large flock movements. Products are not restricted to meat and milk; sheep are also valued for their wool (more than 2 million tonnes of greasy wool was produced globally in 2011), and goats for their mohair and cashmere. Small ruminants also play a crucial role in small-scale, rural and family-based production systems by sustaining livelihoods, contributing to food security and nutrition, providing a way to store and manage wealth and supporting ecosystem services.

Of the range of environmental impacts from livestock systems, climate change associated with greenhouse gas (GHG) emissions has received the most attention during the past decade. This has resulted in efforts to support decision-making of purchases by consumers by making them aware of GHG emissions linked to products they eat through environmental labelling of products (e.g. Tescos scheme in the United Kingdom and one of the indicators in the pending Grenelle scheme in France). Labelling focused on the carbon footprint (i.e. total GHG emissions expressed on a CO_2–equivalent basis) throughout all stages of production and provision of products to consumers has generally involved the use of a Life Cycle Assessment (LCA) approach.

Similarly, an array of environmental assessment methods have been set up in support of product-based environmental performance schemes for business-to-business communication (e.g. environmental product declaration schemes), and of environmental improvement reporting systems (e.g. incentives linked to GHG emission mitigation options). Furthermore, other LCA-based approaches are being examined by some governments to monitor the environmental footprint of the economy and set environmental policy priorities at the sector level accordingly (e.g. the life-cycle based indicators developed by the European Commission).

Given such proliferation, it is desirable that an internationally-acceptable common methodology is used so that products can be assessed on a similar basis. Common and robust methodology tailored to the specific nature of small ruminant supply chains will also enable various stakeholders to identify hotspots and opportunities to reduce environmental impacts. Some sectors have started to work together to agree on a methodology, which has typically been based on use of an LCA approach (e.g. for milk products by the dairy sector; IDF 2010). Similarly, initial work on a draft methodology for lamb meat was initiated by Beef+LambNZ and the International Meat Secretariat. Recently, the Food and Agriculture Organization of the United Nations (FAO) has initiated a broad process to develop harmonized international methodologies and guidelines to assess the environmental performance of livestock supply chains. This resulted in the Livestock Environmental Assessment and Performance (LEAP) Partnership, which is a multi-stakeholder initiative whose goal is to improve the environmental sustainability of the livestock sector through better metrics and data (LEAP 2014a). The LEAP Partnership comprises a large range of government, industry and civil society organizations. The three groups are represented at a Steering Committee, while the Guidelines are primarily developed by Technical Advisory Groups (TAGs) of international experts with experience in LCA, GHG emissions and livestock systems. One of such TAGs was established and has been active over the past year in developing guidelines for assessing GHG emissions and fossil fuel demand for the small ruminant sectors. This paper reports on aspects of methodology development of the small ruminant guidelines and key learnings from it. In March 2014, the draft guidelines for small ruminant supply chains (LEAP 2014b), poultry supply chains (LEAP 2014c) and animal feeds (LEAP 2014d) were released for public review by the FAO, with the intention of revising them and producing a final set of guidelines in late-2014.

2. Methodology

The first key role of the TAG was to define the scope of the methodology. It was decided to limit the small ruminants covered by the guidelines to goats and sheep due to their significance and data availability. However, the principles developed could be applied to other small ruminant species such as alpaca and deer. It was recognized that globally there are a very wide range of products produced from small ruminants with the major ones being meat, milk and fiber. It was decided to confine the system boundary covered by the guidelines to the cradle-to-primary-processing gate (Figure 1), while recognizing that environmental communication and comparisons of products must be based on the full supply chain and, therefore, the importance of future development to extend the guidance to the full life cycle. The primary processing stage for each of the main products was selected as the end point for the guidelines since it is in common to most end products, whereas secondary processing stages can vary greatly depending on the final product(s) produced.

Separate guidelines were developed in parallel for the animal feed supply chain (LEAP 2014d) and these covered emissions from all aspects of feed production through to the animal's mouth, whether the feed was produced on the livestock farm or purchased. Thus, it was important to align the LEAP Animal Feed Guidelines with those on the small ruminants (see Figure 2). Relevant points of alignment to avoid double counting or missed processes include 1) manure leaving a farm for application to feed crops leaves the system boundary of the small ruminants as it is collected (i.e. collection and on-farm storage emissions belong to the small ruminant guidelines), while all subsequent emissions from transport and after application are associated with feed production, and 2) any emissions associated with feed wastage at the animal feeding step on farm are accounted for in the small ruminant guidelines.

The main impact category covered by the small ruminant guidelines is climate change, estimated from the GHG emissions and expressed as CO_2-equivalents. Previous work done on guidelines for animal feeds provided the Feed TAG with the opportunity to expand the scope of the LEAP Animal Feed Guidelines to include other impact categories of eutrophication, acidification and land occupation. The GHG emissions in the small ruminant guidelines include methane (CH_4) emissions from rumen enteric fermentation and from animal dung and manure, nitrous oxide emissions (N_2O) from animal excreta deposited directly on grazing/browsing land and from manure collection and storage on-farm, and energy-related inputs from animal management, water supply and for primary processing (Figure 2). It also includes emissions from animal transportation, and primary processing emissions such as from the use of energy, consumables, refrigeration and wastes and waste-water processing.

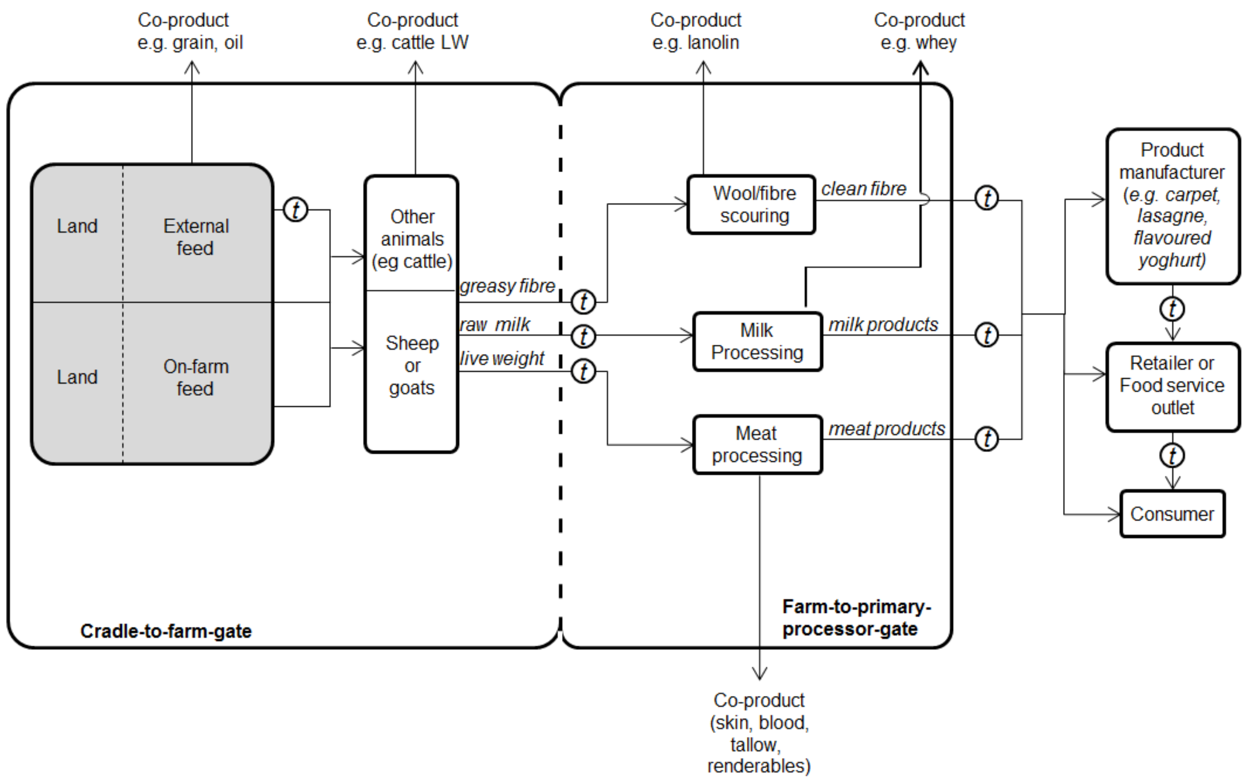

Figure 1. System boundary diagram for the cradle-to-primary-processing-gate for sheep and goat supply chains covering the three main products of fiber, milk and meat. The land and feed (inner shaded left box) is covered in the LEAP Animal Feeds Guidelines (LEAP 2014d). The ⓣ symbols refer to the main transportation stages.

The unit of analysis depends on the relevant stages of the life cycle covered. In view of the significance of the cradle-to-farm-gate stage, and that many published studies are limited to this component of the life cycle, these units have been expressed for this stage as well as for the cradle-to-primary-processing gate (Table 1). The equation for energy-corrected milk (ECM) is based on that from the IDF (2010) for dairy cow milk, to enable comparison between and within animal species, as:

kg ECM = kg milk x (0.1226 x fat% + 0.0776 x true-protein% + 0.0621 x lactose%)

Table 1. Recommended units of analysis for the three different main product types from small ruminants according to whether it is leaving the farm or primary product processing gate.

Main product type	Cradle-to-farm-gate	Cradle to primary-processing-gate
Meat	Live-weight (kg)	Meat product(s) (kg)
Fiber	Greasy weight (kg)	Clean weight (kg)
Milk	Energy-Corrected-Milk (kg)	Milk product(s) (kg)

The TAG was composed of eight selected experts drawn from six countries. Their backgrounds and complementary knowledge of products, systems and regions, allowed them to understand and address different interest groups and so ensure credible representation. While the TAG leader had a key role in drafting the guidelines, workshops and other interactions allowed consensus to be reached within the whole group. Before their release for public review, draft guidelines were reviewed by the LEAP Steering Committee and three independent reviewers.

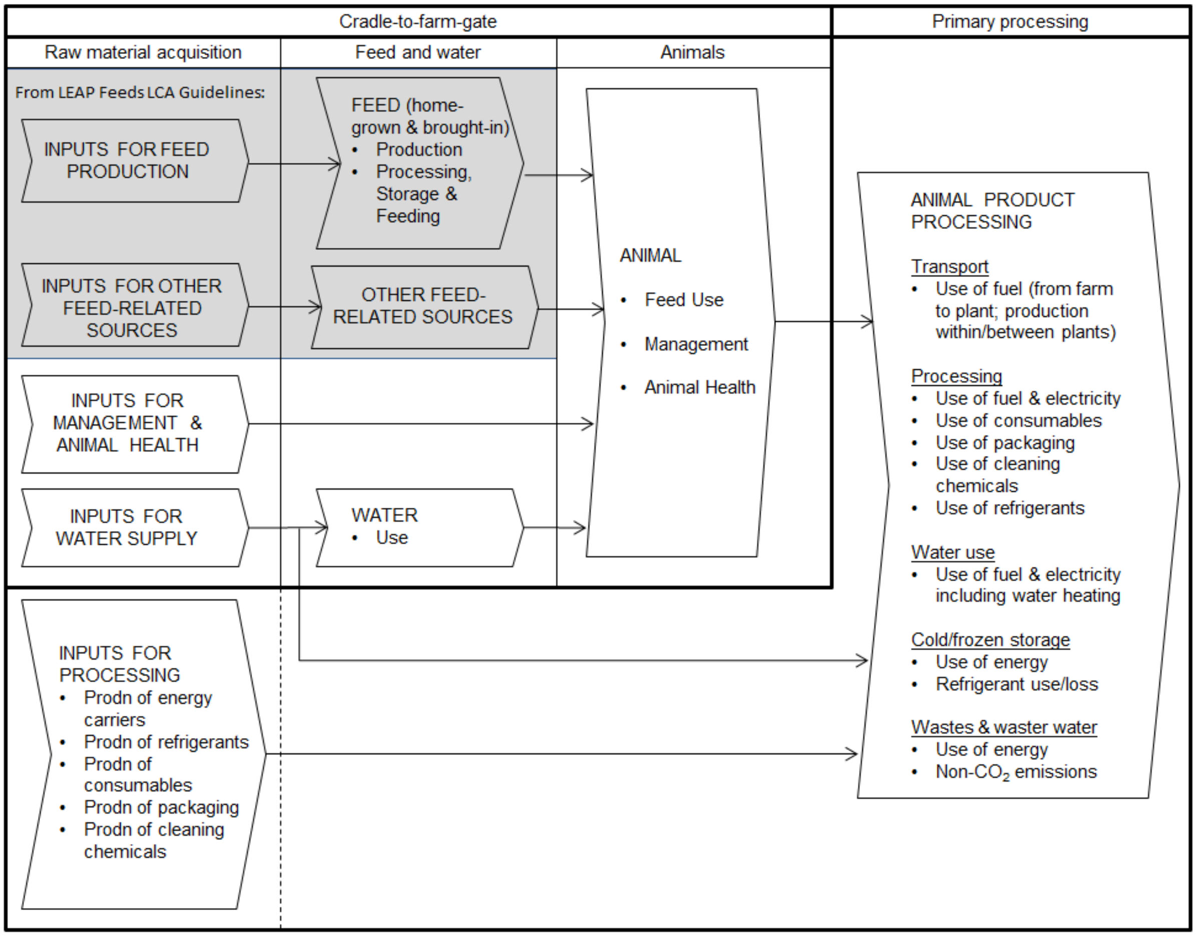

Figure 2. Processes that contribute to GHG emissions and fossil fuel demand within the system boundary of the cradle-to-primary-processing-gate for small ruminants. Note that the upper left shaded box refers to components covered by the LEAP Animal Feeds Guidelines (LEAP 2014d).

3. Results and Discussion

A methodology and guidelines for application were developed for determination of the GHG emissions and fossil energy demand from sheep or goat supply chains within the system boundary of the cradle-to-primary-processing-gate. The cradle-to-farm-gate stage was seen as being particularly important to cover in detail because of its significance to the whole life cycle. For example, Ledgard et al. (2011) evaluated the cradle-to-grave carbon footprint of lamb produced in New Zealand (NZ) and consumed in the United Kingdom and found that the cradle-to-farm-gate stage constituted 80% of total life cycle GHG emissions. The corresponding value for the primary meat processing stage was 3%.

Two areas of methodology identified as of key importance were 1) determining feed requirements by animals, and 2) the methods for handling multi-functional processes including allocation. These are discussed in the following sections.

3.1. Importance of determining feed requirements by animals

Within the cradle-to-farm-gate stage, the majority of GHG emissions from ruminant animals are determined by the amount of feed intake by animals, which is the main driver of enteric CH_4 emissions and of the amount of N excreted (the main source of N_2O emissions). Research in France and NZ (Gac et al. 2012; Ledgard et al. 2011) across diverse surveyed sheep farm systems showed that of total cradle-to-farm-gate GHG emissions, 53-73% were from enteric fermentation and 16-20% from excreta N_2O emissions. Thus, it was considered critical to obtain an accurate estimate of total feed intake and to use an IPCC tier-2 approach rather than a simple tier-1 approach. The latter is simply a constant value per animal and therefore would provide no opportunity to use the methodology to assess potential benefits from improved animal production and management practices.

In many small ruminant systems, much (or all) of the animal's time is spent grazing or browsing a range of forages. Thus, it is difficult to get a direct estimate of feed intake by primary data collection. Actual primary data on feed provided and consumed will often only be possible for the component of feed that might be stored on-farm or brought-in to the farm from an external source (e.g. concentrates). Consequently, an indirect modelling approach is required to calculate feed intake based on the energy requirements of animals. Most models used for calculation of feed requirements derive intake from the energy requirements for animal processes of growth, reproduction, fiber production, milk production, activity (i.e. grazing/walking) and maintenance (e.g. IPCC 2006; NRC 2007). The guidelines recommended that the choice of model/method should be based on a hierarchy of:

1. country-specific models used in the country National Greenhouse Gas Inventory;
2. other models that have been peer-reviewed and published that are appropriate to the region and country;
3. IPCC (2006) model;
4. IPCC default tier-1 values (this should be used as a last resort).

Associated data on the energy concentration of the feed(s) is required to convert energy intake by animals in feed(s) to dry matter intake. Again, this should be based on a hierarchy of: primary data for the specific feed type(s) where available; published values from the region or country for the specific feed type; or general published values (e.g. NRC 2007). Conversely, dry matter intake can be known or assessed from past research (from intake capacity by animals depending on level of productivity, e.g. as used by INRA, France) and energy intake can be derived from data on energy concentration of feeds.

Prior to calculating feed intake, the other critical aspect is to define the animal population and productivity over a representative one-year period. The animal population data must recognize the number of breeding animals (e.g. breeding ewes or does, rams or bucks, and the replacement breeding animals), as well as animals for production (e.g. surplus lambs or kids). This is illustrated for a simplified example of an animal population for a sheep farm system in Figure 3. From the base animal population data, an annual stock reconciliation needs to be derived that accounts for the time of lambing/kidding and time of sale of surplus animals. Ideally, a monthly or seasonal stock reconciliation would be used. The benefit of having a tier-2 methodology (using calculated energy requirements) and specific seasonal or monthly data is that the effects of improvement in animal productivity on reducing the carbon footprint of products can be determined. For example, achieving the final slaughter weight of lambs earlier results in a lower feed intake and the maintenance feed requirement is reduced relative to the feed needed to achieve a given level of animal production.

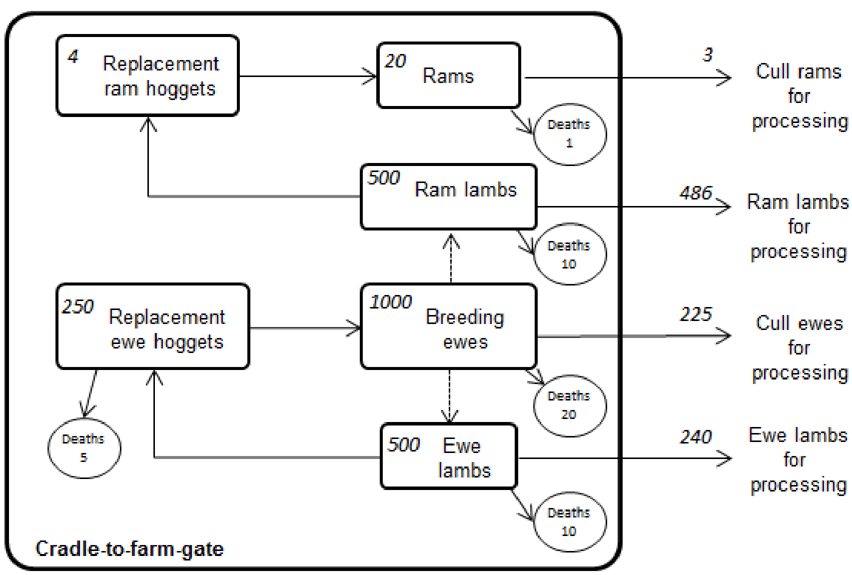

Figure 3: Simplified example of a sheep population illustrating relative numbers of breeding and replacement sheep on-farm and surplus sheep sold for meat processing (based on a breeding ewe flock of 1000, 100 percent lambing, 25 percent replacement rate, 2 percent death rate and first lambing at 2 years of age).

Calculation of animal productivity requires average data on male and female adult live-weight, live-weight of animal classes at slaughter, fiber production and milk production (for milking sheep or goats). Primary data on the animal population and productivity shall be used where possible.

3.2. Handling multi-functional processes including allocation of GHG emissions between co-products

There are a number of stages within the system boundary where multi-functional processes occur and where accounting for GHG emissions between different co-products is required (Figure 1). The ISO 14044 (2006) standard provided a hierarchy approach for accounting for co-products based on system separation wherever possible, followed by system expansion and then allocation options with an approach reflecting the underlying (bio)physical relationships between co-products being the preferred first option. As part of the LEAP process, a multi-functional output decision tree was developed (see LEAP 2014b,c,d) to further aid in selecting a system for handling co-products based on ISO 14044 (2006) and this was applied consistently across the small ruminant and poultry TAGs.

A summary of the recommended methods developed for handling co-products is given in Table 2, although it is also recommended that a sensitivity analysis involving several methods is applied to illustrate the effects of the choice of method used. Within the farm, there are two stages where choices relating to animal co-products may be required, i.e. for mixed species sharing the same feed resources, and for milk, meat and/or fiber production from sheep or goats (Figure 1). The preferred method for accounting for these multi-functional processes and co-products is firstly to separate activities related to the co-products where possible, and then to apply a biophysical approach based on energy intake from feed associated with the different animal species or co-products. This also recognizes that in ruminant livestock systems, the major determinant of GHG emissions within the farm stage is enteric CH_4 and excreta N_2O emissions, and the driver of these is feed intake (as noted in section 3.1).

Table 2. Recommended methods for dealing with multi-functional processes and allocation between co-products for the cradle-to-primary processing gate stages of the life cycle of small ruminant products

Source/stage of co-products	Recommended method*	Basis
Animal species (within farm)	1. Separate farm activities 2. Biophysical causality	First, separate the activities specific to an animal species and attribute the inputs/emissions accordingly. Then, determine emissions specific to feeds relating to the sheep or goats under study. If not possible and for remaining non-feed inputs, use biophysical allocation based on the proportion of total energy requirements for each of the different animal species.
Live-weight, fiber, milk for sheep or goats (at farm gate)	1. Separate activities 2. Biophysical causality	First, separate activities specific to products (e.g. electricity for shearing or milking). Then use biophysical allocation according to energy or protein requirements for animal physiological functions of growth, fiber production, milk production, reproduction, activity and maintenance.
Milk processing to milk products	1. Separate activities 2. Mass of fat + protein	First, separate activities specific to individual products where possible. Then use allocation based on the relative amount of fat + protein in the milk products
Fiber processing to clean fiber and lanolin	1. Separate activities 2. Economic	First, separate the activities specific to individual products where possible. Then use economic allocation based on a minimum of three years of recent average prices.
Meat processing to meat and non-meat products	1. Separate activities 2. Economic	First, separate the activities specific to individual products where possible. Then use economic allocation based a minimum of three years of recent average prices.

* *Note*: Where choice of allocation can have a significant effect on results, it is recommended to use more than one method to illustrate the effects of choice of allocation methodology

Defining a biophysical allocation methodology for handling co-products of milk, meat and fiber from sheep or goats at the farm-gate was most problematical, since this has received little research attention. For sheep or goats where milk is a main co-product, an allocation approach based on relative energy requirements for milk or meat production was considered most appropriate. This method also aligns with that agreed to in international guidelines for milk and meat from dairy cows by the IDF (2010). However, for animals where fiber is an important co-product this allocation approach was considered as less appropriate since fiber production is more commonly limited by protein rather than energy (e.g. CSIRO 2007). Thus, an approach based on use of a protein requirement model was considered as more desirable, but it was recognised that this is relatively untested. Recent studies by Wiedemann et al. (2014) indicated that biophysical allocation based on protein mass of the co-products can give similar results to that using a protein requirement modelling approach and that this may be a simpler methodology to use for allocation between fiber and meat.

An illustration of the effect of method of calculation for allocation between live-weight (for meat) and milk or fiber co-products at the farm gate is given in Table 3, based on use of data from Bett et al. (2007) for a Kenyan smallholder goat milk and meat production system, and from Ledgard et al. (2010) for a NZ hill country sheep production system. This shows relatively large effects of allocation method on the estimated % allocation values. It also shows the importance of applying a sensitivity analysis to illustrate the effects of choice of allocation method on the environmental footprint of co-products from small ruminants.

Table 3. Effect of allocation method on percentage allocation between live-weight (LW for meat) and milk or wool for case study goat or sheep systems

	Goats (Kenya) (Bett et al. 2007)	**Sheep (NZ) (Ledgard et al. 2010)**
Main products	Milk, LW for meat	LW for meat, wool (for carpet-making)
Farm type	Smallholder farm	Extensive-grazing pasture farm
Percent allocation to milk (goats) or wool (sheep):		
Biophysical – energy requirements	70%	16%
Biophysical – protein requirements	n.d.	37%
Biophysical – protein mass	50%	39%
Economic	45%	19%

During the primary processing stage, there can also be multiple co-products depending on the type of main products being processed. As part of the multi-functional output decision tree it was defined that a biophysical allocation approach is appropriate where co-products have similar physical properties and serve similar goals or markets, but that where this does not apply the use of economic allocation is appropriate. Based on these criteria, biophysical allocation is recommended for dealing with different milk products, while economic allocation was identified for handling co-products from fiber and meat processing since the latter produce secondary products for very different end uses. For milk products, fat and protein are the key constituents in the co-products and therefore allocation based on the mass of fat plus protein is recommended. This aligns with recent approaches described for dairy cow milk products (Flysjö 2011; Thoma et al. 2013).

Primary processing of greasy fiber from sheep or goats can result in clean wool, lanolin and residue (vegetable matter and dirt, which usually goes to waste). The latter residue is often a valueless waste, but in some cases it may be further processed to a valuable conditioner or fertilizer, and in such cases it should be treated as a co-product. Economic allocation (based on a recent average of a minimum of three years data to reduce effects of temporal variability) of co-products from primary processing of fiber is recommended. In practice, the recovery of lanolin from greasy wool of sheep amounts to only about 2-7 percent by weight (higher for finer wool and lower for goat fibers) or possibly slightly higher on an economic basis, and therefore most of the resource use and GHG emissions will be allocated to the fiber.

Primary processing of goats and sheep for meat production can result in a wide range of co-products, including hides (for leather), tallow (e.g. for soap, biofuel), pet food, blood (e.g. for pharmaceutical products), fiber and renderable material (e.g. for fertilizer). Also, the proportion and components of the carcass used for meat products for human consumption and for co-products is dependent on culture and economic factors and can differ significantly. In view of the very varied use of these co-products and the protocol relating to the multi-functional output decision tree, economic allocation methodology is appropriate. However, for the various edible meat products, it is recommended that they all be treated the same per-kg (i.e. no separate economic allocation between meat cuts). An example of the differences in weight and relative economic value of different meat cuts and non-meat co-products is given in Table 4 for the average lamb from NZ abattoirs in mid-2009. It shows that there was more than an eight-fold difference in price per kg between the lamb rack and neck cuts of meat and illustrates the potential effect that application of economic allocation between meat cuts could have had. Use of data from Table 4 results in calculated values for the % allocation for meat relative to that for meat plus other non-meat co-products at 88% based on economic allocation and 51% based on mass allocation. This difference reflects the greater economic value of meat than of the non-meat co-products.

Table 4. Variation in the mass and economic value of components of an average New Zealand lamb leaving an abattoir and the effects on allocation calculations (data provided by NZ Meat Industry Association from 2009)

	Average mass of component (kg)	Component as a % of total mass	Price per-kg relative to leg meat	Component as % of total economic value
Meat:				
Neck	0.54	1.5	0.21	0.8
Shoulder	4.6	12.7	0.51	16.1
Rack	1.21	3.4	1.73	14.3
Breast and shank	1.46	4.1	0.47	4.8
Loin	1.43	4.0	1.04	10.2
Legs	4.68	13.0	1.00	32.1
Other meat	2.43	6.7	0.38	6.4
Edible offal	2.0	5.5	0.28	3.9
Co-products:				
Hide/skin	2.21	6.1	0.28	4.3
Wool	1.59	4.4	0.27	3.0
Blood	1.76	4.9	0.01	0.1
Inedible offal	0.65	1.8	0.14	0.6
Rendering/tallow	11.54	32.0	0.04	3.5

4. Conclusions

Key learnings from development of the guidelines included the need to recognize and account for 1) the diversity of small ruminant production and processing systems, 2) the potential for limited data availability, and 3) the importance of several main areas of methodology in determining the final results. The LEAP partnership offered an effective process for stakeholders in the chain to overcome these issues in a concerted manner. The guidelines were structured so that they could be applied to a wide range of production and processing systems using the generic principles and varying levels of specification provided. Additionally, for several processes a hierarchy approach was presented that identified the most appropriate method or data source as well as alternative options that were less detailed or less specific but more achievable for systems with limited data.

Two critical areas of methodology identified were the importance of determining feed requirements by animals and the methods for handling multi-functional processes and allocation. Relatively large sections of the guidelines were dedicated to these areas of methodology, by providing greater specificity on data sources and methods of calculation. In this paper, case study examples were given to show the effects of the methodology choices for co-product handling including allocation options. It was concluded that sensitivity analysis should be carried out and results presented to illustrate the effects of these key methodology choices on the calculated environmental emissions.

An additional learning from development of the draft guidelines for small ruminants concurrently with those for feed and poultry was the importance of harmonization across stages of the supply chain (feed and animal production) and between species. Further adjustments of the Guidelines are expected based on the on-going Public Review and a planned test phase. It is also LEAP's aim to expand the guidelines to the inclusion of other environmental impact categories. This collaborative approach, which is also currently being applied to other species (e.g. large ruminants), has potential to improve consistency in assessing and reporting the environmental performance of livestock and in monitoring improvements.

Comparing UK turkey production systems using analytical error propagation in uncertainty analysis

ABSTRACT

The aim of this study was to quantify the environmental impacts per unit of live weight of the main UK turkey systems, namely stag and hen production with either controlled or natural ventilation. An LCA modeling framework, based on system approach and mechanistic sub-models was applied for this purpose. For the first time, detailed production data from the industry was used as input. The differences between the systems were analyzed using an analytical “top-down” method for uncertainty analysis, developed specifically for this study. The results show that there were only small, mainly non-significant differences in the impacts between the systems, affected mainly by their feed conversion ratio and slaughter weight. The novel uncertainty analysis method makes it possible to obtain exact quantification of the overall uncertainties of outputs of complex systems models without the need of time consuming and approximate Monte Carlo simulations.

Keywords: acidification potential, eutrophication potential, global warming potential, turkey production, uncertainty analysis

1. Introduction

According to Defra (2011), the UK turkey production in 2010 was 162 thousand tons carcass weight, which is over 10% of the total UK poultry meat production. Despite the importance of turkey systems and their potential contribution to the overall environmental consequences of livestock production, the environmental impacts of turkey production have so far only been analyzed using generic UK data (Williams et al. 2006). In order to quantify the current impacts of the main turkey systems, and to find ways to improve their environmental friendliness, detailed production data from the main turkey production companies is required, combined with a systematic assessment methods, such as agricultural LCA.

In earlier studies (Leinonen et al. 2012a; b; Williams et al. 2006), a systems approach-based modeling framework was developed to quantify the environmental impacts of poultry systems. As an essential part of this framework, a method for uncertainty analysis was also developed, in order to make statistical comparisons between the systems under consideration. In these studies, the uncertainty was quantified using Monte Carlo simulations, which is a common practice in agricultural LCA. However, the problem with such an approach is that it requires a lot of computing power, it is time consuming, and the output is only an approximation, the accuracy of which depends on the number of Monte Carlo runs used. Therefore, it is quite clear that there is a need for a more straightforward, preferably analytical method for quantifying the uncertainty in agricultural LCA studies.

The aim of the current study was to apply the LCA method, “from cradle to gate” to quantify and compare the environmental burdens of the main production systems in UK, namely 1) Stags (males) with controlled ventilation, 2) Hens (females) with controlled ventilation, 3) Stags with natural ventilation, and 4) Hens with natural ventilation. Another aim was to develop a novel analytical method for uncertainty analysis, which would allow exact quantification of the system uncertainties, without time consuming Monte Carlo simulations which could give only an approximate solution.

2. Methods

2.1. Systems approach and the data

The general approach taken in the current study was with systems modeling of production. This included structural models of the industry, process models and simulation models that were unified in the systems approach so that changes in one area caused consistent interactions elsewhere. This approach was applied to both feed crop and animal production. The systems modeled in this study included crop production, non-crop nutrient production, feed processing, breeding, turkey brooding, turkey finishing and manure and general waste management, following the overall principles presented by Williams et al. (2006) and Leinonen et al. (2012a;b).

The production systems in this study were considered to represent typical mainstream UK turkey production, i.e. stags and hens, both with either controlled or natural ventilation. The farm energy consumption for heating, lighting, ventilation and feeding was based on average data from typical farms as provided by the main UK turkey production companies. Information about the type and amount of bedding and other material use was also obtained from the industry. The bird performance and production data, including the length of the production cycle, stocking density, final weight, feed intake and mortality came from actual farm data provided by the industry. The main production figures for different systems are presented in Table 1. Additional data, such as life cycle inventories (LCI) of agricultural buildings and machinery, came from Williams et al. (2006). The baseline diets representative of those used in the UK for each system were constructed using information provided by the turkey industry, and the environmental impacts arising from feed production were calculated based on the relative proportion of each ingredient in these diets.

Table 1. The average production figures for the main UK turkey systems considered in this study

System	Age at slaughter, days	Weight at slaughter, kg	Feed conversion ratio, kg feed/kg live weight
Stags, controlled ventilation[1]	133	15.2	3.1
Hens, controlled ventilation	95	7.3	2.8
Stags, natural ventilation	137	16.6	3.1
Hens, natural ventilation	90	6.7	2.6

[1]In this system, the birds were predominantly males, but some farms with mixed flocks with small amount of females are also included.

2.2. The models

The structural model for turkey systems calculated all of the inputs required to produce the functional unit (1000 kg of live weight), allowing for breeding overheads, mortalities and productivity levels. It also calculated the outputs, both useful and unwanted. Changes in the proportion of any activity resulted in changes to the proportions of others in order to keep producing the desired amount of output. Establishing how much of each activity was required was found by solving linear equations that described the relationships that linked the activities together.

The model calculated the N, P and K contents of the manure according to the mass balance principle, i.e. the nutrients retained in the animal body were subtracted from the total amount of nutrients obtained from the feed. For the purpose of the study, it was assumed that all manure was transported for soil improvement.

A separate sub-model for arable production was used to quantify the environmental impacts of the main feed ingredients, with main features as in Williams et al. (2010). All major crops used for production of turkey feed were modeled. For the crops produced overseas (soya, palm oil) the production was modeled as closely as possible using local techniques, and transport burdens for importing were also included. The greenhouse gas emissions arising from land use change were taken into account according to the principles of the carbon footprinting method PAS 2050:2011 (BSI 2011).

A separate sub-model was also used for manure and the nutrient cycle. In the model, the main nutrients that were applied to the soil in manure were accounted for as either crop products or as losses to the environment. N was explicitly partitioned into readily plant available and slow-release organic N. The crop yield response was compared with that from manufactured N and the benefits were credited to poultry by offsetting the need to apply fertilizers to winter wheat as described by Sandars et al. (2003) and implemented by Williams et al. (2006). Losses as nitrate or by denitrification were calculated on a long term basis.

2.3. Environmental impacts

Emissions to the environment were aggregated into environmentally functional groups as follows. Global Warming Potential (GWP) was calculated using a timescale of 100 years. The main sources of GWP in turkey industry are carbon dioxide (CO_2) from fossil fuel, nitrous oxide (N_2O) and methane (CH_4). GWP was quantified as CO_2 equivalent: with a 100 year timescale 1 kg CH_4 and N_2O are equivalent to 25 and 298 kg CO_2 respectively (Foster et al. 2007).

Eutrophication Potential (EP) was calculated using the method of the Institute of Environmental Sciences (CML) at Leiden University (http://www.leidenuniv.nl/interfac/cml/ssp/index.html). The main sources in turkey production are nitrate (NO_3^-) and phosphate (PO_4^{3-}) leaching to water and ammonia (NH_3) emissions to air. EP was quantified in terms of phosphate equivalents: 1 kg NO_3-N and NH_3-N are equivalent to 0.44 and 0.43 kg PO_4^{3-}, respectively.

Acidification Potential (AP) was also calculated using the method of the Institute of Environmental Sciences (CML) at Leiden University. The main source in turkey industry is ammonia emissions, together with sulfur dioxide (SO_2) from fossil fuel combustion. Ammonia contributes to AP despite being alkaline; when emitted into the atmosphere, it is oxidized to nitric acid. AP was quantified in terms of SO_2 equivalents: 1 kg NH_3-N is equivalent to 2.3 kg SO_2.

Primary Energy Use included all the energy needed for extraction and supply of energy carriers.

2.4. Breakdown of the environmental impacts

The results were broken down by the following material (and energy) flow categories (or sub-systems) to demonstrate their relative contribution to the overall impacts:

1) Feed: production of crops and additives, feed processing and transport. This category also includes the water consumed during housing.

2) Farm Electricity: direct electricity consumption at the farms (breeding, brooding and finishing) and hatcheries, not including feed production, processing and transport.

3) Farm Gas and Oil: direct fuel consumption at the farms and hatcheries, not including feed production, processing and transport.

4) Housing: direct emissions of NH_3, CH_4 and N_2O from housing and burdens from construction of farm buildings and vehicles, not including buildings and vehicles used in feed production, processing and transport of ingredients.

5) Manure and Bedding: emissions from manure storage and field spreading and the production of the bedding. This category also includes credits from replacing synthetic fertilizers. It does not include direct emissions of NH_3, CH_4 and N_2O from housing.

2.5. Uncertainty analysis

The uncertainties in the input variables can be divided into two groups, namely “alpha” and “beta” uncertainties, according to a concept first presented by Wiltshire et al. (2009) and Chatterton et al. (2010), and later applied for LCA for poultry production by Leinonen et al. (2012a). Alpha uncertainties can be considered to vary between systems, and therefore they should be taken into account in statistical analyses of the differences between the systems. For example, variation between farms in production, feed intake and energy use figures can all be considered to represent alpha uncertainties. In contrast, beta uncertainties are considered to be similar between the systems, and, following the principles of earlier studies, they were assumed to have no effect on the statistical comparison between the systems (Wiltshire et al. 2009; Chatterton et al. 2010; Leinonen et al. 2012a). Examples of the beta uncertainties are the emission factor for N_2O from manure, conversion factor from electricity to primary energy, and in general errors related to the modeling framework. In this study, the aim was to compare statistically the differences between production systems, and therefore only the alpha uncertainties are considered in the following.

To quantify the overall alpha uncertainty of the outputs of the LCA model, a novel, analytical “top-down” approach was developed for this study. In this analysis, the outputs (i.e. each category of environmental impacts per functional unit) were divided into separate components based on their sources, e.g. feed production, manure management and on-farm electricity use. Each component (*i*) was then expressed as a simplified function, and the total emissions of the system were calculated as their sum. For example for GWP, this can be expressed as:

$$GWP = \sum EC_i \times Activity_i \qquad \text{Eq. 1}$$

where $Activity_i$ represents for example material or energy use per FU, and the “emission coefficient” EC_i is the quantity of greenhouse gas (GHG) emissions per unit of activity. Depending on the context, the emission coefficient can be a simple emission factor, result of a complex function or outcome of the LCA model. In some cases, the EC_i can be considered to have both alpha and beta uncertainties, and in some other cases beta uncertainties only. If the latter option is true, then the uncertainty of the emissions coefficient can be ignored in the uncertainty analysis.

For example in the case of GWP, the emissions arising from feed production and manure management can be expressed with a simple linear function where the "activity" represents the feed consumption per functional unit, i.e. the feed conversion ratio (FCR):

$$F + M = a + (EC_f + EC_m) \times FCR \qquad \text{Eq. 2}$$

where F and M are the GHG emissions from feed production and manure, respectively, EC_f and EC_m are the emissions coefficients (calculated by fitting the above equation to the outputs of the full LCA model) for feed and manure, respectively, and FCR is the average feed conversion ratio, i.e. the mass of feed divided by the liveweight gain. The constant a, which was also calculated from the model outputs, is needed in the equation because the manure emissions are not directly proportional to the feed intake. Instead, it can be considered that there is a theoretical, (very low) level of feed intake where the nutrient intake equals the nutrient retention (assuming that this remains unchanged), and as a result, the emissions from manure are zero at that point.

Now the alpha uncertainty for the GHG emissions from feed production and manure management can be quantified using a general uncertainty propagation rule (e.g. Taylor 1996):

$$\left(\frac{\sigma_{F+M}}{F+M}\right)^2 = \left(\frac{\sigma_{EC_f}}{EC_f + EC_m}\right)^2 + \left(\frac{\sigma_{FCR}}{FCR}\right)^2 \qquad \text{Eq. 3}$$

where σ_{F+M} is the alpha uncertainty (standard deviation) of the combined feed and manure emissions, σ_{ECf} the alpha uncertainty of the feed production emissions (quantified from the output of the crop production sub-model), and σ_{FCR} the variation in the feed conversion ratio, quantified directly from the data provided by the turkey industry. The alpha uncertainty for the manure emission coefficient was considered to be zero and therefore it does not appear in the equation.

For the other GHG emissions, the emissions from direct farm electricity use (E) can be expressed simply as:

$$E = EC_e \times Eu \qquad \text{Eq. 4}$$

where EC_f is the emission coefficient for electricity and Eu is the average farm electricity use per functional unit. The emissions for farm gas consumption (G), or other fuel consumption where applicable, can be expressed exactly in the same way.

Again, the alpha uncertainty for the emissions from direct electricity use (and similarly for direct gas and other fuel use) can be quantified as:

$$\sigma_E^2 = EC_e^2 \times \sigma_{Eu}^2 \qquad \text{Eq. 5}$$

where the variation in the electricity consumption per functional unit (σ_{Ec}) comes directly from the industry data.

The direct GHG emissions from housing (H) are mainly N_2O in turkey production, and they were not included in the manure emissions described above. Instead, the housing N_2O emissions were modeled separately based on the live weight and the duration of housing. Therefore, these emissions per live weight can be expressed as:

$$H = EC_h \times Age \qquad \text{Eq. 6}$$

where Age is the average slaughter age of the birds. Now the alpha uncertainties for the housing emissions can be calculated as:

$$\sigma_H^2 = EC_h^2 \times \sigma_{Age}^2 \qquad \text{Eq. 7}$$

where the variation of the slaughter age (σ_{Age}) comes directly from the industry data.

Finally, the overall alpha uncertainty for the total GHG emissions can be quantified as sum of the alpha uncertainties of the different components presented above:

$$\sigma_{GWP}^2 = \sigma_{F+M}^2 + \sigma_H^2 + \sigma_E^2 + \sigma_G^2 \qquad \text{Eq. 8}$$

It should also be noted that when the uncertainty terms of the above equations are correlated, their covariance should also be taken into account in error propagation. However, in the case of the turkey emission model, most of the activities considered can be assumed to be independent from each other. The only exceptions are the slaughter age (used to model the emissions from housing) and the feed conversion ratio (feed and manure emissions). In theory, FCR should increase with the increasing age of the bird. However, in the data used in the present study, no consistent correlation between these variables was found within the systems, so the covariance between these variables was ignored in Eq. 8.

The uncertainties for other impact categories could be calculated mainly following the principles presented above. The main difference can be found in Eutrophication and Acidification Potentials, where the combined emission from feed production, housing and manure management can be expressed as a linear function of FCR. For example, for Eutrophication Potential this can be expressed as follows:

$$F + H + M = a + (EC_f + EC_h + EC_m) \times FCR \qquad \text{Eq. 9}$$

where F, H and M are the components of Eutrophication potential related to feed production, housing and manure management, respectively, EC_f , EC_h and EC_m are the eutrophication emission coefficients for feed, housing and manure, respectively. The alpha uncertainty for the EP arising from these components can be then quantified as:

$$\left(\frac{\sigma_{F+H+M}}{F+H+M}\right)^2 = \left(\frac{\sigma_{EC_f}}{EC_f+EC_h+EC_m}\right)^2 + \left(\frac{\sigma_{FCR}}{FCR}\right)^2 \qquad \text{Eq. 10}$$

Finally, a statistical analysis was conducted to evaluate the differences (at the P < 0.05 level) between the systems, based on the overall alpha uncertainties of each impact category, as described by Leinonen et al. (2012a).

3. Results

The environmental impacts of different turkey production systems, the contribution of different subsystems, and the alpha uncertainties of the impacts are presented in Figures 1-4. The results show that feed production, processing and transport was the main source of the impacts in the categories of Primary Energy Use and Global Warming Potential, while emissions from manure management had the biggest contribution to Eutrophication and Acidification Potentials. There was a lot of variation in the direct farm energy use (especially gas for heating) between the systems, but this had a relative small contribution to the overall impacts.

When the overall alpha uncertainties were applied in the statistical comparison between the systems, it was found that in most environmental impact categories there were generally no significant differences (P < 0.05) in the environmental impacts between the systems. A significant difference was found in Acidification Potential, where the stag system with controlled ventilation had a higher impact than the hen system with natural ventilation.

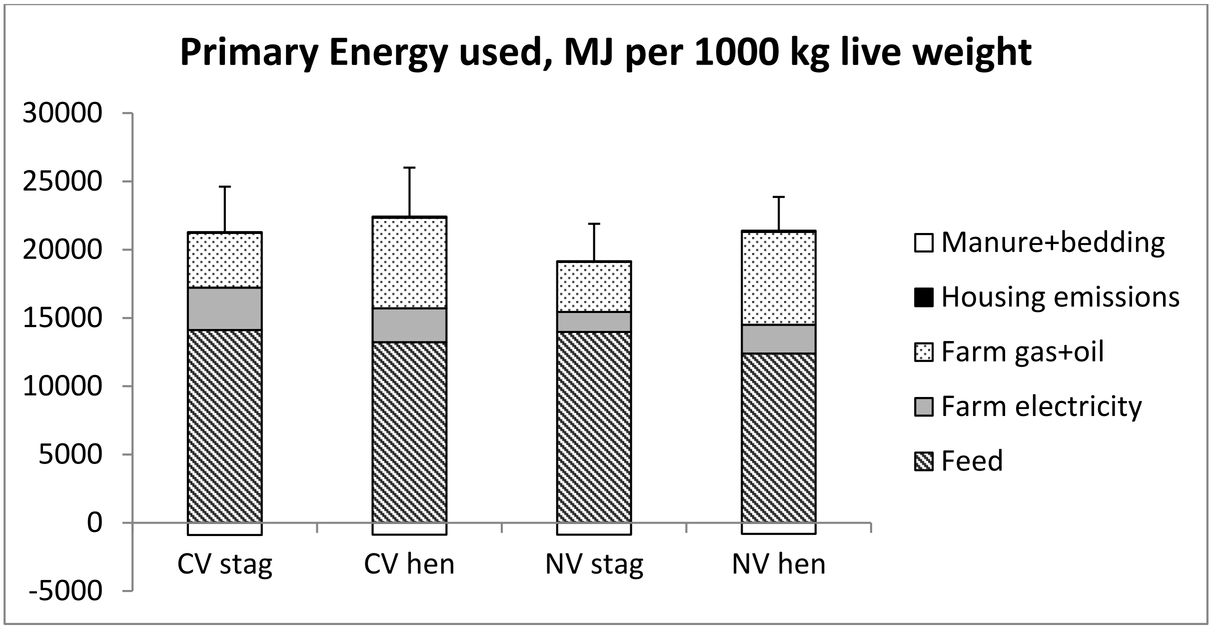

Figure 1. The Primary Energy Use of the four main UK turkey production systems. The error bars indicate standard deviations based on alpha uncertainties. CV=controlled ventilation, NV=natural ventilation.

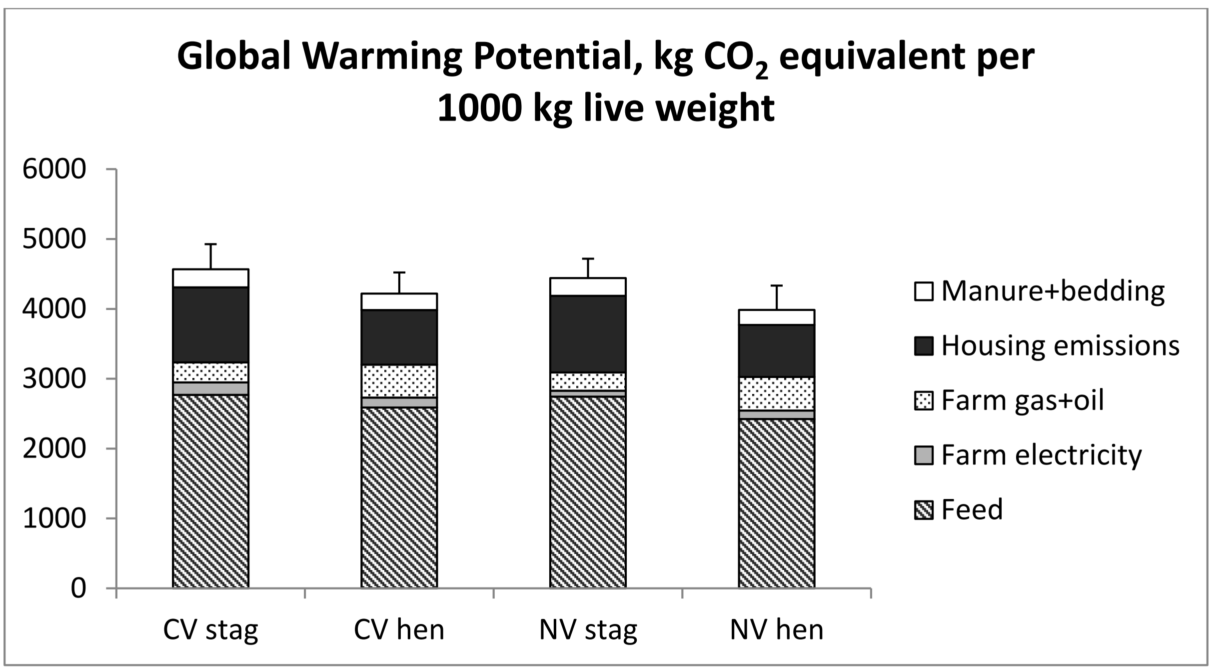

Figure 2. The Global Warming Potential of the four main UK turkey production systems. The error bars indicate standard deviations based on alpha uncertainties. CV = controlled ventilation, NV = natural ventilation.

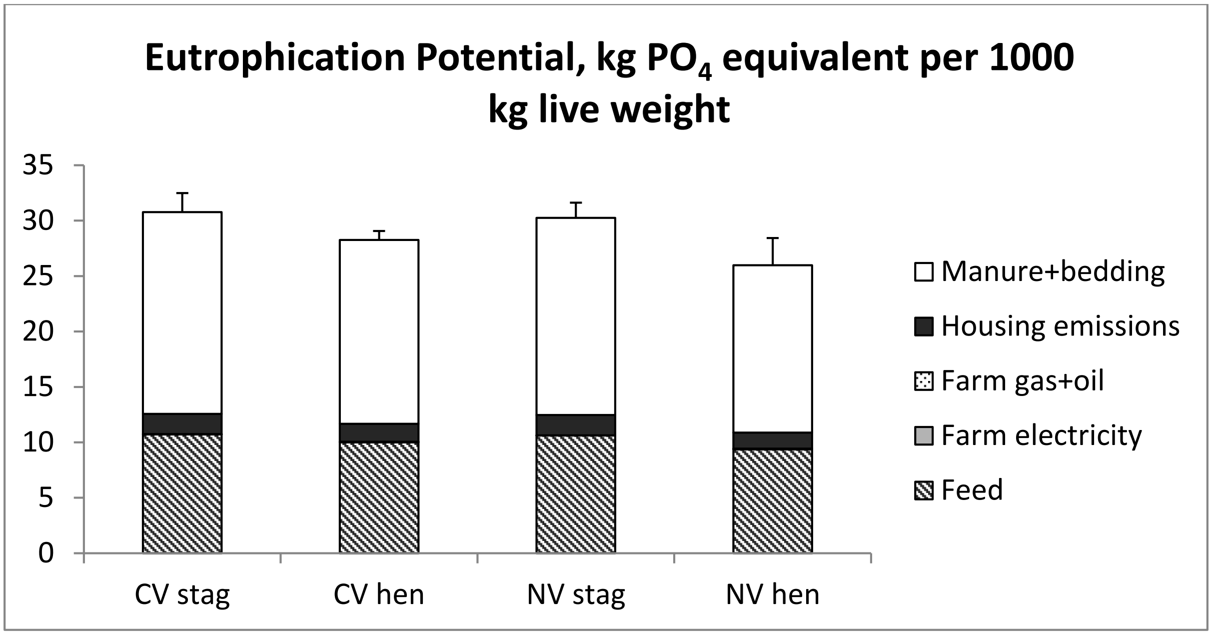

Figure 3. The Eutrophication Potential of the four main UK turkey production systems. The error bars indicate standard deviations based on alpha uncertainties. CV = controlled ventilation, NV = natural ventilation.

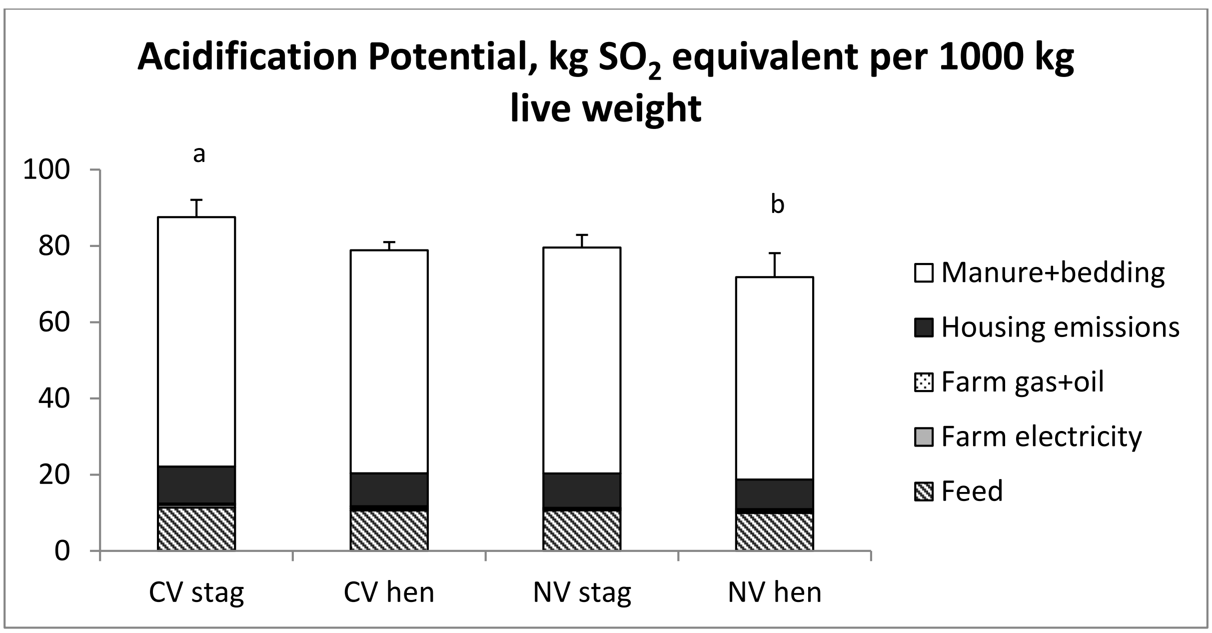

Figure 4. The Acidification Potential of the four main UK turkey production systems. The error bars indicate standard deviations based on alpha uncertainties. Different letters indicate a statistically significant ($P<0.05$) difference between the systems. CV = controlled ventilation, NV = natural ventilation.

4. Discussion

There were only small (mainly non-significant) differences in the environmental impacts between UK turkey production systems, although some systematic trends occurred in certain sources of the impacts. These trends were mainly related to feed conversion ratio, which affected the emissions from feed production, housing and manure management. When the cycle length and the final body weight increase, an increase in the feed intake per unit of live weight is also expected, as the relative contribution of the energy required for maintenance, as opposed to growth, increases with the age of the bird. In the systems compared in this study, the hen systems always had a shorter cycle length and lower body weight compared to the stag systems. For this reason, the FCR was lower for hens than for stags, and the hen systems consequently tended to have lower impacts than the stag systems, especially for the Eutrophication and Acidification potentials.

In contrast, the farm energy consumption, especially heating gas, was higher per unit of live weight for the hen systems than for the stag systems. This difference was again related to lower slaughter weight of hens. Although it can be expected that for example the heating requirement would be similar per bird for stags and hens (as heating is mainly required for young birds only), hens produce less output (i.e. live weight) per bird, and therefore the impact per the functional unit is higher. Thus the better yield in the stag systems partially compensated the higher impacts related to poorer feed conversion in some impact categories. This leads to the observation that mitigation methods, such as using renewable energy for heating young birds would be more effective for hens than stags.

Any quantitative comparison between different systems is not feasible if the range of uncertainty in the results is not available. Despite this well-known fact, uncertainty analysis is not commonly applied in LCA studies for agricultural products. This omission can be partly explained by the extensive requirement of the data, in order to quantify the uncertainties in the input variables reliably. However, another reason might be the limitations of the chosen calculation method itself. Monte Carlo simulations are usually used in uncertainty analysis. Hence, the model used to quantify the environmental impacts is run several (generally thousands) times, and for each run, the input parameters are randomly sampled from a pre-determined distribution. Running of very complex models thousands of times requires a lot of computing power, and is also time consuming. Furthermore, the accuracy of the outputs of the Monte Carlo simulations (e.g. estimates for means or standard deviations) is directly dependent on the number of the runs. Therefore, the results of the Monte Carlo method can be seen as compromise between the reliability of the results and the use of computing power.

The problems related to the use Monte Carlo simulations in uncertainty analysis could be, in theory, avoided if the error propagation within the systems under consideration could be done analytically. The problem here is, however, that with very complex mathematical models, any analytical solution of uncertainty would require a huge amount of complicated calculations and in many cases could be impossible to perform. In the present study, a potential solution for this problem is presented by applying a "top-down" method, where the outputs of a complicated model are expressed with simple functions of the driving "Activity" variables. The contributions of all complicated sub-models are thus aggregated into simple emission coefficients. Quantifying the values of these coefficients would require running the model, in some cases several times (in the case of linear relationships, two model runs is enough), and then examining the broken-down outputs of the model to specify the relationships between the "Activities" and the "Emission coefficients".

Despite its apparent complexity, the approach presented here can save much computing time compared to the thousands Monte Carlo runs, and if done correctly, it also provides an exact solution as opposite to the Monte Carlo approximations. A potential limitation of this analytical method is that in its current form it assumes that all uncertainties are normally distributed, while the Monte Carlo runs can utilize any type of distribution. Although the effect of this assumption was not examined in this study, it can be expected to have only minor effects on the results, keeping in mind that in many cases the actual form of the distribution of the input data may not be very well known anyway. So it can be expected that the overall principles of the analytical uncertainty analysis presented in this study would be applicable and beneficial in several applications of agricultural LCA, especially if their purpose is to perform quantitative comparison between separate systems or scenarios.

5. Conclusion

This study presents the environmental impacts of main UK turkey production systems, quantified for the first time using detailed industry data. Furthermore, a novel approach to uncertainty analysis is presented, where the "alpha" uncertainties, i.e. those varying between the systems under comparison are quantified analytically, thus saving time and computing power generally related to uncertainty analyses carried out with Monte Carlo simulations. The results of the system comparison show that in general there are only small, non-significant differences in the impacts between different systems. The main system-related variables affecting the impacts are the feed conversion ratio, which affects the food, housing and manure emissions, and the slaughter weight, affecting the energy use per functional unit.

ABSTRACT

Approaches to account for land use change-related GHG emissions (LUCE), differing on the basis of the spatial allocation of the emissions, were compared in this study, and the justification of their application was evaluated based on generally accepted criteria from ISO 14040, PAS 2050 and IPCC guidelines. In general, most methods technically fulfilled those criteria, with exception of the "Worst case" or marginal approach which resulted in multiple counting of global emissions. The selection amongst the acceptable methods still remains rather subjective. The conclusions of agricultural LCA studies, related for example to the GHG emissions from livestock feed, are strongly dependent on the selected method, and for this reason a universally accepted single method is needed. One solution might be an application of a modified "Top down" method, which takes into account emissions from indirect LUC and the actual drivers affecting them.

Keywords: global warming potential, greenhouse gas emissions, land use change, livestock feed, soy

1. Introduction

It is becoming increasingly evident in agricultural LCA, especially of livestock production, that selecting the method for accounting for the greenhouse gas (GHG) emissions from land use change (LUCE) is probably the most critical step of the assessment (e.g. Leinonen et al. 2013; Middelaar et al. 2013). At present, there are several different approaches to LUCE, which may give highly varied estimates for the emissions for different agricultural crops, and therefore may have strong impacts on the conclusions of the study in question. Therefore, it is obvious that some kind of agreement on the LUCE accounting methodology is needed, and the criteria for selecting the method should be clearly specified.

Most of the recent LCA studies on agricultural production have aimed to fulfil the requirements of the ISO 14040 standard (BSI 2006), the IPCC Guidelines for National Greenhouse Gas Inventories (IPCC 2006), and more recently, also the more detailed methodological criteria described in the Publicly Available Specification PAS 2050:2011 (BSI 2011). As a result, it could be expected that the methods quantifying the GHG emissions arising from land use change (LUC) should follow the same criteria.

Some common principles required for the methods accounting for LUCE can be identified from the three documents mentioned above. One of such principles is that when quantifying existing LUC emissions, an attributional approach should be applied, meaning "*LCI modelling frame that inventories the inputs and output flows of all processes of a system as they occur*", as defined in ILCD (2010) . This requirement is the one of the overall principles of PAS 2050:2011, and it is stated there as "*unless otherwise indicated, the assessment of the life cycle GHG emissions of products shall be made using the attributional approach, i.e. by describing the inputs and their associated emissions attributed to the delivery of a specified amount of the product functional unit*". Similarly, as the IPCC guidelines aim to quantification of the national GHG emissions, they also concentrate on the existing state, i.e. apply attributional approach as opposed to consequential, which would be applicable for scenarios of potential changes in the future.

A logical consequence of the attributional approach is that the analysis must fulfil the criteria of mass and energy conservation. This is directly stated in the ISO 14040 as "*As each unit process obeys the laws of conservation of mass and energy, mass and energy balances provide a useful check on the validity of a unit process description*". Also, the IPCC Guidelines recommend checking the mass balance of the emissions, "*to avoid omissions or double counting*".

The requirement of mass conservation is also related to some of the criteria of PAS 2050. These criteria include the following:

1) Completeness: "*all product life cycle GHG emissions and removals arising within the system and temporal boundaries for a specified product which provide a material contribution to the assessment of GHG emissions arising from that product have been included*", and

2) Consistency: "*assumptions, methods and data have been applied in the same way throughout the quantification and support reproducible, comparable outcomes*".

In the following, some generally used methods for accounting for LUC-related emissions in LCA studies are considered, the justification of their use is evaluated in terms of the criteria specified above, and their consequences on the application in agricultural LCA are demonstrated. In the latter, the Global Warming Potential of broiler feed is used as an example.

2. Methods

2.1. Alternative approaches to LUCE accounting

In an ideal situation, the net emissions of greenhouse gases from a certain land area, arising as a result of agricultural LUC, should be quantified and allocated to crops that are grown within this area during the time period when the LUC-related emissions are considered to occur. In PAS 2050:2011, this is the preferred situation and is defined as "*where the country of production is known and the previous land use is known, the GHG emissions and removals arising from land use change shall be those resulting from the change in land use from the previous land use to the current land use in that country*". In this paper, this approach is referred as the "Actual LUC scenario". In practice, this approach could be applied to crops originating from a country where no LUC is known to occur, or alternatively to crops that come from a country where LUC may have occurred, but that specific crop is certified to originate from "mature" agricultural land, i.e. land from which no more LUC emissions are assumed to arise. This stage is generally considered to be reached after a selected amortization period (typically 20 years).

In several practical situations, it is not possible to know the exact origin of a certain agricultural commodity, and therefore it is not known whether it originates from land recently converted to agricultural use and whether the LUC-related emissions should be included in the carbon footprint of that product. A solution for this is to quantify the overall LUC emissions from the production of a certain crop within a bigger area, e.g. a country or a region, and then allocate the emissions evenly to that crop, produced at any location within that area. PAS 2050:2011 gives two options for that approach. First, it is stated that "*where the country of production is known, but the former land use is not known, the GHG emissions arising from land use change shall be the estimate of average emissions from the land use change for that crop in that country*". Second, an even more general option in PAS 2050:2011 says that "*where neither the country of production nor the former land use is known, the GHG emissions arising from land use change shall be the weighted average of the average land use change emissions of that commodity in the countries in which it is grown*". In this paper, this approach is referred as the "Best estimate scenario".

An alternative approach to account for the LUC-related emissions considers both the direct and indirect LUC related to crop production. It can be argued that all agricultural activity has indirect LUC effects, i.e. growing more of any crop in any economically-connected location in order to meet global demand will increase the land use pressure elsewhere (although the opposite could happen in the case of intensification of the production). Thus, the global LUC emissions should be equally allocated to all crops per ha, regardless their actual location (Audsley et al. 2009). According to this scenario, equal LUC emissions of 1430 kg CO_2 ha^{-1} y^{-1} should be included in the production of all crops, regardless the country of their origin or the previous land use (Audsley et al. 2009). The GWP from LUC per kg of each feed ingredient is thus dependent on the land area required for its production, so for example crops with high yield per ha have lower LUC emissions than crops with low yield. There is also no distinction in the attribution of LUCE to crops with high or low rates of expansion. In this paper, this approach is referred as the "Top-down" scenario"

The main difference between the approaches described above is how the GHG emissions arising from LUC are allocated spatially, ranging from the level of a single field of a specific crop ("Actual LUC" scenario) to allocation evenly to all agricultural land ("Top-down" scenario). However, a completely different approach to account for LUC emissions has also been proposed, and it was actually included in the earlier version of PAS 2050 (BSI 2008). According to this approach, if the actual LUC emission factor for a certain crop is not known, the highest emission factor for the country of origin in question should be applied. In practice, this would generally mean that transformation from forest to agricultural land is automatically assumed. The idea of this approach is close to the concept of the marginal process, which is generally applied in consequential LCA. For example, according to this approach it can be considered that cultivation of soya is the driving force of the LUC occurring in South America. Therefore, any increase in the demand of soya will automatically lead to increasing LUC (for example clearing of the rainforest), and therefore all related emissions should be allocated to this specific crop. In this paper, this approach is referred as the “Worst case scenario”

2.2. Example problem: GWP of broiler feed

The importance of the selection of the LUCE accounting method is demonstrated in the following by calculating the Global Warming Potential (GWP) for broiler feeds, based on two alternative diets as applied during the whole production cycle. The diets applied here were the standard soy meal-based diet, generally used by broiler industry, and an alternative diet, where part of the soy has been replaced by field peas (up to 30% of the total mass of the feed). Leinonen et al. (2013) gives the more details and the justification of the composition of these diets.

In the calculations carried out for this study, the GHG emissions for soy production were included in the diets using each of the four accounting methods described above, i.e. 1) “Actual LUC”, 2) “Best estimate”, 3) “Top down” and 4) “Worst case” scenarios. The GHG emissions for soy production were calculated as follows. First, following UK import statistics, it was assumed that the soy originates mainly from Brazil (48%) and from Argentina (41%), i.e. from countries where recent LUC related to soy production has occurred. Then, the GHG emissions per land area for different LUC types and countries were specified on the basis of the guidelines given in BSI (2011). After that, the LUCE emissions were allocated to soy beans and subsequently to soy bean meal (and to other crops, depending on the scenario), following each of the above mentioned accounting method. In practice, this was done by using one of the following options: 1) It was assumed that the origin of the soy was known and certified, i.e. it originated from “mature” agricultural land, so no LUCE was allocated to soy (“Actual LUC” scenario). 2) The relative proportion of soy growing in land with a certain land use history, including “new” agricultural land converted from other land use types during the last 20 year period, was estimated on the basis of FAO (2011) statistics, and the weighted average of LUC emissions from these land use types was allocated to soy (“Best estimate” scenario). Leinonen et al. (2013) gives the details of the LUC calculations related to South American soy production. 3) The global LUCE were evenly allocated to all agricultural crops, so the emissions of 1430 kg CO_2 ha^{-1} y^{-1} were applied for all crops used in broiler feed, including soy (“Top-down” scenario). 4) The maximum LUCE, i.e. assuming conversion from tropical rainforest to agricultural land, was applied for all South American soy used in the feed (“Worst case” scenario). Finally, the GHG emissions from feed production, processing and transport were calculated using the method by Williams et al. (2010), and after adding the LUCE, as calculated separately for each scenario, the overall GWP per 1000 kg broiler feed was quantified.

3. Results

The results of the comparison of broiler diets (Table 1) show that the LUCE accounting method has a strong effect on the overall GWP estimate of the broiler feed. For example, in the case of the standard soya diet, the GWP is almost four times as high in the “Worst case” scenario as in the scenario where no LUCE are allocated to soy. However, even a more important consequence can be found when the two alternative diets are compared with each other. The question to be asked here is: does the use of alternative protein sources (in this case field peas) replacing soy reduce the GHG emissions arising from the feed? The answer depends clearly on LUCE accounting method selected. With the “Actual LUC” and the “Top down” methods, no major benefit can be achieved with the use of the alternative pea diet. If the “Best estimate” scenario is used, a relatively high 17% reduction in GWP occurs if the soya diet is replaced by the pea diet. However, with the “Worst case” scenario, a dramatic reduction by 41% can be achieved with the use of the alternative diet. All these different figures can be obtained without any actual physical differences in the systems in consideration; they are only a result of a subjective selection of the method, or traceability of the origin of feed ingredients. Thus the conclusion of agricultural LCA studies that have involved potential LUCE may have been strongly affected by other factors than the actual properties of the system themselves, as discussed below.

Table 1. Global warming potential per 1000 kg broiler feed (kg CO_2e) for either standard soy–based diet, or for the diet where up to 30% peas are used as protein source, using different methods for accounting for LUCE related to soya production.

	Actual LUC[a]	Best estimate	Top down	Worst case
Soy diet	788	1085	1003	3026
30% pea diet	770	902	983	1771
Pea/soy	0.98	0.83	0.98	0.59

[a] Assumes certified sustainable source i.e. no LUCE

The principal differences in the spatial allocation of LUCE of different accounting methods are demonstrated in Figure 1. This figure assumes a theoretical, simplified situation where the global crop production is equally divided between two countries (Country 1 and Country 2). Further, it is assumed that the Country 1 produces one single crop, and half of this crop is produced in an area that has been recently converted from another land use type (e.g. forest). Now in the "Actual LUC" scenario, all LUCE are allocated to the area where they occurred, while in the "Best estimate" scenario only half is allocated to this area, and in the "Top Down" only one fourth. However, in all these cases the global sum of the LUCE is the same, and equal to the actual emissions from the converted area. In contrast, in the "Worst case scenario", although the LUCE of the actually converted area equals the actual emission occurring in that area, the global estimate for the emissions is in this example double compared to its actual amount.

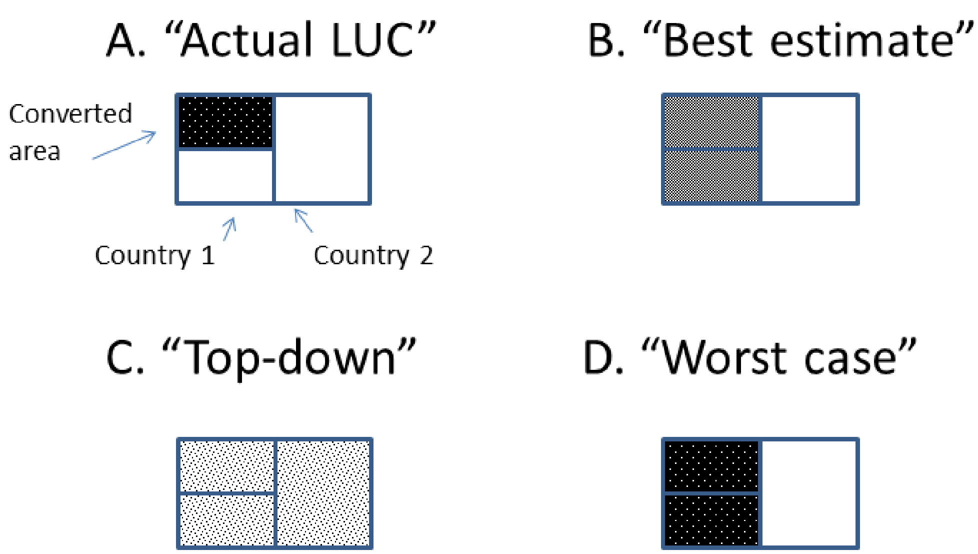

Figure 1. Demonstration of the spatial allocation of LUCE when different accounting methods are used. The darkness of the shading indicates the amount of emissions allocated per unit of land area. In the "Worst case" scenario, the total emissions are estimated to be higher than in the other scenarios, thus indicating double counting.

4. Discussion

When evaluating the alternative LUCE accounting methods against the criteria described above, the key questions are the following: First, does the method follow the principles of attributional LCA, i.e. does it model the systems as they occur or have occurred? Second, does it follow the principle of mass conservation, i.e. accounts for all emissions arising from LUC and allocates them to the products, and at the same time makes sure that no double counting occurs?

In theory, the first approach discussed above, the "Actual LUC" scenario clearly follows all these criteria. It considers a certain, known area of crop production, and as the history of this area is expected to be known, all emissions that have occurred as a result of possible LUC can be quantified, and allocated to the crops grown in this specific area.

It can be considered that the "Best estimate" scenario follows basically the same principles as the "Actual LUC" scenario. The only difference between these two approaches is the spatial scale. While the "Actual LUC" scenario specifies an actual location of certain crop, in the "Best estimate" scenario this area is extended to the whole area of this crop grown in a certain country, or in the extreme case in the whole world. Again, in theory, all the LUC emission within this extended area are accounted for and allocated to the specific crop grown in this same area. Thus, also this approach follows the principles of mass conservation, completeness and consistency.

Although the starting point of the third approach, the "Top-down" scenario, seems different than the first two approaches, as it is based on the concept of including both direct and indirect LUC, it actually can be seen as a further extended version of the "Best estimate" scenario, and it also avoids any double counting. In this approach, all agricultural crops are considered as a uniform group, instead of separating single crops as in the other approaches. The area under consideration is the whole cropland of the world, not the area of any specific crop as in the other approaches. Therefore, it can be concluded that theoretically all these three approaches to LUC accounting are based on the principle of mass conservation, and they fulfil the requirements of ISO 14040, PAS 2050:2011 and the IPCC guidelines. As a result, there is no scientific reason to reject any of these three approaches, and the selection of one of these methods is very much dependent on aim of the study and the availability of the data.

The fourth method, the "Worst case" scenario, is based on the principles of marginal processes, generally applicable in consequential LCA. However, by definition, PAS 2050:2011 is based on the attributional approach, and the same principle is also obvious in the IPCC guidelines. Therefore, it is clear that in any studies following these principles, marginal LUC accounting would not be an acceptable method. The practical consequence when using this approach would be multiple counting of the LUC effect, and therefore considerable overestimation of the GHGs arising from LUC. However, in reality this approach is widely used in literature, also in connection of attributional studies, and this can partly explain the big differences observed in the LUC effect in different studies.

As the results of the broiler feed example above demonstrate, the conclusions of an LCA study on agricultural products, whenever crops with potential LUC are involved, can be solely determined by the selected LUCE accounting method. Probably one of the most significant areas where this problem occurs is the evaluation whether reduction of soya in feeds can reduce the GHG emissions arising from livestock production, and this is where the profound effect of the selection of the methodology has been demonstrated in earlier studies by for example Leinonen et al. (2013) and Meul et al. (2012). In another similar study, Nguyen et al. (2012) quantified the global warming potential of poultry feed, and found a relative moderate potential for reduction of the impact by changing the composition of the feed. One reason for this result is that they used the "Best estimate" approach for LUCE from Brazilian soy (Prudêncio da Silva et al. 2010), based on regional, rather than national averages of production. As a result, the LUCE allocated to soy were relatively low, and therefore removing soy from the diet had only slight effect on the overall GWP. A completely different approach was taken in a recent FAO report, (McLeod et al. 2013), where the global GHG emissions from global pig and poultry production were estimated. In this case the "Worst case" scenario was applied for Brazilian soy, as stated by the authors: "*We thus assume that all incremental soybean area [in Brazil] is gained at the expense of forest area*".

In general, despite its inconsistencies and double counting of the emissions, the "Worst case" approach is apparently still used in agricultural LCA studies. One reason for this is that it was recommended in the earlier version of PAS 2050, the UK specification for assessment of GHG emissions (BSI 2008), before it was replaced by the "Best estimate" approach for its current version (BSI 2011). However, it is interesting that recently some supplementary requirements of PAS 2050 for horticultural products have been published (BSI 2012), and in these requirements further details for LUCE accounting were provided in a way which seem to contradict the general guidelines of PAS2050:2011. In these new requirements, it is stated that: "*To promote the collection of primary data on land use change the principle is adopted that these emissions should not be underestimated. Therefore in deviation of PAS 2050:2011 5.6.2.b, the highest calculated value of the average and weighted average is taken*". This indicates that, despite seemingly conflicting with their Completeness and Consistency principles, the PAS 2050 guidelines are moving back towards the "Worst case" approach.

Although in principle each of the three methods “Actual LUC” scenario, “Best estimate” scenario and the “Top-down” scenario fulfils the requirements of mass conservation, care should be taken when combining these methods, in order to avoid violation of the PAS 2050:2011 consistency principle. For example, it may be possible that in a single LCA study, some of the crop data can be considered to belong to a category “where the country of production is known and the previous land use is known”, while for some other crop production data this cannot be applied. In such a case, either the “Actual LUC” scenario or the “Best estimate” scenario could be applied for separate crops, depending on the traceability of the crop in each dataset. However this combination of the methods is actually against the consistency principle. This problem can be demonstrated with an example where the environmental impacts of soya coming from different sources in Brazil are compared in an LCA study. Assume that one subgroup of this soya is certified so that it is does not cause LUC, and the exact origin of the other subgroup is not known. According to PAS 2050, the “Actual LUC” scenario can be applied to the first subgroup. However, if the “Best estimate” scenario i.e. the LUC effect for “average” Brazilian soya is applied to the other subgroup, this will actually lead to an underestimate of the combined LUC effect of the both groups, as in reality the proportion of the non-LUC related soya in the “unknown” subgroup is smaller than the national average, as part of it is included in the “certified” subgroup.

Another example of the problems of combining the LUCE accounting methods was presented by Meul et al. (2012). In that paper, the authors propose the use of a two-step decision rule to formulate livestock diets with low GHG emissions, i.e. first try to minimize direct LUC (e.g. by using the “Best estimate” approach) and then within this precondition, minimize total land use change risk (i.e. the “Top down” approach) by selecting ingredients with low land use requirements. The problem with this method is that, although technically the LUCE obtained from these two methods are not treated additively, in effect the final conclusions would be based on double counting. Although this principle would effectively eliminate both direct and indirect LUCE from the diets, it would lead to an underestimate the effects of other, potentially significant components of the GWP arising from feed production.

It can thus be concluded that there are three different approaches to account for the LUCE, which can be considered to fulfill the requirements of attributional agricultural LCA, and which differ only in their method of spatial allocation of the emissions. The choice between these methods remains subjective, and is complicated by the fact that despite being justifiable, each of these methods still has its own limitations. Although the “Actual LUC” appears to be able to quantify accurately the LUCE of any crop in consideration, in practice in many cases it could be almost impossible to get specific enough data on the exact origin that crop as this could require site visits to several countries of crop origin. This would be the case especially when the consistency principle is taken into account and double counting is strictly tried to be avoided. This would require that the origin of each crop in any specific study should be precisely tracked, so that a combination of different approaches could be avoided. The problem of traceability can be avoided by using the “Best estimate” approach which has relatively low demands for data if based on national FAO statistics. However, here the question can be raised whether it is justified to make the LUCE country specific, rather than considering the actual global drivers of LUC, or ignoring for example regional differences within a certain country. The idea of the indirect LUC in the “Top down” approach can be justified when considering the land requirement as part of global market of agricultural commodities. In terms of applicability, this approach has an intermediate data need to set up the analysis, but after that it is trivial to implement. However, this approach does not consider any certain crop to be any stronger driver of LUC than any other. A direct consequence of using this method is that higher LUCE are allocated for example to rapeseed oil than to palm oil, just because of the differences of the yield and hence land requirements of these crops.

Due to the limitations discussed above, it seems likely that none of these LUCE accounting approaches, including those which were found technically correct, is likely to become generally accepted “universal” approach to be used in LCA studies. Instead, an attempt should be made to create a new approach that would combine the generally acceptable aspects of the existing methods, while still following all the requirements discussed above. One suggestion for such an approach has been recently presented by Williams et al. (2014), where the “Top down” method is further developed by including the actual drivers of LUC, and still avoiding double counting in spatial allocation of LUCE.

5. Conclusion

Several approaches to account for LUCE of agricultural products appear to fulfil the generally accepted requirements for attributional LCA and avoid double counting. The acceptable methods differ in their spatial allocation of the emissions, and the selection between them remains subjective. However, it should be possible to combine the benefits of several methods to achieve only one generally accepted approach to be used universally in agricultural LCA. A modified "Top down" method, weighted for different crops based on their roles as actual drivers of LUC, might be one option.

ABSTRACT
The modelling of reactive nitrogen (Nr) releases poses a big challenge to the life cycle assessment (LCA) of crop production. This study aims at providing an overview of potential aspects that need to be taken into account for improved modelling of Nr releases in the LCA of crop production. The definition of a crop product system and considerations of the crop, the soil, and the spatial scale were revisited. The major pathways of releases of nitrate, nitrous oxide, and ammonia were distinguished. Empirical emission-factor-based methods and process-based models for the development of unit process dataset of on-site crop production were summarised and compared. The importance of modelling fates of Nr releases was discussed. At the end, several conclusions were drawn.

Keywords: nitrate, nitrous oxide, ammonia, release, crop production

1. Introduction

Crops are plants that can be grown and harvested extensively for profit or subsistence (Encyclopædia Britannica 2014). Crop production, whist contributing to ensuring ample food and feed supply and enabling adequate farmer income, has induced numerous detrimental impacts on the quality of air, water, and soil, terrestrial ecosystems and biodiversity, greenhouse gas balance, etc. (Tilman 1999; National Research Council 2010). Crop production is the single largest cause of human alteration of the global nitrogen cycle (Liu et al. 2010). Life cycle assessment (LCA) has been identified as a valuable tool for the evaluation of potential environmental impacts of farming systems (van der Werf and Petit 2002) and applied increasingly to crop production as well as animal production (Brentrup et al. 2001; Haas et al. 2001; Bessou et al. 2013; Perrin et al. 2014).

However, originally developed for industrial production, the application of LCA to crop production faces challenges, which are determined by the features of crop production that are more complicated than industrial production. A main complicating feature is that crop production uses the soil. The dynamics of crop nutrients such as nitrogen, phosphorus, and potassium as controlled by biophysical soil processes need careful consideration (Harris and Narayanaswamy 2009). The development of models to estimate on-site pollutant emissions of crop production has been identified as a topic that leads the methodological development in LCA (van der Werf et al. 2014).

Amongst crop nutrients, nitrogen is of crucial importance, as it is a major determinant of crop growth and yield (Goulding et al. 2008). The large increases in reactive nitrogen substances (Nr) as fertilisers used in crop production, observed after the Second World War in many parts of the world, have triggered a cascade process generating Nr releases to air, soil, and water at each stage of the cascade (Galloway et al. 2003). Nr have been systematically catalogued in life cycle inventory (LCI) results and assessed against several important potential environmental impacts in life cycle impact assessment (LCIA).

The aim of this study is to provide an overview of potential aspects that need to be considered for improved modelling of Nr releases in the LCA of crop production.

2. Goal and scope definition

2.1. The crop product system

In LCA studies the boundary should be delineated clearly between the product system and the ecosphere. In the LCA of crop production, a crop product system encompasses both the upstream processes, i.e., the extraction of natural resources and the supply chain of various intermediate products such as fertilisers, pesticides, machinery, infrastructure, energy, etc., and the on-site crop production. The crop delivered at the farm gate is used for several possible functions such as food, livestock fodder, biofuel stock, clothing, medicine, etc. (A detailed classification of crops and crop functions can be found in the FAO World Programme for the Census of Agriculture (2010)).

The analysis of on-site crop production involves modelling consideration in three dimensions, vertically about the crop and the soil and horizontally about the spatial scale. The harvested portion of the crop and the remaining non-harvested portion are regarded as part of the product system and part of the ecosphere, respectively. Soil can either be included in the ecosphere based on the hypothesis that damage to the soil should be regarded as an environmental impact so as to distinguish systems differing in their impacts on soil quality, as suggested by Wegener Sleeswijk et al. (1996), or be regarded as an integral part of the product system, as proposed by Audsley et al. (1997). This study follows Audsley et al. (1997) to take into account the crop and the soil with a depth right down to the water table, which is location specific and changes along with seasons, in delineating the crop product system. On-site crop production can be modelled and analysed on a range of spatial scales, from the field through the farm to the farming region or even broader scales (e.g., a nation). The different spatial scales may include different compartments of the ecosphere and thus imply different fates of Nr releases in the assessment.

2.2. Major Nr under consideration

A non-exhaustive list of various forms of Nr under consideration in LCA studies is provided in Table 1.1. The three most important Nr releases in the LCA of crop production are nitrate (NO_3^-), nitrous oxide (N_2O, a.k.a. dinitrogen oxide), and ammonia (NH_3), which contribute to the impact categories of terrestrial and aquatic eutrophication, climate change, and acidification.

Table 1. Overview of reactive nitrogen substances and their contributed environmental impacts in LCA

Nr Substance	formula	Impact category
Nitrate	NO_3^-	Eutrophication
Nitrite	NO_2^-	Eutrophication
Ammonia	NH_3	Acidification and eutrophication
ammonium	NH_4^+	Acidification and eutrophication
Nitrous oxide	N_2O	Climate change and ozone depletion
Nitrogen oxides	NO_X	Acidification, eutrophication and photochemical ozone formation

2.2. Pathways of Nr releases

Based on the aforementioned definition of a crop product system, two types of Nr releases can be distinguished: upstream Nr releases and on-site Nr releases, which are elementary flows from the crop product system to the ecosphere. Upstream releases are associated typically with inputs to the on-site production, for instance, the release of NOx due to fuel use. Their data are usually obtained from existing databases such as ecoinvent (Swiss Centre of Life Cycle Inventories 2010). Whilst increased Nr mineralisation/nitrification can be a significant source, on-site releases are mainly due to the applied nitrogen fertilisers, which are transformed and transferred in the soil and taken up by crops that are modelled as part of the product system. Crop residues can be a major contributor to the release of N_2O (Baggs et al. 2000). Most on-site Nr releases are attributed to a range of transformations including ammonia volatilisation, nitrification and denitrification, and to the transfer in terms of nitrate runoff and leaching and organic Nr runoff, as shown in Figure 1 (Parnaudeau et al. 2012) (Note that processes of exportation and fixation in Figure 1 are actually outside of the crop product system).

Outside of the crop product system, upstream and on-site Nr releases experience various transformations and affect the environmental quality and human health. These transformations correspond to the cause-effect chain between releases and environmental impacts and are the basis for modelling nitrogen-related impacts in LCIA. Table 2 summarises the major pathways that are within and outside of the crop product system.

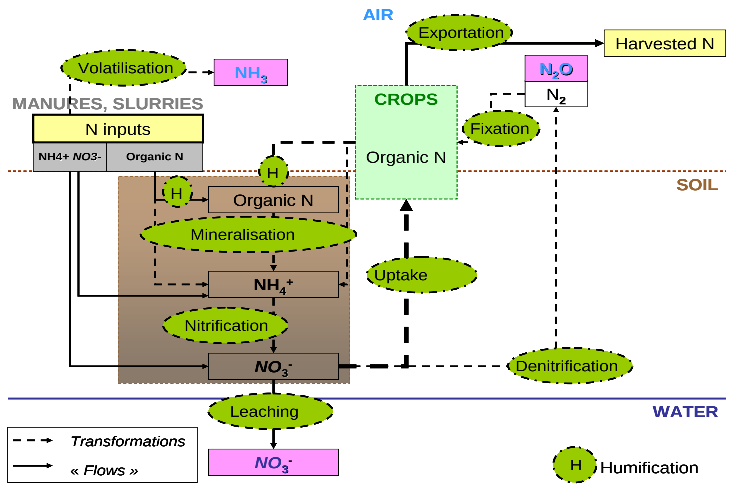

Figure 1. Nr releases from the on-site crop production (Parnaudeau et al. 2012)

Table 2. Overview of pathways of Nr releases related to crop production

Nr	Within crop product system		Outside crop product system
	Upstream release	On-site release	Transformation
NO_3^-	Discharge	Leaching and runoff	Denitrification, ammonification
N_2O	Emission	Denitrification of NO_3^- in soil, crop residues	Denitrification, nitrification
NH_3	Emission	Volatilisation	Nitrification

3. LCI related to Nr releases

Nr release rates can vary greatly depending on farmer practices, weather conditions, soil characteristics, landscape characteristics, hydrological processes, etc. (IFA/FAO 2001). On-site measurements of the Nr releases are costly and time-consuming, and in any case display great variations, because they only reflect a snapshot of the specific conditions of the on-site crop production at the time of measurement (Brentrup et al. 2000). In practice, the unit process dataset of on-site crop production is seldom built based on on-site measurements but rather created by linking raw data from various sources with pertinent mathematical relationships. Two types of mathematical relationships are distinguished, i.e., empirical emission-factor-based methods and process-based models.

3.1. Empirical emission-factor-based methods

An emission factor (EF) is defined as the average emission rate of a given (gaseous) pollutant for a given source, relative to units of activity. Emission factors are traditionally used to quantify air, water and soil pollutants at relatively high aggregation levels (e.g., the national scale), rather than at the individual source of emissions. In most cases, these factors are simply averages of all available data of acceptable quality. For instance, a default EF of 0.01 (range: 0.3–3%) was suggested by the Intergovernmental Panel for Climate Change (IPCC, 2006) to calculate the N_2O emission due to fertiliser application to managed soil at the national scale.

Bessou et al. (2013) and Perrin et al. (2014) reviewed 155 publications on perennial crop production and 17 publications on vegetable crop production, respectively. Three common references were identified as the general guidelines in estimating “field emissions” (i.e., on-site Nr releases), viz. Audsley et al. (1997), Nemecek and Kägi (2007), and Brentrup et al. (2000), as summarised in Table 3. In addition, the 4th report of the Intergovernmental Panel for Climate Change (IPCC, 2006) was also identified as an important guideline for perennial crops by Bessou et al. (2013).

Table 3. Empirical emission-factor-based methods for estimating on-site Nr releases of crop product systems (following Bessou et al. (2013) and Perrin et al. (2014))

Nr	Audsley et al. (1997)	Brentrup et al. (2000)	Nemecek and Kägi (2007)
NO_3^-	n.a. [a]	$N\text{-}NO_{3}^{-}{}_{,soil}$	n.a. [a]
N_2O	EF% of $N_{fertiliser}$	EF=1.25% $N_{fertiliser}$– NH_{3loss}	EF=1.25% N_{soil}
$NH_{3,fertiliser}$	EF% of $N_{fertiliser}$	EF% of $N_{fertiliser}$	EF% of $N_{fertiliser}$
$NH_{3,manure}$	EF=50% of $N\text{-}NH_{4,manure}$	$N\text{-}NH_{4,manure}$	$N\text{-}NH_{4,manure}$

[a] n.a.: not available in English.

3.2. Process-based models

Process-based models try to represent physical/biological/hydrological processes observed in the reality (Korzukhin et al. 1996). They are spatialised (semi-distributed or distributed) models, which can take into account different scales of representation of crop production (field, farm, farming region, etc.) and the interactions between the subsystems of the crop product system. Typically, for the estimation of releases from crop production such models contain representations of surface runoff, subsurface flow, evapotranspiration, and channel flow. Process-based models are increasingly recognised as alternatives to empirical emission-factor-based methods. We selected several process-based models through a search for peer reviewed English publications in the ISI Web of Knowledge (accessed on 9 April 2014), which is summarised in Table 4.

Table 4. Selected process-based models for estimating Nr releases from crop production

Process-based model [a]	Reference	Simulated Nr	Scale
CERES-EGC	Gabrielle et al. (2006), Bessou et al. (2013)	N_2O	Farming region
DNDC	Li (2000) Deng et al. (2011)	NO_3^-, N_2O, NH_3	Farming region, nation
DayCent	Parton et al. (1998), Del Grosso et al. 2005)	N_2O, NO_x	Farming region
DNMT	Liu et al. (2005)	NO_3^-	Farming region
SWAT	Arnold et al. (1998), Gramig et al. (2013)	NO_3^-	Farming region
FASSET	Jacobsen et al. (1998), Chatskikh et al. (2005)	NO_3^- and NH_3	Field, farm
HERMES	Kersebaum (2007)	NO_3^- and NH_3	Field
TNT2	(Beaujouan et al. 2002)	NO_3^-, NH_3	Farming region
INCA	(Wade et al. 1999)	NO_3^-, NH_4^+	Farming region

As two types of mathematical relationships to create unit process datasets from raw data, empirical emission-factor-based methods and process-based models differs for several characteristics, as indicated in Table 5. Process-based model can simulate the Nr dynamics related to the crop product system by parameterising various influencing mechanisms. Data representativeness and model uncertainty depend on the data availability, which will often determine which approach is used. Whenever sufficient data are available, process-based models are recommended. However, special attention should be paid to ensure the consistent spatial scale of stand-alone LCA studies of crop production and those coupled with process-based models.

Table 5. Comparison between empirical emission-factor-based methods and process-based models in LCA of crop production.

Characteristic	Empirical emission-factor based methods	process-based models
Mathematical relationship	Stochastic	Deterministic
Data requirements	lower	Higher
Data representativeness	lower	Higher
Primary error source	Extrapolation	Unknown parameters
Model uncertainty	Lower	Higher

4. LCIA related to Nr releases

The fate of an on-site Nr release consists of its transfer, transformation, and accumulation or dilution in a compartment of the ecosphere (Basset-Mens et al. 2006). The fate of a specific release plays an important role in the cause-effect chain linking its release to its potential environmental impacts and needs to be carefully modelled. Considering the aforementioned definition of the crop product system, such a compartment can be the atmosphere, the hydrosphere, or part of the pedosphere that is not included in the crop product system. The formation of N_2O outside of the crop product system (cf. Table 2) indicates that the fate factors of leached NO_3^- and volatilised NH_3 from the on-site crop production are both intrinsically inferior to 1 in the hydrosphere and the atmosphere, respectively. Fates of an Nr releases are usually ignored by assuming them equal to 1 excepted in rare studies such as Basset-Mens et al. (2006). Basset-Mens et al. (2006) looked into the fate factors of NO_3^- releases in three different catchments in west France, based on the fate factor for NO_3^- which was defined as the ratio of the NO_3^- quantity at the outlet of a catchment over the NO_3^- discharged from the catchment's soils. It can be a valuable reference for future studies on simulating the fate, for instance, of NH_3.

5. Conclusion

The following aspects need to be taken into account for improved modelling of Nr releases in the LCA of crop production:

- The crop product system consists of upstream processes and the on-site crop production. The on-site crop production includes the harvested portion of the crop and the soil with a changing depth down to the water table
- Nitrate, nitrous oxide, and ammonia are three important reactive nitrogen substances under consideration. They should be distinguished within the crop product system and between the crop product system and the ecosphere.
- Empirical emission-factor-based methods and process-based models are typical approaches for the development of unit process dataset for on-site crop production. Stand-alone LCA studies of crop production and those coupled with process-based models should be based on the consistent spatial scale.
- Fates of reactive nitrogen releases in the ecosphere should be explicitly modelled in the life cycle impact assessment phase of the LCA of crop production.

ABSTRACT

New LCA databases in the feed and food sector have recently been published or are announced to be forthcoming. The objective of this publication is to present key aspects of implementation of one of these databases, the "GaBi feed and food database" (to be released in autumn 2014). Firstly, the GaBi LCA agrarian plant model, which has been continuously developed over the past decade and is embedded in a methodological and scientific framework, serves as a basis for modelling feed and food products. The model is based on a synthesis of relevant scientific and methodological approaches which are described in this publication. The specific approaches chosen to address the agricultural LCA modelling challenges of nitrogen cycle, reference system, CO_2 uptake and storage in biomass, land use, land use change, irrigation and agricultural chemicals are described. Secondly, the approach to allow for a scientifically sound, feasible, consistent and applicable scaling of dataset generation for use in industry is explained in principle. Parameters in the model have been identified, analyzed and grouped and are determined via sequences of data collection. Thirdly, the modelling approach includes management, update and maintenance procedures to enable the data to follow the natural, agricultural, political and technical dynamics, prices and supply chain key parameters in time. The management and maintenance concept includes a professional systematic review process with yearly update schedules.

Keywords: Feed and Food, LCA, agrarian plant model, database development, GaBi

1. Introduction

The feed and food industry is considered to have a major contribution on the overall anthropogenic impact on the environment (FAO 2006, IPCC 2014a, IPCC 2014b). Several reports on strategies to abate this impact propose to focus efforts on energy efficiency, emissions efficiency and on a change and reduction of demand (IPPC 2014a). The latter implies action and interaction of consumers, governments and industry, for example to decrease the amount of lost, wasted, unused food (FAO 2006, FAO 2013). Producers of feed and food are also responsible for identifying and applying suitable technical solutions for a more sustainable and efficient use of resources. The possible benefits for companies are manifold, including potential cost savings and proactive mitigation of potential harm on their business by changing the environment and the environmental resources on which they depend (Callieri et al. 2008).

Life cycle assessment (LCA) can be used to achieve these objectives: LCA is a tool used by companies to benchmark and implement sustainability measures over an improvement processes into their daily operations and business. Many companies that successfully implemented sustainability measures conclude that "you can only improve what you can measure" and that "only what gets measured gets managed" e.g. (Warsen 2013). The relevance of implementing applicable approaches in the agri-food practice is underlined by the estimate that around 25% of all LCA studies are related to agriculture (Blonk 2014a).

Besides ethical and economic reasons for the sector to be actively engaged in sustainability, in particular LCA, several drivers increase the importance of LCA in the agri-food sector: policy developments, such as the green market initiative of the European Commission and its Product Environmental Footprint (PEF) pilots, sector specific initiatives, such as the ENVIFOOD protocol (ENVIFOOD 2013), FAO LEAP (FAO LEAP 2014), Feed LCA guidelines (IFIF 2014) and others offer new possibilities for the topic and for companies.

Different stakeholders, including companies, universities and external data providers, are working independently on data solutions to respond to an increased data demand. Many databases were recently published or are forthcoming: "Agri-footprint®", "AGRIBALYSE®", "World food LCA database", "Feed and food database" (see references for details on the databases). The main objective of this publication is to describe 3 key aspects of implementing the "Feed and food database", which is released in autumn 2014.

Many feed and food products are based on raw materials derived from agricultural plant systems. Different processing steps, agricultural management, farming and plant growing, handling, packaging, transport are required before a final product is ready for use (and, at end of life, specific disposal scenarios may need to be considered). The focus of this publication is on the plant system part that forms the data backbone of the “Feed and food database”. This is the major aspect covered in this publication.

Agrarian plant systems belong to complex production systems within LCA due to their dependence on environmental conditions that are variable in time (e.g. within a year, from year to year) and in space (e.g. varies by country, region, local site conditions). Also the correlation between inputs (of fertilizers, pesticides, agricultural engineering, etc.) to outputs (of harvested crop, gaseous field emissions, leachate, etc.) is complex and often non-linear in nature. The following factors contribute to the complexity of agricultural modeling:

- The variety of different locations,
- Small scale soil variability within and between locations,
- The large number of farms,
- The variety of agricultural practices (e.g. conventional vs. organic) and equipments,
- Technically, there is no well-defined border with the environment (´open system`),
- Complex and indirect dependence of the output (harvest, emissions) from the input (fertilizers, location conditions etc.),
- Variable weather conditions within and between different years,
- Different cultivation periods (e.g. annual, perennial, plantations),
- Quality and properties of products,
- Multi-output systems (product(s) and by-products) and allocation diversity,
- Various and big amount of Functional Units (FU),
- Farming intensity (e.g. extensive vs. intensive),
- Water availability and importance,
- Variable pest populations (insects, weeds, disease pathogens, etc.),
- Different cropping systems (e.g. monoculture, polyculture), and
- Political conditions influencing cultivation.

In addition to the appropriate consideration of these technical modelling aspects, customers of LCA datasets and databases want datasets to be highly reliable, to be easily understandable and marketable and to be delivered at a reasonable cost and time (Deimling et al. 2008). The transparency of the underlying model, of the raw data sources, of the applied QA procedures and of the external review processes are also of high importance to ensure the required professional credibility.

2. Methods

The GaBi LCA agrarian plant model is the basis for all standard agrarian datasets that are provided in GaBi databases. The following requirements were identified by the authors during their experience over the last 12 years as being crucial for an integrated approach to develop new agri-food datasets:

1) Scope: agrarian models (in this publication the focus is on terrestrial agrarian plant systems)
2) Scale: agri-food data development and supply, based on clearly defined processes and quality assurance
3) Management & maintenance: frequent updates, reviews and improvements of data and databases

These requirements are explained in more detail in the following sections. The precondition for these 3 requirements is a framework, which includes a collaborative review of suitable existing scientific methods, databases and inclusion of identified aspects (this requirement is not covered in this publication).

2.1. Scope

Due to the inherent complex characteristics of an agricultural system, a relatively extensive and comprehensive, nonlinear, computing model for agrarian plant and plantation processes was developed and implemented in the GaBi software (Deimling et al. 2008). The model includes a multitude of input data, emission factors and parameters and its proper application of the model necessarily requires both agricultural expertise and LCA experience.

Each processing step has been broken down into separate production modules such as soil cultivation and preparation, weed control, pest control, fertilization including organic fertilizers, harvest main product, by-product etc., and others (i.e. irrigation). For each of these modules data on the inputs and outputs (i.e. fertilizers, pesticides, fuel for machinery, etc.) have to be collected and calculated.

As shown in Figure 1, key characteristics of the model are different implicit mapped compartments (in particular: field operations, general agricultural process, land use change, clearing process, agrochemical processes, reference system land use, land use, allocation, carbon correction, soil leaching, irrigation process). This structure creates a comprehensive, flexible model that is highly parameterized and includes many background processes. As such, it is applicable for assessing any agrarian and plantation product of the world. Parameters can be fine-tuned to a high degree while the operating effort is reasonable. This allows inclusion of e.g. effects of crop rotation and periods with limited plant growth. The advantage and prerequisite is the delivery of consistent and exact results (Deimling et al 2008).

Besides life cycle inventories, different life cycle impacts assessment methods for environmental indicators and impact categories can be applied.

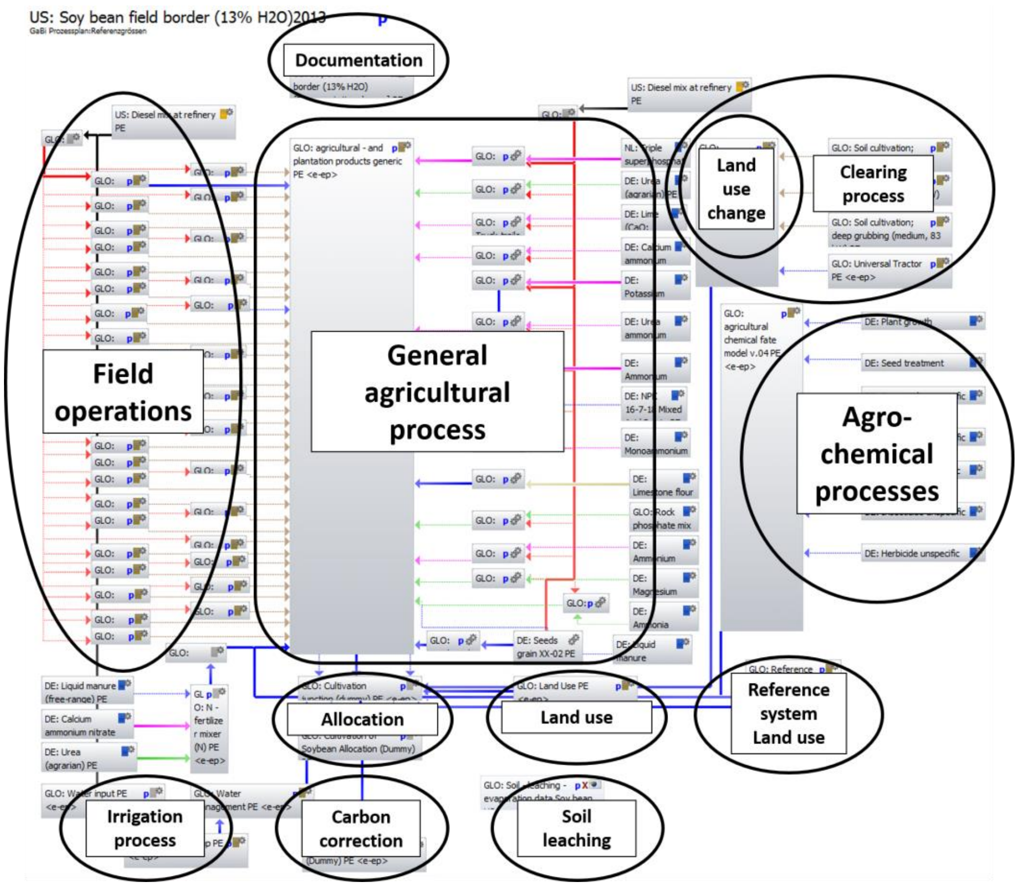

Figure 1. Screenshot of the GaBi LCA agrarian plant model with illustration of different modelling modules.

The system boundaries of the GaBi LCA agrarian plant model encompass agricultural production as well as post-harvest processes and transportation, and are shown in Figure 2. Some aspects were excluded from the GaBi LCA agrarian plant model as their relevance to the environmental profiles was found to be low, these include:

- In case of human labor, social issues are outside the scope
- Construction of capital equipment and maintenance of support equipment, and
- Packaging materials for seeds, fertilizer, pesticides etc.

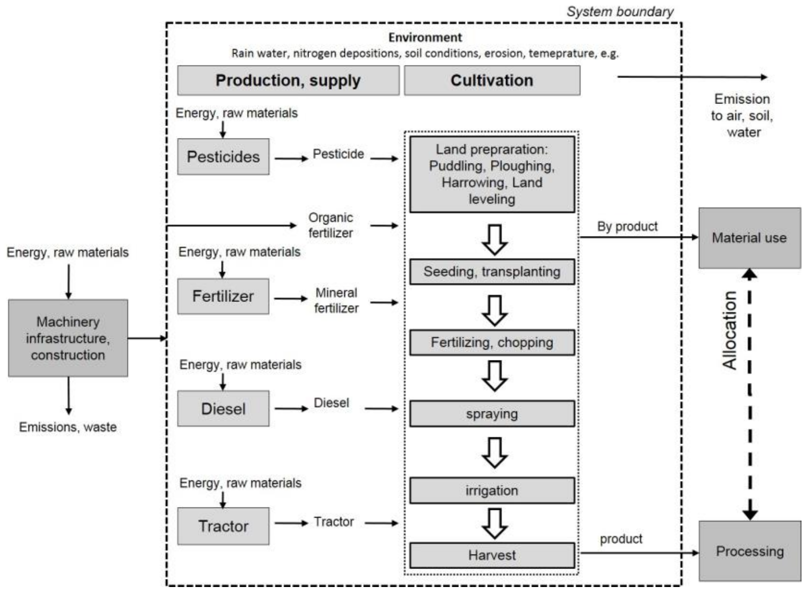

Figure 2. System boundaries of the GaBi LCA agrarian plant model.

To illustrate the background of the GaBi LCA agrarian plant model, seven key functionalities of the model are further explained below.

Nitrogen cycle (as part of the modeling module "general agricultural process"): Nitrogen plays a fundamental role for agricultural productivity and is also a major driver for the environmental performance of an agricultural production system (Eickhout et al. 2006). For these reasons it is essential to evaluate all relevant nitrogen flows within, to and from the agricultural system. GaBi LCA agrarian plant model accounts for the nitrogen cycle that occurs in agricultural systems. The model ensures that nitrogen emissions are consistent for all cultivated species. Specifically the model includes emissions of nitrate ($NO3^-$) in water and nitrous oxide (N_2O), nitrogen oxide (NO) and ammonia (NH_3) into air. The different N-based emissions are calculated as follows:

- NH_3 emissions to air from mineral and organic fertilizers are adapted from the model of rentrup and modeled specifically for the cropping system dependent on the fertilizer-NH_4^+ content, the soil-pH, rainfall and temperature. The following emission factors are used by default and adjusted in case more specific information is available. For ammonium nitrate, calcium ammonium nitrate, monoammonium phosphate, diammonium phosphate 2% of fertilizer N input, for ammonium sulphate 10%, for urea ammonium nitrate 8% and for urea 15% are emitted. These values are identical with data from Döhler et al. 2002 (with exception NH_3-N).
- N_2 is the final product of denitrification. Denitrification is a process of microbial nitrate reduction that ultimately produces molecular nitrogen through a series of intermediate gaseous nitrogen oxide products. N_2 emissions are assumed to be 9% of the N-fertilizer input based on a literature review made by Van Cleemput 1998. N_2 emissons are also taken into consideration to determine the nitrate leaching potential.
- NO is an intermediate product produced in microbial denitrification. NO emissions are calculated from the reference system after N-input from air plus 0.43% of the N-fertilizer input specific for the cultivation system as NO according to Bouwman et al. 2001.
- N_2O is an intermediate product produced in microbial denitrification. According to IPCC 2006, N_2O emissions were calculated as 1% of all nitrogen available including nitrogen applied with fertilizers, atmospheric deposition, microbial nitrogen fixation, nitrogen available from previous crop cultivation and indirect emissions.

- NO_3^- emission to groundwater is calculated based on available nitrogen (N not lost in gaseous form or taken up by the plant, stored in litter, storage in soil, etc.). Depending on the leaching water quantity and soil type, a fraction of this available nitrogen is calculated to be leached nitrate. When available N is calculated to be negative, (for instance due to a higher extraction than fertilizer input) a minimum N-loss factor is applied on the applied fertilizer and N_{min} quantity.
- N_{org} and NO_3^- emissions to water occur due to erosive surface run-off. It is very difficult to generalize erosion rates and deposition rates, as they are highly dependent on regional conditions such as climate, relief, soiltype, crop cultivated and vegetation. Soil erosion rates are estimated based on USDA 2003 and Wurbs and Steiniger 2011. It is assumed that 10% of the eroded soil accesses the waters, based on an evaluation of different literature sources Fuchs and Schwarz 2007, Hillebrand et al. 2005, Helbig et al. 2009, Nearing et al. 2005, while the rest accumulates to colluviums on other surfaces and is assumed irrelevant in the life cycle assessment.

Compared to a pure N-balance model, this approach allows the illustration of N-losses in case of very low N-fertilization (e.g. N-deficit in rubber-tree plantations). In the case of high N-fertilization (e.g. intensive farming applications), the models correspond with the total N-balance approach. Emissions from erosion, the reference system, and nutrient transfers within crop rotations are also modeled consistently.

Reference system (modelling module “Reference System Land Use”): Reinhardt 1998 (amongst others) illustrated the importance of usage of a reference systems in agricultural systems. The reference system is an inverse process used to assess the behavior of land that is not used agriculturally or influenced anthropogenically. In particular losses of nitrate to groundwater and emission of gaseous nitrogen compounds that result from nitrogen deposition onto this land are considered. This takes place in both the main cropping system as well as on land not under cultivation. Therefore not all occurring emissions can be assigned to the crop as they also occur on non-cultivated land, e.g. if this is fallow or a nature reserve. Here it is assumed that the nitrogen balance is neutral for the reference system, as any entry of nitrogen with rainfall is re-emitted from the systems in various forms into ground water and air.

In addition to the emissions of nitrogen compounds, the soil erosion is mapped including the associated conditional entries of organic carbon contained in the soil and some heavy metals in surface waters. The same principle is applied that this erosion occurs to a lesser extent also in non-utilized natural systems and therefore cannot be assigned completely to the main crop.

CO_2 uptake and storage in biomass (part of modelling module “general agricultural process”; if allocations are applied, modelling compartment “carbon correction”): The product bound CO_2 has to be accounted for directly as 100 % on the input side (flow: carbon dioxide resources) comparable to CO_2 emissions into air on the output side (flow: carbon dioxide biotic). The CO_2 quantities from renewables emitted during later stages in the life cycle (e.g. burning, composting etc.) have to be accounted as emissions to air (ILCD 2010). For fast moving consumer goods, this means that over the life cycle all bound CO_2 is released at a later stage. Carbon emissions (besides CO_2 e.g. CH_4 and CO) during biomass production, its conversion and its end of life are also considered.

In case of allocation, the carbon uptake of the product (after allocation) is corrected to the carbon stored in the product via an adjustment of the carbon dioxide resources flow.

Land Use (modeling module “land use”): Further inventory data on land use is provided site specifically for the foreground system using the LANCA method (Beck et al. 2010). In order to include land use issues, the impacts on ecosystem services are considered, especially for the indicators erosion resistance, mechanical filtration, physicochemical filtration, groundwater replenishment and biotic production.

Irrigation (modeling module “irrigation process”): water use is modeled based on the calculations of Pfister et al. 2011. A generic water model allows the selection of different plant water requirements and irrigation regimes depending on the specific regional conditions (e.g. precipitation, (fert)irrigation demand and irrigation technique). For details please refer to Pfister et al. 2011 and also Thylmann et al. 2012.

Agricultural chemicals (modeling module "agrochemical processes"): eco-toxicity is an indicator that is becoming increasingly important in LCA. Therefore a close look at pesticide use and its environmental impact is necessary when performing a LCA of agricultural products. Both the production and use of pesticides contribute to their environmental burden. The life cycle inventories of pesticide production are based on literature data as primary data is only very rarely available. The LCIs cover all input and output flows relating to pesticide production. All pesticide LCIs are based on representative LCIs (background datasets) that are valid for all active ingredients within the same effect category (herbicide, fungicide, etc.). All available data on energy use in pesticide production is discussed in Audsley et al. 2009. A Pest LCI approach was integrated into the model based on the approach described by Dijkman et al. 2012. The Pest LCI model provides emission factors for active ingredients (AI) to water (ground and surface) and air. About 125 scenarios with different parameter settings for pesticide AI, crop and location were calculated and are available as parameters in the GaBi LCA agrarian plant model. In case of more specific data availability these parameters are specifically adjusted.

Land use change (modeling module "land use change")**:** Emissions from direct land use change were calculated with the direct land use change assessment tool (Blonk 2014b) for the approach "weighted average" (as mandatorily required by the Envifood protocol and in line with WRI/WBCSD GHG protocol requirements) based on the approach from PAS 2050-1:2012 and WRI/WBCSD GHG protocol. This approach is crop-specific: The impacts from land use change are allocated to all crops, which increased in area harvested in a specific country, dependent on their respective share of area increase. According to all 3 standards, these emissions are distributed over a time period of 20 years. The tool works with statistical data from FAOSTAT for crop yields, harvested area of crops and area of forest and grassland, from FAO's global forest resource assessment for carbon stocks (in case former land use is unknown) (FAO 2010), from EC JRC world map of climate types and world map of soil types (EC 2013a) and from IPCC for above ground mass carbon stock (if land use change is known), values of soil organic carbon stock and stock change factors (IPCC 2006a). Changes in soil organic carbon stock are taken into account with that methodology. The emissions are reported separately with a flow "carbon dioxide from land use change" as required by certain guidelines (e.g. ISO/TS 14067).

Indirect land use change (please see EC 2010 for definition) is currently not considered as there are no international accounting standards available and while LCA is based on physical flows iLUC is based on market predictions (Finkbeiner 2014).

2.2. Scale

Deimling et al. 2008 already concluded that some challenges remain as agricultural systems are complicated, so the model developed to assess them is also complicated and both data- and resource-intensive to use. Questions regarding the scalability of LCA in the feed and food industry were raised, especially with focus on retailers, who may stock thousands of food items but who do not manufacture these themselves. A need for "a streamlined data collection processes or central resource where the data requirements of the model can be easily accessed" was identified (Deimling et al. 2008).

To ensure the high feasibility and applicability of the GaBi LCA agrarian plant model the significance of parameters was identified by the authors of this study, based on general LCA experience and specific experience with the GaBi LCA agrarian plant model and other literature (e.g. Nemecek and Schnetzer 2011). According to their importance, the parameters were prioritized by grouping them into three different groups, which are shown in Figure 3.

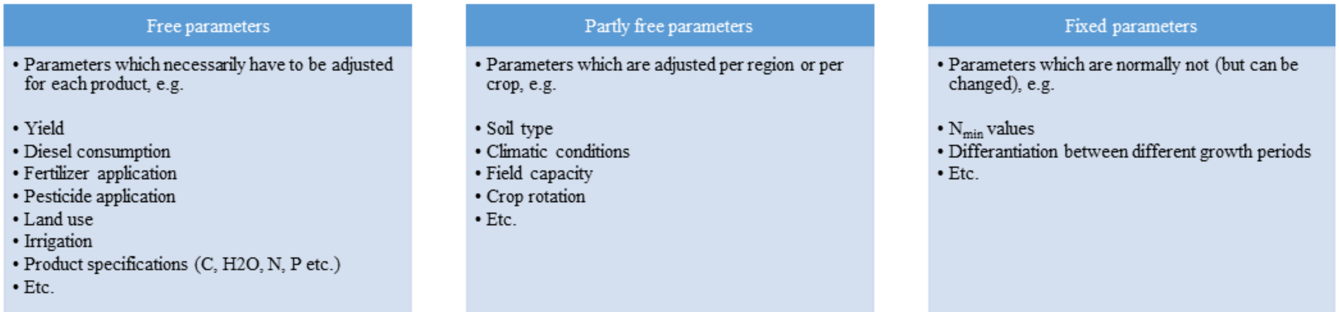

Figure 3. Display of three different parameter groups for agrarian plant modelling with the GaBi LCA agrarian plant model.

Sequences of data collection for parameter determination were defined, including flow diagrams for all "free" parameters. These flow diagrams and the parameter list will be made publically available in the documentation of the "feed and food database", which is released in autumn 2014. The data collection process always starts with specific primary data - if available - before moving to more generic data. The most specific data are used preferentially. A framework for determination of sources is provided to the LCA practitioners in charge of data development. The most generic solution is an expert judgment of discrete, quantified steps which lie in a predefined and suitable bandwidth of values. This estimation of parameters is the last resort option if no better data can be obtained elsewhere.

Full transparency of the approach is essential for all aspects relating to "management & maintenance" as described in the next section.

2.3. Management & Maintenance

This chapter discusses how to convert agrarian plant LCA models into broadly usable data, while maintaining its scientifc soundness and technical quality over time.

Feed and food data are the base and fuel for related LCA results. However in LCA different "planets" of users exist (Klöpffer and Heinrich 2001). These have different backgrounds but still talk about the "same" tasks and concepts. As a result, professional stakeholders have sought to develop approaches that can reduce misunderstandings and improve credibility (e.g. Rebitzer 2001). Even though different stakeholder backgrounds and some miscommunication still remains a decade later (Baitz et al. 2012), it is time to move another step forward.

Stakeholders all aim to support LCA, but each one has his own, often a different interpretation of what this means. However for application in agroindustry it is important to consistently base their work on reliable and risk mitigating professional data solutions. Reliability, consistency and conformity of data are, besides scientific soundness, key for success for professional use.

A professional environment necessarily includes reviews, verification, continuous improvement and yearly updates. To move from "scientific sound models" towards "scientific sound models that are constantly reviewed, maintained and updated" certain maintenance and quality assurance processes must be implemented. Consistency, continuity and reliability are core features of technology development, provision and maintenance for LCA software and database providers. The challenge is to manage the different inputs of stakeholders in a way that valuable data can be released and published in a consistent framework while immature or fuzzy data are filtered out. Data provision and use should be understood by any stakeholder as part of the "normal" management cycle: Plan-Do-Check-Act (or, to translate into the LCA data world, maybe: Plan—Implement—Review–Maintain).

Figure 4 explains the external review and auditing process which is implemented in PE INTERNATIONAL and also true for the feed and food database. The figure shows the development of databases over time (for the time period 2012-2014; whereas the procedure continues after 2014). Jira is used as program for quality assurance to allow users and employees to report issues, improvements on the LCA software and LCA database content. The treatment of these reports issues is documented and continuously reviewed by an external auditing company (DEKRA). Spot checks were performed by ENEA and Ciemat on behalf of the European Commission

(EC 2013b, ENEA 2014). Databases are updated once per year – inconsistencies are corrected immediately. Figure 5 shows the main review and audit aspects, displayed in a circle, which underpins the interaction and sequence of the different aspects.

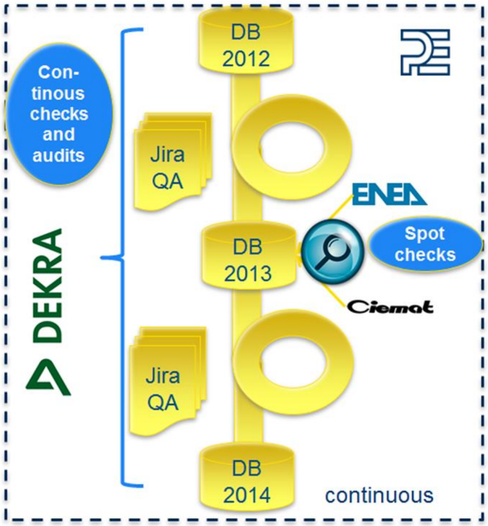

Figure 4. External Review and Auditing in a periodic continuous improvement setting of LCA databases (DB).

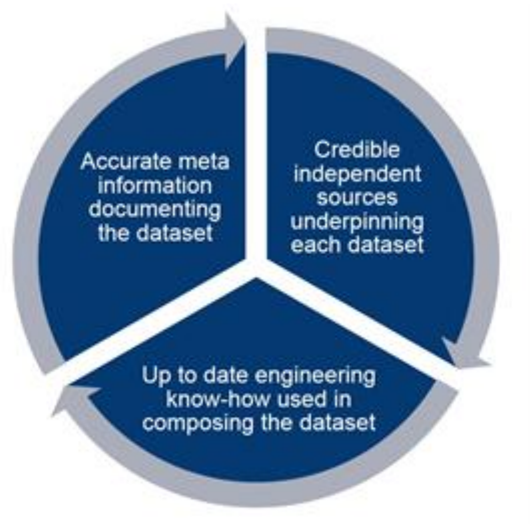

Figure 5. Main review and audit aspects.

"Demand" is the core driver when planning data provision. New technologies, regulations, standards or new market regions are decisive. The core aspects concerning implementation of data are: overall relevancy, accuracy, methodological consistency and technical adequacy. Data implementation needs some LCI experts and many engineering and agri-food experts to generate adequate data results. Concerning maintenance of data, the frequency, the possibility of auto-updates of own-developed user systems and the proactive update or fade-out of older data is essential. A "review of the current situation" is closing the loop. Therefore also the "review of data" by suitable parties and the users groups with the related improvement input is a core aspect for the new planning of the next update cycle.

The key of a professional review process is a systematic approach and continuous process embedded into well defined update routines covering

- Basic or core technologies , e.g. power plants, refineries and water treatment units
- Dependent datasets derived from these core models
- Quality assurance processes

This process increases the overall transparency of data generation (with the additional benefit of independent verification), strengthens quality and credibility and leads to high confidence by the users of the data.

Feedback of stakeholders, demand determination of users and feedback from and into standardization processes and best practice guidelines is also important. Synergy of science and industry in database development is possible, if the different stakeholders stick to a modular system and their related responsibilities are understood and taken (Baitz et al. 2007).

3. Summary, conclusion and resulting actions

Specific feed and food data needs feed and food specific knowhow. However, any sector database must be usable and understandable in all branches. It is a long way from field to retailer, with environmental impacts from many different branches along the chain (see Figure 6). Therefore, isolated or sector specific data that are only understandable, communicable or exchangeable within the same industry branch are of less value for the LCA environment.

Figure 6. Data solutions in the network of branches.

Three key aspects, as an example of implementation for food and feed LCA databases, are provided in this publication. Based on scientific and methodological approaches, the GaBi LCA agrarian plant model covers all relevant LCA agricultural aspects. Parameterization provides the necessary flexibility and applicability to cover all agricultural plant products with a global applicability. The scope of the model is constantly developed and improved. For a scientifically sound, feasible and applicable scaling of dataset generation for use in industry, model parameters are prioritized and grouped and are determined via sequences of data collection. Using reasonable operating efforts the model provides consistent and very accurate results for various agricultural and plantation products and differentiated adjustable farming practices. A management and maintenance concept allows the use of the scientifically sound agrarian plant LCA models in practice and with broadly usable data. This management and maintenance concept includes a professional systematic review process with well-defined update procedures.

Ensuring the feasibility and practicability of a scientifically sound approach is essential for a professional database solution. Documentation of modeling approaches supports maximum transparency of various important aspects such as sources, quality assurance and review process. This approach is the basis and stepping stone towards regionalized (LCI and LCIA) dataset creation in the future. Similar approaches are to be applied for processing, by-products and other agricultural products with a special focus on the interconnection with other industry sectors.

ABSTRACT

The LCA community is moving forward in developing methods to address biodiversity in impact assessments and the required inventory data. However, biodiversity is a notoriously fuzzy topic. Underlying preferences and perspectives on biodiversity vary considerably among stakeholders. The method presented herein allows for both broad-brush and detailed assessments of critical processes. The goal is to enable LCA users to generate product-related biodiversity impact information and manage biodiversity along value chains. The method represents the impact category "biodiversity" in the UNEP-SETAC land use impact assessment framework. It is inspired by the method proposed by Michelsen (2008) in that it employs region-specific characterization models yet allows aggregation across regions. Preliminary results for a western European ecoregion show that landscape structure and pesticide use contribute to the biodiversity impact. Fertilizer input is relevant, but a low dose is tolerable.

Keywords: biodiversity, land use, impact assessment, method integration, landscape ecology, normative aspects

1. Introduction

Many international declarations and studies have built a strong case for protecting global and local biodiversity (e.g. UNEP 1992, MA 2005, TEEB 2010). The LCA community is moving forward in developing methods to address biodiversity in impact assessments and the required inventory data. In this paper we present an impact assessment method for terrestrial biodiversity. The method bears structural resemblance to the Michelsen (2008, 2013) method and takes advantage of expert judgment. It also aligns with the UNEP-SETAC land use LCIA framework (Milà i Canals et al. 2007, Koellner et al. 2013). Other LCIA methods for biodiversity, namely those that rely on statistical analyses of species inventories, lack the flexibility that our method offers. The statistical methods better suit unknown supply chains, i.e. background systems. Future unification of the various approaches may be possible.

2. Methods

Creating a biodiversity impact assessment category builds on previous work in developing an LCIA category for land use and land use change. Figure 1 shows a simplified schematic of land use change as described by the UNEP-SETAC land use framework (Milà i Canals et al. 2007, Koellner et al. 2013). A given land use impact can be described by Equation 1.

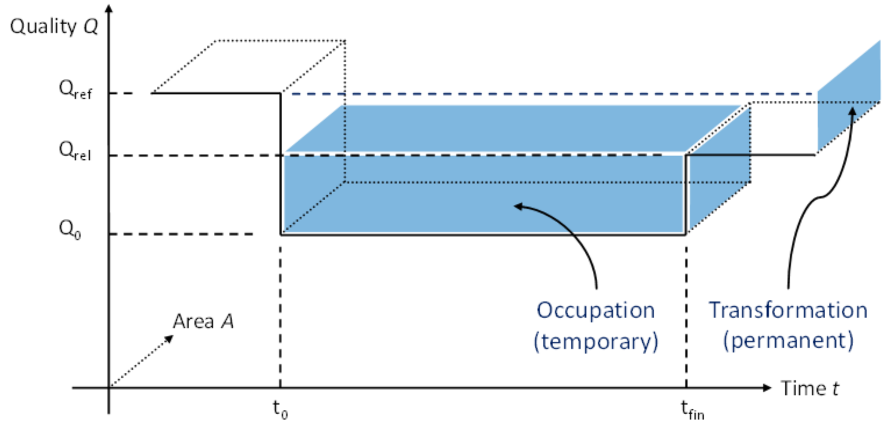

Figure 1. Simplified schematic of land use change as described by the UNEP-SETAC Framework. (Simplified from Milà i Canals et al. 2007, Koellner et al. 2013.)

$$\text{Impact} = \Delta Q \times A \times \Delta t \qquad \text{Eq. 1}$$

where:

Q = land quality (or other impact category)
A = area affected
t = time

In this description, the land use impact is the product of the land quality *Q*, the area of land directly affected *A*, and the duration time *t* of the impact. "Quality" on the y-axis represents applies to any impact category considered: in the UNEP-SETAC Framework, the y-axis refers to land quality, whereas here it refers to biodiversity quality.

The overall quantification of biodiversity is composed of two factors: an ecoregion factor and the actual assessment of the state of biodiversity at the given location. Biodiversity can be expressed via Equation 2 while the impact on biodiversity can be expressed via Equation 3:

$$\text{Biodiversity} = EF \times BP \qquad \text{Eq. 2}$$

where

EF = ecoregion factor
BP = biodiversity potential

$$\text{Biodiversity impact} = EF \times (1 - BP) \qquad \text{Eq. 3}$$

The biodiversity potential corresponds to a point in a multidimensional parameter space. The user obtains the function's value by entering a handful of parameter values x_i into (an ecoregion-specific version of) Equation 4. The scalar result can be interpreted in a similar manner as a potential function in field theory (e.g. a pressure potential that forces a fluid through a porous medium). The parameters are specific to each ecoregion, as is their combination in the biodiversity potential function. The values of these parameters are specific to processes in each ecoregion.

2.1. Ecoregion factor

The ecoregion factor is based on globally acknowledged biodiversity parameters, including total species richness, endemism, and vulnerability. Pertinent data, or proxies for the data, are obtained via online databases such as the World Wildlife Fund's WildFinder (WWF 2006). Michelsen (2008) does not call it an ecoregion factor but describes essentially the same methodological element as the combination of ecosystem scarcity (i.e. inverse area, or “smallness”) and ecosystem vulnerability (i.e. inverse pristine fraction remaining, or “anthropogenic encroachment”). This factor makes impacts comparable across ecoregions by assigning a weighting factor to each region. We use a similar but refined system, in which the ecoregion factor is calculated using the area of a given ecoregion, combined with the species richness, endemic species richness, and conservation status. (Brethauer 2013) The calculation details of the ecoregion factor are beyond the scope of this paper; this paper focuses instead on the biodiversity potential functions. (For calculation details, see Brethauer 2013).

Each data point is processed through a function to yield a contribution. The contributions are combined through compromise programming, which uses a behavioral model to aggregate the various ecoregions and compute the ecoregion factor. Table 1 lists sample input data and corresponding ecoregion factors. Ecoregion factors typically range from 0.4 to 2.2. Approximately 75% of all ecoregions are assigned a factor between 1.2 and 2.1, indicating that most biodiversity impact potentials would be doubled (at most) after applying the ecoregion factor.

Table 1. Sample ecoregion factors and their required data inputs.

Code	**Ecoregion name**	**Area [km²]**	**Total species**	**Endemic species**	**Conservation status[a]**	**Ecoregion factor**
AT0117	Madagascar Lowland Forest	111,760	509	230	1	1.99
NA0612	Northern Canadian Shield Taiga	617,319	182	0	3	0.58
PA0445	Western European Broadleaf Forests	493,836	381	0	1	1.37

[a] Conservation status is a measure of threat to an ecoregion assigned by the WWF.

2.2. Regional biodiversity parameters and contribution functions

Regional biodiversity parameters form the building blocks of the biodiversity potential functions. A contribution function for each parameter links the value of the parameter to a biodiversity contribution value. The contribution values lie between zero and one, where zero corresponds to the minimum contribution and one to the maximum contribution. The closer the contribution value is to one, the closer the considered state of biodiversity is to “good”. The term “good” is left deliberately undefined to accommodate varying conservation goals across ecoregions.

Picking appropriate parameters and defining the respective contribution functions require the developer to review the literature and to conduct a few expert interviews. National biodiversity strategies serve as a good starting point since every country participating in the Convention on Biological Diversity is required to have such a strategy document (UNEP 1992); reports from the International Union for Conservation of Nature (IUCN) and WWF reports are also good resources. The set of chosen parameters should include a mix of descriptive and management parameters, also known as pressure and state indicators, respectively, in the Driving-Force, Pressure- State- Impact- Response (DPSIR) Framework.

The expert interviews consist of a qualitative and a quantitative discussion of the parameters’ relation to biodiversity. First, the qualitative discussion: the developer and the experts being interviewed identify the general form of each contribution function. The parameter value is measured on the x-axis and the state of biodiversity on the y-axis. A large parameter value, indicating a good state of biodiversity, would be reprepresented by a point along the curve in the upper right corner. A factor detrimental to biodiversity would be indicated by a downward slope along the x-axis.

Second, the quantitative discussion: once the general shape of each function has been determined, a mathematical description of the curve can be developed. Each parameter x_i is related to its biodiversity contribution y_i through the function $y_i(x_i)$. A few general equations, each with some extra variables for curve-fitting, usually suffice. Most contribution functions thus far have been straight lines, s-shapes or u-shapes (upward or downward). The specific equations, graphs, and critical points are presented to the experts being interviewed and adjustments are made when necessary. The curve can also be critiqued by a wider audience, e.g. in a webinar or via an online questionnaire, to avoid overdependence on a few selected experts (this has not been done yet in our ongoing project).

2.3. Regional biodiversity potential functions

Once the relevant parameters for a given ecoregion have been identified and their respective contribution functions have been determined, the biodiversity potential function for the given ecoregion can be constructed. The biodiversity potential function combines *n* parameter contribution functions and normalizes the sum to the (0, 1) interval, as shown in Equation 4.

$$BP = \frac{1}{n} \times \left[y_1(x_1) + y_2(x_2) + y_3(x_3) ... + y_n(x_n) \right] \qquad \text{Eq. 4}$$

Equation 4 would be appropriate for a situation in which the parameters impact biodiversity independently from one other and in which all parameters have the same degree of influence. If this is not the case and instead some parameters are deemed more important than others, the more important parameters can be given a higher weight (greater than 1/n) and others a correspondingly lower weight.

When the interaction between parameters is more complex, two or more contributions functions can combined in other ways. They could be multiplied together so that both y-values must be large to reach a large total contribution. Instead of multiplying the functions, a fuzzy intersection can also be suitable in such a situation. When parameters compensate each other's contribution, a fuzzy union may be the best operational choice.

The result *BP* is the biodiversity potential function for a given ecoregion. It uses parameters as defined above as inputs and produces a scalar biodiversity value as the output.

3. Results

Parameters for the ecoregion PA0445 Western European Broadleaf Forests have been derived from the German National Strategy on Biodiversity (BMU 2007) and from expert discussions. Overall, nature conservation in Germany aims at producing and protecting low-intensity cultural landscapes (rather than pristine wilderness as in other parts of the world). The biodiversity contribution curves $y_i(x_i)$ are represented schematically in Figure 2.

Keeping the German context in mind, biomass removal is selected as the first parameter and is used as a proxy for management intensity. It is measured in multitudes of biomass production per harvest year. For example, a meadow from which all regrown biomass is harvested each year receives a parameter value of one. If half of the regrown biomass is removed, the parameter value is 0.5. A forest that is allowed to grow for 50 years and is then completely removed in a clear-cutting fashion receives a parameter value of 50 (probably not 50 because not all biomass remains to be harvested). These parameter values are the x-values of the contribution function. The function curve begins at large y-values, though not at the maximum. As the x-values increase, the biodiversity contribution rises to the top of the curve and then drops, eventually reaching a y-value close to zero (Figure 2, curve a).

The second parameter is fertilizer application, measured in kg N-surplus per hectare per year. Typically, ecosystems in the PA0445 ecoregion can cope with some N-surplus but an oversupply will allow fast-absorbing generalist plant species to outcompete the diversity of rarer niche species that are valued relatively high in conservation regulations. Fertilizer's contribution curve is s-shaped, starting at the high end of the y-axis before descending and leveling out close to zero at high x-values (Figure 2, curve b).

The third parameter is pesticide application. The experts interviewed agreed that every bit of pesticide is too much. The contribution function therefore is a curve that begins at the high end of the y-axis but declines sharply from the onset, eventually leveling out near zero (Figure 2, curve c). As a possible measurement that allows capturing of the variety of pesticides, eco-toxicity scores make for a good starting point (e.g. "comparative toxic units, ecotoxicity" or CTUe from the USEtox model).

The fourth and final parameter was chosen to be small landscape structures, measured in total covered area. In open landscapes, the structures could be walls made from loosely stacked stones separating fields, hedgerows, groups of trees or even single trees, strips of alluvial forest alongside bodies of water, etc. The contribution curve begins with low y-values, rises to the maximum, and drops again as the x-values increase (Figure 2, curve d). The curve levels out with small y-values. This curve illustrates that an overly structured landscape will not allow for as much biodiversity as a spacious landscape with some small structures sprinkled throughout. Conversely, too few small structures would characterize an overly homogenous landscape.

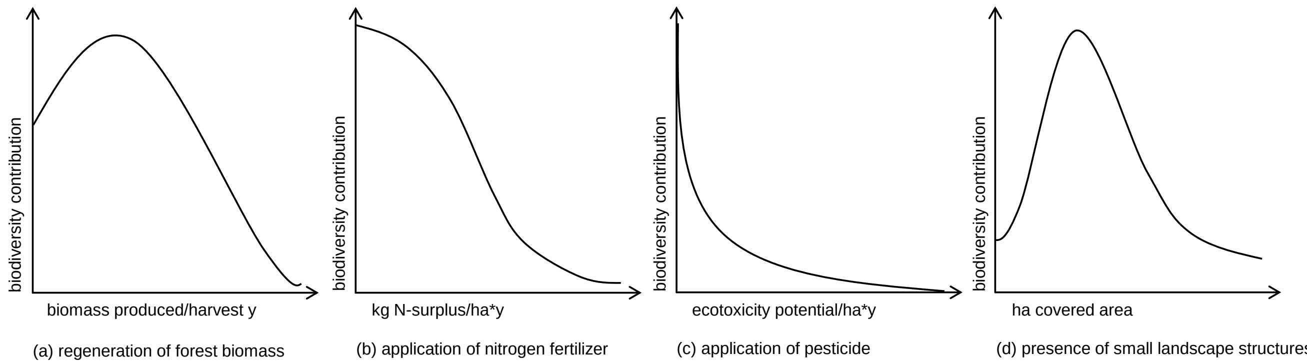

Figure 2. Biodiversity contribution curves of various parameters in ecoregion PA0445 Western European Broad-leaf Forests (schematic).

The functions were combined via summation. This very simple function combination process is to be understood as a first iteration and will likely be revised in future developments of the method.

4. Discussion

As far as we can tell at this point, the methodological framework generally functions as intended. It is possible to capture a range of differing interpretations of biodiversity as a conservation target. If desired, the potential field function can be replaced by a regionally agreed-upon method and integrated into the overall framework (hence the word "unified" in the title). With all input parameters on a continuous scale—as opposed to categorized by land use classes—differences in management practices that would otherwise go unnoticed can be captured and evaluated.

Our method trades consistency for comprehensiveness. Its structure tries to mimic an expert's impression of the overall state of biodiversity on an observed patch of land. Other methods that focus on particular measurable aspects of biodiversity (e.g. species diversity) are more consistent, however such methods (1) fail to capture biodiversity "as a whole" within a given region and (2) fail to acknowledge the varying interpretations of biodiversity across the globe. The method presented here is rooted in the conviction that a fuzzy subject like biodiversity requires an impact assessment capable of fuzzy analysis.

The reference state—a critical element for anything that uses the UNEP-SETAC land use framework—is implicitly defined as a byproduct of identifying the biodiversity parameters per ecoregion. For every parameter, there is a maximum biodiversity contribution. Anything below the maximum contribution is considered an impact. This means that the reference state represents a desired state of biodiversity as defined in national strategy documents. It acknowledges that whenever the term biodiversity makes the leap from a statistic to a political goal, it picks up a heavy normative load. We cannot define biodiversity as a conservation subject without naming what kind of biodiversity is actually desired. This defining task falls to governmental bodies, likely with the support of respected experts and conservation organizations.

Obviously, our biodiversity impact assessment method requires land use impact information that is typically only available for foreground systems. This challenge can be managed in two ways: (1) Archetypal combinations of parameter values can be developed that represent the majority of operations in a given ecoregion (e.g. "medium-sized cattle grazing operation in PA0445"), similar to archetypal emission profiles for industrial plants or vehicles. (2) Other more top-down biodiversity LCIA methods may be used for background system information, e.g. de Baan et al. (2012).

In regions with poorly defined conservation targets, hemeroby may serve as a surrogate since it is essentially a measure of naturalness. In absence of a specific "cultural" definition for biodiversity, such as the German one, naturalness seems like a good default. Michelsen and Coelho used hemeroby in a case study of the Michelsen method in New Zealand with moderate effort. As a composite index, hemeroby is not too different from the biodiversity potential described in this paper.

For more flexibility in the application of the method, distinguishing mandatory and optional parameters could help accommodate various types of activities. Parameters with general relevance for a given ecoregion would be mandatory while others would be selected from a list relevant only to certain activities.

5. Conclusion

This paper presents a method for biodiversity impact assessment in LCA. The first version of the method is currently being tested and is expected to undergo revisions over the course of the research project. Preliminary results, however, are promising and demonstrate the method's basic feasibility.

Inherent to the method is the concept of biodiversity as a fuzzy subject, both quantitatively and qualitatively. Depending on regional definitions and conservation goals, a regional biodiversity potential is defined. How much of this potential is conserved depends on regionally specific input parameters. The regional impact is weighted by the ecoregion factor to enable global aggregation. Other biodiversity LCIA methods are seen as contributors rather than competitors. This is especially true for regionally-specific methods, while the role of other methods as sources of background system information has been described as well.

To operationalize this method, the parameter list for PA0445 Western European Broadleaf Forests needs to be expanded and refined, and biodiversity potential functions for other regions need to be developed. Five case studies on various industry products are currently underway and are expected to offer further insight into the feasibility and accuracy of the method. Readers are encouraged to contact the corresponding author with criticism and other comments.

ABSTRACT

The different environmental impacts of commercial pig production for two regions (Eastern and Western) in Canada were compared in a cradle to farm gate Life Cycle Assessment (LCA) using Monte Carlo simulations for statistical analysis. For the first time detailed production data from Canadian farms was used to quantify the impacts of commercial Canadian pig systems. The impacts were defined using 5 metrics – Global Warming Potential (GWP), Acidification Potential (AP), Eutrophication Potential (EP), Abiotic Resource Use (ARU) and Non-renewable Energy Use (NRE). Uncertainties in the model outputs were separated into two types: uncertainty in the data used to describe the system (alpha uncertainties) and uncertainty in impact calculations or background data which affects all systems equally (beta uncertainties). Using this method pig production in these two regions was systematically compared based on the differences in the systems (alpha uncertainties). The environmental impacts for impact categories GWP, EP, AP, NRE and ARU were found not to be significantly different ($P<0.05$) between Eastern and Western system, despite differences in the feed ingredients used and typical pig performance in the systems. The study quantified uncertainty systematically when comparing multiple environmental impacts measures in an LCA for pig systems for the first time.

Keywords: Uncertainty, Pig Production, Monte-Carlo Simulations, Canada

1. Introduction

Several recent LCA studies have quantified the environmental impact of pork supply chains in various farming systems using multiple environmental impact categories (e.g. Reckmann et al. 2013; Wiedemann et al. 2010; Pelletier et al. 2010; Nguyen et al. 2011). A smaller number, whilst quantifying a single impact category (namely Carbon Footprint) have introduced uncertainty in their results using Monte Carlo simulations (Thoma et al. 2011; Macleod et al. 2013). The aim of this study was to quantify the environmental impacts of typical pig production systems in Canada using multiple impact metrics, while integrating uncertainty in the LCA results using Monte Carlo simulations. An LCA was conducted to compare the environmental impacts of typical pork production systems in two regions of Canada; Eastern Canada (Ontario and Quebec) and Western Canada (Manitoba, Saskatchewan and Alberta). In 2012, production in these regions was ~13.5 million marketed pigs in Eastern Provinces and ~13.3 million finished pigs in Western provinces, a combined total representing ~98% of commercial pig production in Canada (Canadian Pork Council 2014). The two systems have several differences in pork production; including the feed ingredients used in typical diets, herd performance measures such as Feed Conversion Ratio (FCR) and mortality rates, as well as farm management practices such as finishing weights.

2. Methods

2.1. Model structure

A cradle to farm gate LCA was conducted to compare the environmental impact of pork production supply chains in Eastern (Ontario and Quebec) and Western (Manitoba, Saskatchewan and Alberta) Canada. The three main compartments of material flow in the Life Cycle Inventory (LCI) were the production of feed ingredients, the use of energy and materials in on farm pig production and the storage and land application of manure. The LCA modelled three separate stages in the pig production system; breeding (including suckling piglets), nursery (up to ~28 kg) and grower/finisher (from nursery to finishing weight). The functional unit of the LCA was 1 kg expected carcass weight at farm gate. For both regions typical diets for each stage of production were devised based on expert advice from Nutreco Canada: the Eastern diets were corn based with the western diets based on Wheat and Barley. LCI data for the major crop ingredients were taken from previous LCA studies of Canadian crops (Schmidt 2007; Pelletier et al. 2008). Using these diets and the herd performance data shown in Table 1 the nitrogen (N), phosphorus (P) and potassium (K) content of the resulting excretion was predicted. N retention in the finished pigs was calculated using an animal growth model using the principles of Wellock et al (2003); P retention was calculated using the method of (Symeou et al. 2014) and K using allometric relationships of body composition ((National Research Council 2012). All N, P, K not retained by the finished pigs was assumed to be excreted in faeces or urine and applied to land as fertilizer once losses during manure storage and spreading were accounted for.

The on-farm energy consumption data were based on studies of conventional pig housing systems in North America (Lammers et al. 2010). The mix of electricity generation in the LCA was the national mix for the Canadian grid (Statistics-Canada 2012); this was assumed for all Canadian unit processes in the LCA. The housing/manure model of important enteric emissions as well as those during manure storage and spreading was based on the principles of the IPCC guidelines for greenhouse gas inventories, using a tier 2 methodology. The model estimated the emissions of CH_4, NH_3, N_2O and NO during storage and application as well as the leaching of NO_3 and PO_4. The proportional mix of manure stored and spread using different techniques was based on the Statistics Canada records regarding the storage and application of swine manure (Statistics-Canada 2003; Beaulieu 2004). The calculated available N, P and K to the soil in the manure after land application were credited to the pig system by offsetting the need to apply synthetic fertilizers to land. As such the LCA modelled the net difference in emissions caused by applying manure instead of inorganic fertilizer, while accounting for the avoided burdens of fertilizer production. The proportional mixture of synthetic fertilizers applied to land in each region was derived from sales figures in a Canadian fertilizer shipments survey (Korol 2004).

2.2. Herd Performance data

The herd performance data used is shown in Table 1 and based on benchmark data from farms in Eastern and Western Canada. The Eastern data covered the performance of 73,880 sows, 1.47 million nursery pigs and > 1 million finished pigs, the Western data were based on 58,886 sows, 63,757 nursery pigs and 26,910 finished pigs. Using this data the model calculated the feed intake at each production stage per finished pig accounting for mortality at all stages and the flow of gilts to replace culled sows.

2.3. Environmental impact calculations

The environmental impact of the systems was quantified using the following metrics: Global Warming Potential (GWP), Eutrophication Potential (EP), Acidification Potential (AP), Non-Renewable Energy (NRE) and Abiotic Resource Use (ARU). GWP was quantified as CO_2 equivalent: with a 100 year timescale 1 kg CH_4 and N_2O are equivalent to 25 and 298 kg CO_2 respectively. EP, AP and ARU were calculated using the method of the institute of Environmental Sciences (CML) at Leiden University (http://www.leidenuniv.nl/interfac/cml/ssp/index.html). NRU was calculated based on the IMPACT 2002+ method. The impacts were calculated for a functional unit of 1 kg of pig carcass weight (CW) at farm gate, using a Canadian definition regarding yield (including head and trotters), meaning typical carcass yield was 80% (+/- 2%). The LCA calculations and Monte Carlo simulations were conducted using the SimaPro 7.2 software package.

2.4. Separating impacts

The results for each impact metric were assigned to the following material (and energy) flow categories to demonstrate their relative contribution to the overall impacts:

1) Feed: production of crops and additives, feed processing and transport. This category also includes the water consumed during housing.
2) Electricity: direct electricity consumption at the farm (breeding, nursery and grower/finisher stages) not including feed production, processing and transport.
3) Fuel: direct fuel consumption at the farms, not including feed production, processing and transport.
4) Housing: direct emissions of NH_3, CH_4, NO and N_2O from housing and manure storage
5) Manure: Emissions of NH_3, CH_4, NO and N_2O resulting from field spreading. This category also includes credits from replacing synthetic fertilizers.

Table 1. Mean, maximum and minimum values for key herd performance parameters

Indicator	East mean 2012	East min	East max	West mean 2012	West min	West max
Feed conversion Ratio Nursery	1.57	1.38	1.80	1.58	1.40	1.86
Feed conversion Ratio Grower/finisher	2.74	2.50	3.09	2.90	2.77	3.16
Average Daily Gain Nursery (g/d)	428	335	515	455	363	515
Average Daily Gain Grower/Finisher (g/d)	882	752	983	836	801	953
Start weight (kg)	6.32	5.50	7.30	6.22	5.40	7.00
Weight end Nursery (kg)	27.4	21.0	34.0	28.8	22.0	34.0
Weight Finish (kg)	123.6	118	130	118	114	126.6
Average weaned litter size (piglets)	11	9.7	11.6	10.8	10.1	12
Average weaning period (days)	20.0	18.0	23.0	20.6	18.6	26.5
Wean to eastrus (kg)	6.90	5.00	9.50	6.90	5.30	8.90
Litters /sow / year	2.45	2.20	2.55	2.43	2.30	2.50
Gestation feed/ weaned (kg)	28.8	25.0	34.5	28.0	25.6	34.5
Lactation feed / weaned (kg)	11.8	10	15.4	11.4	10	15.4
Creep feed / weaned (kg)	0.1	0.001	0.3	0.1	0.1	1.2
Still born	7.2%	4%	10%	7.6%	5.10%	11.9%
Post birth mortality	12.5%	6.20%	19.2%	13.6%	8.80%	20.4%
Nursery Mortality	2.8%	0.64%	7.50%	3.1%	0.90%	6.00%
Grower/finisher mortality	4.0%	1.50%	9.00%	3.0%	1.80%	5.90%
Sow Mortality	6.8%	3.60%	10.00	5.0%	2.00%	9.00%
Sow culling rate	36.1%	22.0%	58.0%	41.6%	27.7%	55.6%

2.5. Quantifying Uncertainty

A Monte Carlo approach was applied to quantify the uncertainties of the impacts in both systems (Leinonen et al. 2012). The LCA was run 1000 times, and during each run a value of each input variable was randomly selected from a distribution for this variable. Distributions were assigned to variables in the LCA based on the data available in each case. For example for major crops, yield data from 2010 to 2014 was used to estimate the average and typical ranges in the yield. In cases such as this or the herd performance benchmark data, triangular distributions were assigned where the position of the mean in the range did not suggest a normal distribution. Many of the distributions in generic unit processes taken from the ecoinvent database (e.g. transport emissions) came with log-normal distributions. The distributions for each impact metric were not assumed to be normal due to the effects of multiplying normal and non-normal distribution curves as part of the LCA uncertainty analysis. The outcome of the analysis was a minimum and maximum level of impact for each metric, which was used to evaluate the statistical significance of the differences between the Eastern and Western at 95% confidence. The uncertainties in the input variables were divided into two groups, namely system “alpha” and calculation “beta” uncertainty (Leinonen et al. 2012).

Alpha errors were considered to vary between systems, and therefore were taken into account in statistical analysis of the differences between the systems. For example, variation in the herd performance parameters seen in Table 1, used to calculate feed intake, were all considered to represent alpha errors. In contrast, beta errors were considered to be similar between the systems, and had no effect in the statistical comparison between the systems, e.g. the emission factor for N_2O from manure. The errors in the emission factors were associated with errors in the models used to generate them, and therefore considered as beta errors (Wiltshire et al. 2009; Leinonen et al. 2012). The error distributions of the emission factors in the manure model followed the IPCC (2006) guidelines as well the recent review by Liu et al. (2013).

3. Results

The LCA showed no significant difference ($P<0.05$) between Eastern and Western systems for ARU, AP, EP, GWP & NRE despite differences between both systems in terms of feed ingredients used and typical herd performance characteristics (Figures 1-5). As can be seen in figure 1-5 the range of results for most of the impact metrics do not reflect perfectly normal distributions.

For all impact categories the grower/finisher production stage accounted for >75% of impacts for both production systems. The nursery phase contributed not more than 11% of impacts for any impact category, with breeding no more than 16% for any impact category (Table 2). The production of feed ingredients accounted for the >90% of ARU and NRE and > 50% of GWP for both systems. Housing emissions from animals and manure storage were the largest contributors to AP in both systems (60 and 56 % respectively), housing and manure was also the largest cause of EP in the East (52%). However in Western systems feed ingredients were the largest cause of EP (49 %) due to the different feed ingredients used in the diet. The Coefficient of Variance (CV) for all impact categories was between 9 – 16 % for both systems. Manure application was associated with credits for ARU, GWP and NRE due to it replacing the production of synthetic fertilizers. For AP and EP the net effect of manure application was considered to increase emissions and leaching associated with these negative impacts.

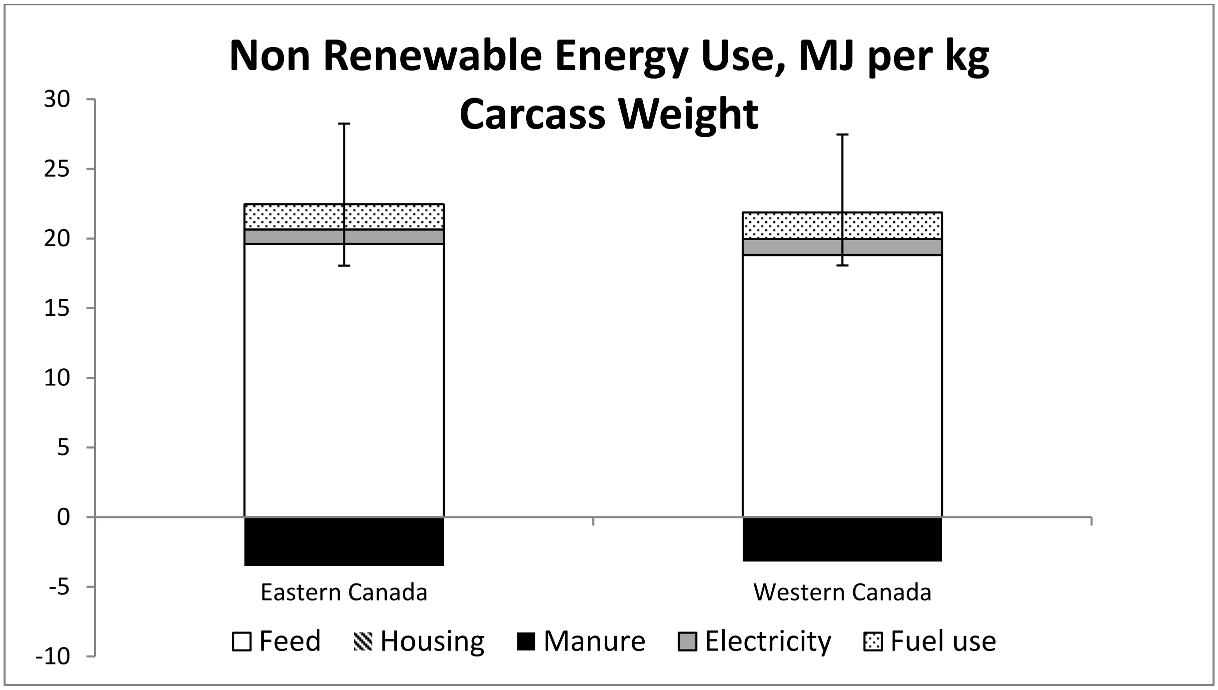

Figure 5. The Non Renewable Energy Use for typical Eastern and Western Canadian pig production. The error bars indicate standard deviations based on alpha uncertainties

4. Discussion

In all of the environmental impacts calculated, no significant differences between the Eastern and Western pig production systems were found. This was despite contrasting input data of the feed ingredients, herd performance and the manure applied to land as fertilizer. Although the Western system had numerically higher mean levels of GWP, EP and AP resulting from increased fertilizer requirements of major feed ingredients wheat and barley, in statistical comparison no significant difference in the environmental impact between the two systems was found.

The environmental impacts (particularly GWP) of pig production systems in many different countries have been quantified in previous studies, and summarized recently in the FAO report on Greenhouse Gases (GHG's) which result from monogastric livestock production (Macleod et al. 2013). This report sets out a new methodology to compare the results of pig LCA's in order to correct for differing assumptions and scope. Following this methodology, the results quoted for the three LCA's below are adjusted to represent the same FU and system boundaries as this study. The GWP results of this study do not appear different from the only previous peer reviewed carbon footprint study of Canadian pig production (Vergé et al. 2009), which reported 2.96 kg CO_2/ kg CW in Eastern systems and 2.85 CO_2/ kg CW. Previous LCA studies of US pork production have also reported figures within the range of uncertainty of this study for GWP of conventional pig production systems: 3.08 CO_2/ kg CW reported by Pelletier et al (2010) and 3.56 by Thoma et al (2010). It should be noted however that comparing results of LCA studies in a systematic manner is not feasible where the uncertainty range in those results is not reported. This is the case for most pig LCAs currently, especially for impact categories other than GWP.

Through separating different error categories in the input data, this study demonstrates a methodology for evaluating the differences between pig production systems in a consistent way. The use of Monte-Carlo simulations allows uncertainty analysis to incorporate the complexities of different types of distribution and incorporate covariance between parameters where this is suitable. Using this baseline model it will be possible to assess whether future changes to Canadian pig production systems such as an increased use of co products from biorefineries in pig diets or potential genetic changes can significantly reduce the environmental burdens of these systems.

5. Conclusion

The LCA examines the environmental impacts of commercial Canadian pig production, quantified for the first time using detailed industry data, multiple impact metrics and a systematic analysis of uncertainty. The study showed the importance of accounting for uncertainty when comparing the impacts of pig production systems. Such analysis has been lacking in previously published peer reviewed LCA's on pig systems. Monte Carlo simulations are a suitable tool for complex models such as LCA's to intrinsically account for uncertainty and allow for the complexity of non-normal distributions in the data. When modelling the systems stochastically the LCA found no significant differences ($P<0.05$) between pig production systems in Eastern and Western Canada for the environmental impact categories assessed. This was despite differences in the LCI of the systems compared regarding the typical feed ingredients used, herd performance data and predicted emission factors.

The Sustainability Contributions of Urban Agriculture: Exploring a community garden and a community farm

Abstract

This exploratory analysis of the potential of urban food production in cities of the global North is based on empirical examination of a community garden in New York City and a community farm in London, combined with secondary analysis of studies in six cities in the United States (US) and the United Kingdom (UK). Urban cultivation is promoted by environmental and food activists and organizations who may overstate the potential scale of urban food production: cities will be able to grow a maximum of about one-twelfth of a healthy plate for their inhabitants, and realistically much less. The main benefits of urban cultivation are social, and differ between urban and peri-urban farms. Capturing these benefits as contributions to the social component of sustainability represents a challenge for the development of social Life Cycle Assessment (LCA) or life cycle sustainability assessment.

Keywords: social sustainability, ecological education, food production, social LCA

1. Introduction

Community gardens and farms are a leading edge of the contemporary upsurge in urban cultivation. A sign of popularity is the endorsement of political leaders. For example, Michelle Obama planted a garden in 2009 with the help of school children--the first White House plot since Eleanor Roosevelt's World War II Victory Garden. The rise in interest is also indicated by a change in the status of urban cultivation, increasingly referred to as *urban agriculture* amongst academics (McClintock 2010). "Agriculture" projects a new frame and a larger scale than does "cultivation": agriculture is about food production, so that the horticultural gardens which dominate present urban cultivation are downplayed. The shift in perception raises research questions about the present reality and future potential of urban agriculture's output and sustainability. We address these questions based on case studies of a community garden and a community farm. The study is exploratory and descriptive, and addresses cultivation only as practiced in cities of the global North; the picture is quite different in the global South (Altieri 2012; Zezza and Tasciotti 2010).

There are pressing reasons for the interest in urban cultivation. Starting with the *macro* context, the world has a rising and increasingly urban population (UN 2011). There will be 2 billion more to feed by 2050, when 69 percent of our population of 9 billion will be urban, compared to 50 percent today. This growth is projected to increase food demand by 60 to120 % (Conforti 2011; Foley *et al*. 2011; Tilman *et al.* 2011; cited in Garnett & Godfray 2012). Progressive urbanization leads to loss of farmland (Seto *et al.* 2011). Between 1970 and 2000, the land equivalent of Denmark was converted from farmland to urban settlement. The projection for 2000 to 2030 is the equivalent of Mongolia, about 36 times the area of Denmark. Urban growth is also associated with tropical deforestation (DeFries *et al.* 2010). To exacerbate the problems, climate change is projected to result in farm yield loss (IPCC 2014; USDA 2013). Although there is debate around how large the loss may be, there is agreement that food security is one of the principal concerns humanity must address in the context of global climate change. The US is currently the world's 3rd largest food producer and its largest food exporter (FAO 2013) yet the US Department of Agriculture projects the yields of major US crops to decline by mid-century due to rising temperature and precipitation extremes. Thus agriculture faces a number of challenges in raising sustainable production levels. Many hope and argue that increasing production in cities and their suburban and exurban peripheries can contribute to meeting these challenges.

The institutional or *meso* context for rising interest in urban agriculture includes the environmental movement and related food consumption campaigns (*i.e.,* organic, locally-sourced, healthy and sustainable diets). Community gardening and farming evoke a cultural orientation different from that of traditional urban allotments. Allotments were in large measure institutionalized as compensation for the land clearances involved in the emergence of industrial agriculture in the late 18th--early 19th centuries in Northwestern Europe (see Fairlie 2009). In the UK, statutory allotment sites receive protection under the Allotment act of 1925, although there are fewer safeguards for private and temporary sites (RCEP 2007). Contemporary community gardening and farming represent a more recent movement, arising in the late 20th Century largely as neighborhood mobilizations to reclaim deteriorating open lands in post-industrial cities in North America and Europe.

It is at the local or *micro* level that urban agriculture has become a force for social change. In the context of this paper, "urban" refers to metropolitan areas (cities, suburbs and exurbs), while "cultivation" refers to controlled growing of any flora. The cases examined exemplify two common modalities of urban cultivation: one very small inner-city community garden and one larger but still small peri-urban community farm.

2. Methods

Data were collected through field observation, documentary and verbal information provided by informants, and accessing studies online. The main informants were the President of the West Side Community Garden (WSCG) and the Manager of the Sutton Community Farm (SCF). The WSCG in New York City was selected because one author had done volunteer work there since 2003 and began to study it in 2011; another author has visited it. The SCF in the southern outskirts of suburban London was selected because it had been the subject of a recent LCA (Kulak *et al*. 2013). All the authors took part in a site tour of the SCF in September 2013; one of the authors had worked on a similarly sized commercial market garden (known locally as a "smallholding") at that location some 50 years previously.

3. Results

3.1. Very small gardening: New York City's *West Side Community Garden*

The Garden began in the context of the massive 1970s Urban Renewal Program in the slums of gutted post-industrial cities (Martin 2011). The City of New York evicted occupants and razed tenement buildings in much of Manhattan's Upper West Side, leaving brown-field land available for redevelopment and gentrification (Wilson 1987). A high-rise condominium building was built on a site which included the future WSCG and another was awaiting capital investment. In the meantime the site became a dump for abandoned automobiles and other urban detritus. This dump site was transformed into a verdant garden in a spontaneous response by local residents to clean up a dangerous area in their midst that was also an eyesore. With construction imminent the neighborhood was assisted in saving this open space by the local Community Board and the Trust for Public Land. City government and developers acquiesced in part because community gardens enhance property values, thereby adding to tax revenues (while also, of course, adding to value for property owners). In an analysis of community gardens established in New York City between 1977 and 2000, Voicu and Been (2008:268) found that "gardens were located on sites that acted as local disamenities within their communities. . . after opening, gardens have a positive impact on surrounding property values, which grows steadily over time." The City administered a "sunshine test" and approved the site as a garden—with two stipulations for becoming untaxed land: that it would be open to the public and that it would pay for its upkeep.

The WSCG is located near the geographic center of New York City's Manhattan Borough. The land, 2/5 of an acre, is held by the Trust for Public Land and is governed by a board of officers elected annually from its 300+ paid members ("participants"). Membership is open to the public at a nominal annual fee.

Only about one-third of the Garden's space is used to grow food. Each gardener gets one raised bed of 30 ft^2. Gardeners reported that they do not grow much food—enough fruit and vegetables (f&v) for several meals a week over the late summer harvest period. "I just grow some nibbles," one said. Several informants related that growing food is not the main reason they gardened—rather, it was because they like to garden. Also, they reported that they like the cooperative aspects of the Garden and enjoy its ambience—a quiet, safe, public, and green island amidst Manhattan skyscrapers. Of the remaining 2/3 of Garden space 1/3 is devoted to horticulture. The final 1/3 is dominated by an amphitheater used for cultural productions.

The WSCG depends on a steady replenishment of labor to maintain compost bins and public areas, as well as to raise money. The Garden requires about $75,000 annually to operate. The bulk of the money goes to maintain pavements, towards insurance, and to purchase gardening supplies and tools. The labor required is skilled. This limits the available pool. Finding volunteer gardeners has been a general problem for community gardens. The largest pool of potential gardeners is women, mainly retired. New York City's gardens have declined in number since the mid-1980s largely due to lack of participation—many rely on one or two "tireless souls" (Tortorello

2012). The WSCG provides a range of cultural programs which attract thousands of visitors in the summer season who are potential sources of finance and labor.

3.2. Peri-urban small holding: London's *Sutton Community Farm*

This Farm comprises 7.1 acres, 3.5 of which are cultivated. It lies in the Borough of Sutton at the southern fringes of greater London, in what is termed "the green belt" in the UK planning system. It occupies green-field land but the soil is very poor. Until the 20^{th} Century lavender had been grown on the site as it can thrive in poor soils. The land use was changed as part of the mid-century drive to increase food production in the UK and took advantage of labor from a nearby camp for prisoners of war. Fifty years ago, the smallholding was operated by a family who lived there; it produced mainly high-value glasshouse crops, primarily salad vegetables and cut flowers sold via large wholesale markets in London, with high inputs including horse manure. There are now 500 m^2 of poly tunnels at the SCF providing for year-around production but it requires large inputs of compost, an expensive appetite for a non-residential farm with no manure-producing animals.

The SCF is London's largest community farm. It was started in 2010 with the blessing of Surrey County Council, which owns the land and collects ground rent. It operates as a co-operative and plans to offer shares within its local community. Similar social enterprises engaged in up-scaling local food production include *Urbivore* in Stoke (Williams 2013) and *Farmscape* in Los Angeles (Collins 2013).

The SCF is not solvent and there are no plans to make a profit. The goal is to make the Farm pay for itself and become a platform for activities for the local community; examples include making gardening experiences available to local school children and to disabled people. However, because of its location and the lack of public transport, a visit must be a planned activity. Salad crops are still the most profitable output, accounting for around 1/3 of income but only 1/7 of acreage, but the produce is consumed more locally than 50 years ago. About 3/4 of the Farm's produce is distributed to retail customers in "vegetable boxes"; this scheme currently has 142 customers, with a capacity for 350. The remaining 1/4 is sold wholesale, largely to local restaurants and cafes. The demographics of vegetable box customers reflect the local residential area: they are largely middle class. Many are seasonal customers who grow their own f&v and therefore buy much less in the summer. The Farm's unsold produce is collected by a local charity which makes soup from it. The two major expenses are compost (purchased from a local municipal site) for which haulage is the principal outlay, and water for irrigation.

The Farm's manager is a university graduate who used to be a chef and became interested in food security issues. He has organized an apprentice scheme at SCF. His view is that expertise in managing small-scale farms is generally lacking in the UK. The manager also organizes volunteer gardeners. The volunteers are diverse: some are employees of local businesses who are paid to work on the Farm as part of a Corporate Social Responsibility program.

Most of the Farm's tilled acreage is devoted to leaf crops. Surrey County Council requires the land to be turned over within two years, and so the Farm has no fruit trees. The Farm has not applied for Organic Certification, although the manager said that its production is "based on organic principles" and the Farm is open to anyone who wants to come and see for themselves. The Farm uses small tractors but most work is manual. The sole full-time employee is the manager. A "sustainable farming" apprentice grower is paid for three days per week. One grower is paid for one day per week. The vegetable box scheme has one employee working 3.5 days per week to deal with customers, and two drivers are employed, each for one day per week. Total paid labor is equivalent to 2.7 full-time workers.

3.3. Comparison between the two cases

The WSCG is an example of an inner city brown-field site coopted for social benefits; it depends on volunteer labor and contributions. The SCF is an example of a low-productivity green-field site which has transmuted into a social enterprise with some income and a paid work force. Both have outreach educational programs for their local communities. The Garden gets a large number of "walk-in" users and provides a sizeable cultural program, while the Farm produces considerably more food.

Using present formatting the very small Garden can grow the f&v portion of an annual *Eatwell* plate for about 3 people; the small Farm, for about 71 people. Extrapolation of these calculations, which are based on

FoodPrinting Oxford data (LCO 2012:28), show that it would require about 40 % of the total land areas of the New York and London urban agglomerations (UN 2011) to provide the f&v portion of an *Eatwell* plate for their populations. As f&v represent one-third of the plate, it would take more than **all** the land areas of the two agglomerations to grow full plates for their populations.

4. Discussion

4.1. Food production

Studies in 6 cities in the UK and the US have produced good and bad news for the potential of urban agriculture. The good news is that there is room for great expansion. The bad news is that this growth would come from a very low base and the maximum potential is low. Our initial analysis of research in Cleveland (Grewal and Grewal 2012), Detroit (Colasanti *et al.* 2010), London (Garnett 2001), New York (Ackerman 2012), Oakland (McClintock *et al.* 2013), and Oxford (*LCO* 2012) shows that an average of about 6 % of current f&v consumption is produced locally; this could be tripled to a maximum of about 18 %, which would still only represent about 6 % of an *Eatwell* plate.

This maximum potential is reachable only by overcoming some challenging conditions. Cities struggle today to maintain their current green spaces. In London the area of domestic gardens which comprise 25 percent of the land upon which f&v could be grown is declining. Between 1998 and 2008 "the area of plant-covered land fell by 12 % and the area of hard surfacing increased by 26 %" (Vidal 2011:3)—largely due to paving for car parking (Smith 2010). This is but one example of an imposing array of structural limits to urban food production: land, sustainability, labor and capital. With regard to land, urban settlement covers only 1 percent of the earth's land mass (FAO 2011) and it is expensive property subject to intense economic and political competition.

Another challenge to expanding urban agricultural production is the condition of brown-field urban soils. A study of lead contamination in vacant sites in Oakland found a high level of variability that must be considered when undertaking cultivation (McClintock 2013). Finally, there are sustainability questions about the advisability of converting urban green spaces (parks, greenbelts, etc.) to food production. These spaces already provide for carbon sequestration, urban cooling, biological diversity and social sustainability.

One touted technical solution for the lack of urban land is vertical farming or *z*-farming, for zero acreage (Despommier 2009). There are two major sustainability obstacles for high-rise *z*-farming: the energy required for artificial lighting to grow plants away from windows, and the industrial fertilizers needed to optimize yields from hydroponic production (Specht *et al.* 2013:10). These inputs obviously add substantially to the life cycle impacts of food production; see below. A technical issue for roof-top greenhouses is their integration with buildings, especially with recycling systems.

While structural obstacles will likely prevent the development of urban cultivation into urban agriculture, it has niche roles in local food production. One study has shown that it can make a significant contribution to the tables of low-income immigrants from agricultural backgrounds (Mares and Pena 2010). Another study has shown that it can make a substantial contribution to improving the diets of low-income persons with high rates of obesity and diabetes, and limited sources of fresh produce (McMillan 2008). However, in both cases the (volunteer) gardeners had free access to large plots of arable land.

4.2. Ecological sustainability

Underlining the caveats entered above concerning the potential for urban food growing, Kulak *et al.* (2013) have carried out an LCA study of the SCF which indicates that ecological benefits over the life cycle are localized rather than distributed along the supply chain. For example, reductions in greenhouse gas emissions are gained from appropriate choice of local crops that can substitute for foods grown in energy-intensive glasshouses or flown to the UK from overseas. A locally sensitive design approach is crucial in maximizing the potential for urban farming as a contributor to ecological sustainability.

Like all urban green spaces, community cultivation plots make contributions to local ecological sustainability—by providing natural habitats, improving soil quality, reducing soil erosion, and mitigating the city heat island effect (Bousse 2009; Brown and Jameton 2000; Cattell *et al.* 2008; Comstock *et al.* 2010; Ferris *et al.* 2001; Louv 2008; Pugh 2013; Relf 1992; SDC 2008; RCEP 2007; RHS 2011). Urban cultivation may make a greater contribution to carbon sequestration than other urban green spaces such as parks; Kulak *et al.* (2013) found this to be the case in their LCA study of the SCF. They may also reduce the run-off loss of rainwater exacerbated by the "concreting over" of cities and their environs (RCEP 2007); this is significant where, as in London, a principal aquifer may lie below the city itself.

Another contribution to ecological sustainability in which cultivation may outperform other urban green spaces is that it shelters biological diversity through a wide variety of flora—agricultural and horticultural. However, the contributions are dependent on local conditions; as a specific example, agriculture both supports and depends on the presence of bees to pollinate plants. The Farm at Sutton has three hives tended by a volunteer keeper, and is close to woodland and other commercial bee hives. Also, calendula, porridge, and ornamental flowers are grown to encourage pollination. In spite of being in the center of a large city, the WSCG has a good supply of bees from hives on nearby roofs and wild colonies in Central Park (Satow 2013). Thus, both the Farm and the Garden support bee populations by providing a diversity of flora—paralleling the practice of spacing ribbons of flowers amidst fields of crops in rural agriculture.

4.3. Social sustainability

The example of low-income immigrants illustrates that urban cultivation can make meaningful contributions to two major components of social sustainability—environmental justice and public health. However, it is in *education* that the WSCG and SCF make impressive efforts. The inter-generational principle of sustainability relies on ecological education. The Garden and the Farm are places where the practice of gardening is maintained and passed on to all age groups. The Garden reserves six plots for school children who participate in an ecology learning module during which they grow food. As follow-up to their experiences, children and their teachers have constructed several raised-bed plots in their schoolyard. In New York City, the number of registered school-based gardens has multiplied six-fold (Foderaro 2012). It is significant that most of the adult gardeners in the Garden have had previous gardening experience, many in their childhoods. The Sutton Farm operates a funded schools program, the *Green Grub Club*, in which pupils and after-school staff grow, cook, and eat vegetables. In addition, 16 students and their caretakers from a local school participate in a sponsored Disabled Farming Assistance program.

Informal education is a part of community cultivation as well. For example, whether WSCG should be primarily functional or "ornamental" is subject to on-going debate. There are four parties. "Foodists" make an environmental justice argument for converting flower space to f&v space in order to shorten the queue for beds (now a year) and provide more opportunity for those who are poor to grow their own. "Ornamentalists" make an aesthetic point for the beauty of flowers and its social psychological rewards, which are expanded to include a public health benefit. "Pragmatists" make an economic argument that flowers attract people who then contribute money and work to the Garden. "Ecologists" make a sustainability case for the biological diversity provided by flowers—and the bees that depend on them.

A latent result of the Garden's "great ornamental debate" is its contribution to the ecological knowledge of its participants. The debate takes place in informal interactions. Arguments are presented; this results in an exchange of information. Gardeners hear from each other about some of the complexities of food production and its relationship to sustainability. Several reported that they had learned about the four positions and "leaned" towards one or two of them. This communal learning is an example of the unique synergies that exist between ecological and social sustainability (see Martin 2013) and supports the argument here that small inner-urban plots mainly have social value. They add to conventional urban horticulture by being communal. The communality is a basis for development of social capital based on use value.

The social benefits of urban cultivation are felt mainly at a local level rather than distributed along a supply chain; they are outside the familiar framework of LCA. It is therefore questionable whether or not the benefits or relative disadvantages of urban cultivation can be captured by an approach based in LCA as currently conceived. The guidelines on social LCA (Benoit and Mazijn 2009) are "still very much in the developmental phase" (Paragahawena *et al.* 2009) and are in any case directed at detecting social "bads" in international supply chains. By contrast, urban cultivation can deliver social benefits which are then the driver for the activity. Similarly, the supply systems depend on inputs like imported compost, but also on affluent consumers—of vegetable boxes delivered to the doorstep in the case of SCF, and of cultural programs at WSCG.

Production, distribution and consumption are to be seen not just as a one-way flow of resources from supplier to consumer, leaving impacts in their wake, but as a channel by which benefits can flow back from the "consumer" (of food or land use) to the other agents in the chain (Clift *et al.* 2013). Adapting social LCA or life cycle sustainability analysis to this kind of case represents a new methodological challenge.

4.4. The role and future of urban cultivation

The difference between the two sites which are the focus of this study illustrates the big dilemma confronting urban cultivation. The WSCG is too small to provide a significant food output but has a high amenity value due to its location and accessibility. The SCF is large enough to provide a significant food output and some jobs, but its location makes its social value educational rather than amenity-based. Given the demand and price for land in "successful" cities such as New York and London, this distinction between urban and peri-urban land is likely to be persistent. The distinction is mitigated in distressed cities like Detroit where "abandoned houses, vacant lots and empty factories now make up about a third" of the city (Harris 2010:47).

Recognizing the difference between urban and peri-urban cultivation suggests a different approach to land provision, with planning and regulation on a regional or ecosystem basis. Being in the green-belt provides a measure of protection against development for the SCF. This kind of provision could protect existing food-growing land, particularly at urban peripheries, and could integrate food-growing spaces into new build and re-build. One vision for the UK is an increase from the current 4 % to 25 % of f&v urban and peri-urban production (*Growing Communities* 2012), representing 8 % of the *Eatwell* plate.

5. Conclusion

While structural limits prevent urban cultivation from becoming urban agriculture (at least in cities of the global North), there is a case to be made for it on the grounds of its contributions to ecological and social sustainability. Urban agriculture can produce little more than "nibbles" of food but it can contribute "oodles" to social-ecological sustainability. One can imagine an urban regional cultivation scheme in which there are more community gardens in the center, more allotments and domestic gardens in the suburbs, and more community farms in the exurbs. The WSCG and SCF cases illustrate that "To be a viable alternative in cities and compete with other land uses, the justification for urban agriculture must include the ecological and cultural function these systems offer, in addition to the direct benefits of food produced" (Lovell 2010:2516). Moreover, the co-benefits could include 'spill-over' of interest in local food to changes in other practices at household and community level, such as greater awareness of waste reduction, long-life product use and reduction in car dependency. How engagement in urban farming can act as a catalyst for wider practices of 'sustainable lifestyles' is a rich field for research.

Concerning the scope for the scalability of urban cultivation, perhaps we should be looking at food systems differently? What if there is a parallel with utilities in energy, and with the scope for distributed community energy systems? In this case food should be seen as a good currently supplied by oligopolistic intermediaries (retailers) from ever more consolidated primary producers (farmers), a state of affairs that needs reform for greater resilience - there are many parallels with energy generation and distribution. What if we had community farms that are hubs of services and production, with 'sub-stations' in residential areas (allotment tillers and keen back garden food growers) acting as the equivalent of a localized energy grid and generation system? As with decentralized energy, the aim would not be to achieve total self-sufficiency and grid-independence, but instead to boost system-wide resilience via redundancy, diversity and storage. After all, food systems represent flows.

The looming food security crisis will not be resolved by transforming urban cultivation into urban agriculture. Instead this will depend on meeting a daunting list of challenges: Reducing food waste, which accounts for up to one-third of production throughout the food chain (Kummo *et al.* 2012); shifting crops away from animal feeds and biofuels to human foods, which can increase global calories by up to 70 per cent (Cassidy *et al.* 2013); adopting *sustainable intensification*, in which productivity is raised without increasing environmental impact and without using more land (Garnett and Godfray 2012); and shifting to ***sustainable*** *Eatwell* plates on the consumption side (Harland *et al.* 2012; Macdiarmid *et al.* 2011; Thompson *et al.* 2013). Urban cultivation can have a small but significant role in such an evolving sustainable food system, as a provider of some local food, and as a catalyst for socio-economic sustainability.

Science has provided us with the ecological metrics needed to specify the requirements of food sustainability. The big gap in our knowledge is an understanding of the *social* processes and practices necessary to provide for food security. *Society* is the neglected child in the sustainability family. Urban cultivation offers a unique venue for assessing social sustainability and its synergies with ecological sustainability. The needed calculations pose a challenge to social LCA methodologies.

ABSTRACT

A process-based life cycle assessment (LCA) model was constructed for almond, pistachio, and walnut production in California. Agrochemical inputs, mechanized operations, soil processes, geospatial variation, and biomass accumulation were explicitly modeled based on technical reports, economic cost-and-return studies, field data collection, and grower interviews. Mean annual greenhouse gas (GHG) footprints for a typical hectare of orchard, from nursery to hulling/shelling facility gate, were calculated at 4260 kg CO_2e ha^{-1} yr^{-1} for almond, 3480 kg CO_2e ha^{-1} yr^{-1} for pistachio, and 4050 CO_2e ha^{-1} yr^{-1} kg for walnut. These results can be expressed by orchard product (nut kernel) as 1.76 CO_2e kg^{-1} for almond, 0.95 CO_2e kg^{-1} for walnut, and 3.83 CO_2e kg^{-1} for pistachio. Variations in biomass accumulation, yield and orchard lifespan between these crops result in different total life cycle emissions and potential management options for net GHG reduction and credit opportunities under California GHG cap-and-trade legislation.

Keywords: perennial cropping systems, orchard, greenhouse gas footprint, almond, walnut, pistachio

1. Introduction

Though LCA has been applied to a wide variety of food production systems, orchards have been examined relatively infrequently, with studies focusing on apple (Milà i Canals et al. 2006; Mouron et al. 2006; Page et al. 2011; Hester & Cacho 2003; Alaphilippe et al. 2012), kiwi (Xiloyannis et al. 2011), and citrus (Coltro et al. 2009; Mordini et al. 2009; Beccali et al. 2009; Beccali et al. 2010). Walnut production has also been examined although primarily in the context of timber production (Cambria & Pierangeli 2011). Many of these studies examine a single year for a production system, and thus do not consider the entire orchard life cycle, which includes orchard establishment, tree growth, and eventual removal (Bessou et al. 2012). Also, these studies generally do not consistently address the flow of carbon and nitrogen through the orchard and the woody biomass generated from orchard systems.

This study characterizes the greenhouse gas impacts of typical almond, walnut, and pistachio orchard production systems in the U.S. state of California using a comprehensive process-based life cycle assessment model that specifically accounts for carbon and nitrogen flow in biomass accumulation and fertilizer application. These highly industrialized agro-ecosystems are of great economic and environmental importance, occupying more than 500,000 ha of California agricultural land and yielding more than 83% of world almond production, 46% of walnut production, and 37% of pistachio production (USDA Office of Global Analysis 2013). Commercial orchards in California's Central Valley demand significant agrochemical, water, and fuel inputs throughout their productive lifespans (Beede et al. 2008; Connell et al. 2012; Grant et al. 2007; Micke & Kester 1997). Irrigation accesses groundwater via on-site pumps and surface water via the California Aqueduct system and other surface water transport infrastructure, entailing significant energy inputs for onsite and upstream pumping. Due to its relatively high input intensity, the California nut industry is responsible for significant emissions of greenhouse gases (GHGs) and other atmospheric pollutants.

However, perennial cropping systems such as almond, walnut and pistachio orchards have the potential to sequester carbon in soils and biomass as a consequence of their long life cycles and high biomass production (Kroodsma & Field 2006). In California, much orchard waste biomass is used to produce electricity at regional electricity generation plants, widely distributed in California (Wallace & Leland 2007). The potential for sequestration versus emissions offset through use of waste biomass as an energy feedstock is dependent on management characteristics, orchard lifespan, and other factors. We examined the effects of various biomass fates on net orchard GHG and energy consumption footprints, accounting for potential GHG credits from biomass-based energy production and temporary storage in standing biomass under both a business-as-usual scenario based on estimates of current practices, and a maximized energy production scenario assuming that all biomass co-products are directed to energy generation.

2. Methods

2.1. Model Development

This orchard LCA model was developed originally for analysis of almond production, and subsequently adapted for analysis of walnut and pistachio production. The general model structure remained the same, with multiple years of the orchard life cycle treated separately in order to account for changing input requirements and yields as trees mature, and model subunits for calculation of irrigation energy requirement, soil nitrous oxide emissions, and fuel combustion emissions were identical. The major differences between the three systems are in agrochemical and water input requirements, fuel use in field operations, typical yield per hectare, planting density and biomass accumulation, orchard lifespan and length of time before full bearing, and geospatial distribution and spatial relationships with irrigation infrastructure.

Where data were not available, particularly in the case of pistachio and walnut hulling and shelling operations, emissions from pistachio and walnut orchard floor soils, and pistachio nursery sapling production, data were substituted from the almond model (Kendall et al. 2012). Although data on the major system drivers of lifespan, nutrient management, irrigation, and yield are complete for almond, walnut, and pistachio, data collection for some aspects of walnut and pistachio production remains ongoing and will be included in further model iterations and published as stand-alone LCAs of walnut and pistachio production. The results presented are calculated from generalized, statewide data; however, the model framework is also usable for case studies of individual orchard operations.

2.2. Data Collection and Sources

To date, the most complete data were available for almond production. Data on input requirements, field operations, planting density, orchard productive lifespan, and irrigation systems were obtained from University of California Davis (UCD) Cost and Return studies. These studies document annual crop production costs for various California crops, by inventorying typical inputs and cultural practices on a regional basis up to the farm gate (M. A. Freeman et al. 2003; M. W. Freeman et al. 2003; Duncan et al. 2006; Connell et al. 2006; Freeman et al. 2008; Duncan, Verdegaal, Holtz, Doll, K. A. Klonsky, et al. 2011; Duncan, Verdegaal, Holtz, Doll, K. M. Klonsky, et al. 2011; Connell et al. 2012; Beede et al. 2008; Grant et al. 2007). The most recent available data was used, ranging from 2003 – 2012 for almond, 2007 for walnut, and 2008 for pistachio.

These Cost and Return studies are developed based on data collected from growers, orchard managers, and UC Cooperative Extension farm advisors through surveys, interviews, and focus groups. They provide a picture of the typical nutrient, pesticide, fuel, water use, equipment use patterns (including equipment type and hours of operation), and annual yields for an orchard under a particular irrigation system type in a particular growing region (Sacramento Valley, San Joaquin Valley North, and San Joaquin Valley South). In this LCA, the most conservative available regional data from the studies is used. The term “conservative” here refers to the use of the highest typical input values, which reduces the risk of underestimating inputs and associated GHG emissions.

Because growing region and irrigation type can affect key factors such as yield, results are calculated as a weighted average based on the number of hectares of orchard per region, and the type of irrigation system used; flood, micro-sprinkler, sprinkler or drip. Regional distribution information on almond irrigation methods and the proportion of groundwater versus surface water used by growers was obtained from survey data commissioned by the Almond Board of California to develop a sustainability program for the state’s almond growers. For walnut and pistachio, these data were obtained through interviews with UC Cooperative extension crop specialists and farm advisors.

One shortcoming of using these studies to inventory inputs and operations is that custom operations, those operations conducted by contractors rather than the orchard owners and managers, are tracked only as a cost in these studies, omitting information such as the hours of equipment operation and chemical or fuel inputs associated with these operations. To fill these and other data gaps in the LCA model, additional data were obtained through surveys of businesses and individuals involved in nut production. Surveys were administered to nursery operators, growers and their orchard managers, custom harvest operators, and orchard clearing operators. These surveys were conducted by both on-line survey and in-person interviews. In-person interviews were conducted to collect data for specific aspects of an operation, particularly equipment use and time needed for various tasks. No primary survey data for individual respondents are reported in this article to protect the anonymity of cooperating individuals and businesses, but wherever possible aggregated or composite results from surveys are provided.

Data for hulling and shelling were collected for almond through surveys and interviews of facility operators, as reported in (Kendall et al. 2012). In absence of similar data for walnut and pistachio, almond values were used. Further data collection is ongoing, but given the relatively small contribution of post-harvest operations to the overall GHG footprint of nut production (Figure 5), significant changes to overall net GHG footprints are not expected from the use of walnut and pistachio specific hulling and shelling data.

2.3. Goal and Scope Definition

The goal of this project is to conduct process-based LCAs for typical commercial California almond, walnut, and pistachio production to estimate the GHG emissions associated with production activities. Operations and inputs that contribute the most to total emissions and energy (i.e., ‘hotspots’) over the orchard life cycle are also identified to assist growers and policy-makers in targeting the highest-emitting or highest energy-using processes for reduction. The processes and operations included within the LCA system boundary are illustrated in Figure 1 below.

The units of analysis are one hectare of orchard assessed over a time horizon equal to the productive lifespan of the orchard plus one year for orchard clearing and fallow: 26 years for almond, 36 years for walnut, and 61 years for pistachio; and one kilogram of nut-meat or kernel (obtained by dividing through by mean annual yield on a kg ha^{-1} basis) at the hulling and shelling facility gate. Both GHG emissions and yield vary as the orchard matures, so annual yields were averaged over the orchard lifespan including non-productive and fallow years in order to calculate a generalized value for GHG emission expressed on a per kilogram yield basis. This functional unit can be simply converted to nutritional units such as calories of food energy.

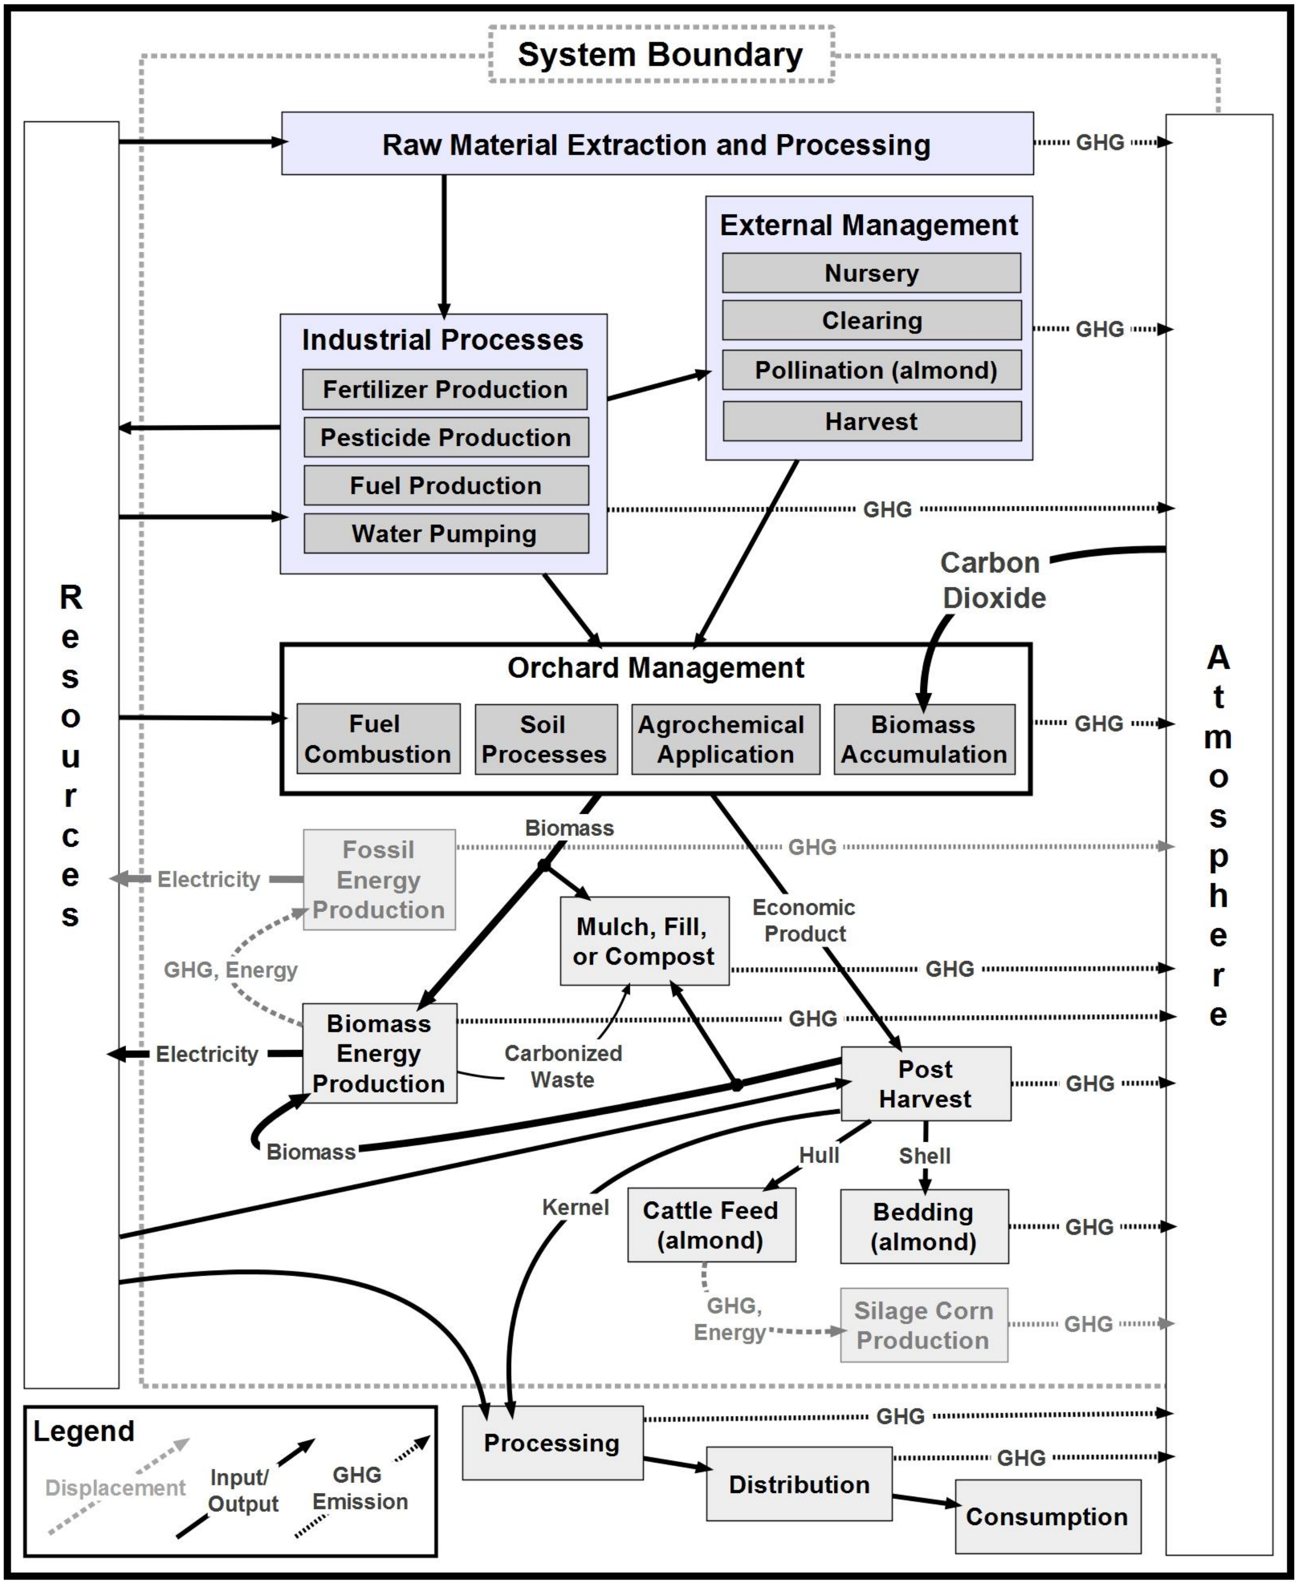

Figure 1. Orchard LCA system boundary. Transportation emissions, though accounted for at each stage, are excluded for clarity.

2.4. Model Assumptions

Model assumptions follow those reported previously for almond production (Kendall et al. 2012), and include the following:

- One percent of trees in each cropping system die and are replaced each year.
- The land occupied by the modeled orchard is assumed to be continuously planted as orchard, resulting in no net change in soil carbon over an orchard's life cycle. Though soil carbon changes over an orchard life cycle it is assumed that the soil carbon level at the time of orchard removal is identical to the soil carbon level following orchard establishment, due to loss of soil carbon during land clearing, tillage, and planting. Additionally, since potential carbon storage in soil is highly dependent on site-specific soil characteristics and orchard floor management (Six et al. 2004), accurate assessment of potential soil carbon sequestration in orchards on a statewide basis will require further field data collection and will be addressed in future publications.
- Different irrigation systems are modeled independently because they result in differences in both water input (including pumping and pressurization requirements) and direct and indirect nitrous oxide (N_2O) emissions from the field (estimated using IPCC Tier 2 methods). In terms of N_2O emission factors, the different crops are assumed identical and only differences between irrigation systems are accounted for.
- Agricultural equipment production is unlikely to have a major impact on the results of this analysis and is excluded - an exclusion common in other LCA studies (British Standards Institution (BSI) 2011).
- For purposes of comparison, each of the three orchard types is examined on a time horizon of 61 years: 1 pistachio life cycle, 1.71 walnut life cycles, and 2.40 almond life cycles.
- Inputs, especially nitrogen fertilizer and irrigation water (Figure 2), vary according to the nutritional needs of the different crops and the regional climate as well as over time as the orchard matures.

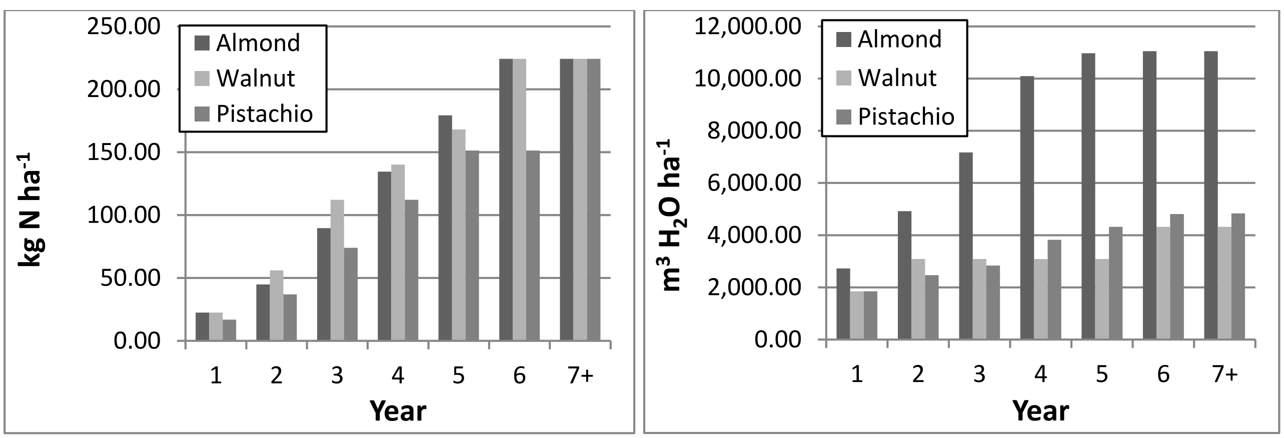

Figure 2. Variation in applied nitrogen and irrigation water by crop and year.

- Irrigation energy use is regionally dependent due to the spatial relationship with surface water delivery infrastructure (e.g., the number of California aqueduct pumping stations upstream of a given water diversion) and average groundwater depth, and thus the region of the Central Valley in which an orchard is located determines the energy requirement and the resulting GHG emissions embedded per unit applied water. A GIS-based model was used to generate a weighted mean irrigation energy value based on prevalent irrigation system types and spatial distribution of almond, walnut, and pistachio orchards. A detailed explanation of this model as applied to almond is available in (Kendall et al. 2012). Pistachio orchards are mostly concentrated in the southern Central Valley where groundwater is deeper and surface water delivery more energy intensive (Klein & Krebs 2005; GEI Consultants & California Institute for Energy and Environment 2010), while walnut orchards tend to be located in the northern Central Valley where surface water is gravity-fed and groundwater is closer to the surface. This results in higher typical irrigation energy use for pistachio and lower for walnut as compared to almond (Table 1).

Table 1. Almond, walnut, and pistachio irrigation characteristics.

Crop	Irrigation Energy	Main Irrigation Type	Mean Annual Applied H_2O
Almond	0.59 MJ m^{-3}	Microsprinkler	10307 MJ ha^{-1}
Walnut	0.40 MJ m^{-3}	Solid-set Sprinkler	4112 MJ ha^{-1}
Pistachio	0.83 MJ m^{-3}	Drip	4686 MJ ha^{-1}

2.5. Co-product treatment

As above, model treatment of biomass co-products including hulls, shells, prunings, and removed trees follows that reported in (Kendall et al. 2012). Some of the major differences between co-product treatment in almond, walnut, and pistachio are as follows:

- Biomass accumulation in almond was modeled according to a logistic curve, fit to measurements of biomass cleared per hectare obtained through collaboration with a Central Valley agricultural services firm. This method results in accurate calculation of total biomass per hectare at the end of the orchard productive lifespan (here 25, 35, and 60 years for almond, walnut, and pistachio respectively), but total biomass at any given year between establishment and clearing remains uncertain. Destructive sampling of individual trees of known age was used in , although actual biomass at end of life could only be estimated based on the logistic growth model (Agueron & Roberts 2013). In walnut, both destructive sampling of trees of known ages and measurements of orchard clearing biomass were used, giving accurate estimates of orchard biomass at all stages of growth.

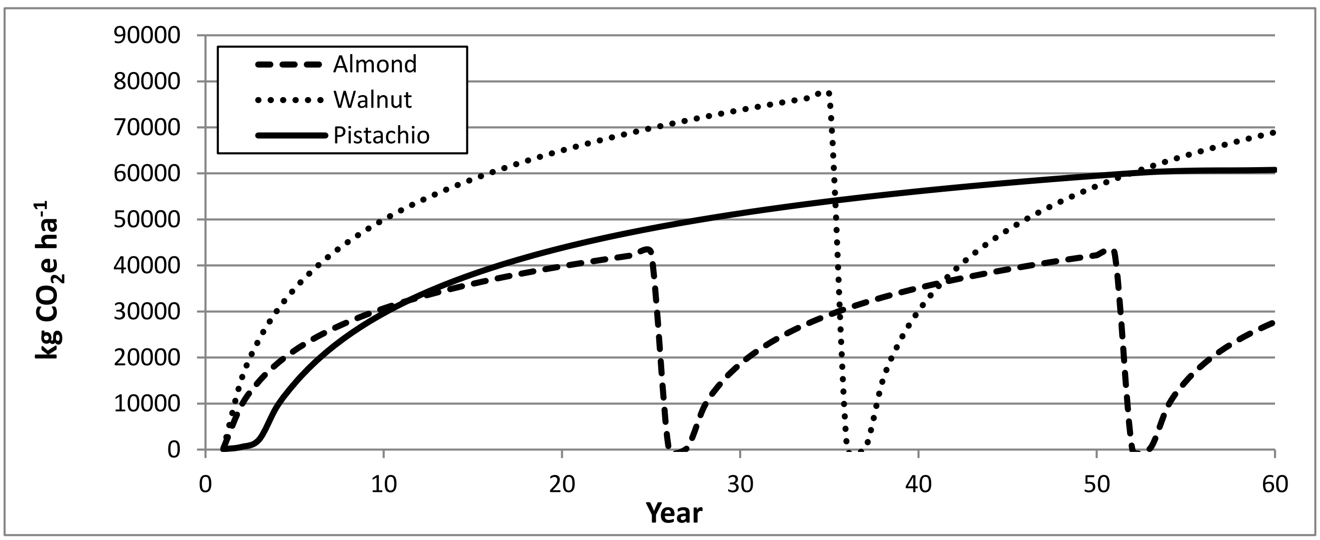

Figure 3. Biomass accumulation as CO_2e ha^{-1} in almond, walnut, and pistachio orchards over a 60 year time horizon.

- Pruning removal was calculated as a function of total tree biomass per hectare and pruning removal estimates (kg ha^{-1} yr^{-1}) from mature orchards. This base rate varied from 1060 kg ha^{-1} in almond to 1460 kg ha^{-1} in walnut and pistachio (Williams et al. 2008).
- Ratios of hull and shell to kernel (Table 2) were obtained directly from hulling/shelling facility records for almond, and from literature for walnut and pistachio (Monselise 1986).

Table 2. Mean annual yield and hull and shell to kernel ratios for almond, walnut, and pistachio.

Crop	Shell: kernel mass ratio	Hull: kernel mass ratio	Mean Annual Yield (kernel)	Mean Annual Yield (total)
Almond	0.45	1.56	1359 kg ha^{-1}	4091 kg ha^{-1}
Walnut	0.77	1.77	2631 kg ha^{-1}	9314 kg ha^{-1}
Pistachio	1.01	2.63	1375 kg ha^{-1}	6380 kg ha^{-1}

- Typically, almond hulls are used as dairy cattle feed while pistachio and walnut hulls are mulched. Specific information on shell fate was not available, so shells were assumed to be mulched for all three crops.

As reported in (Kendall et al. 2012), the rate of cleared biomass directed to energy production was reported as 95% for walnut and almond. In absence of specific data, the same rate was assumed for pistachio. The energy content of wood was obtained from (Wallace & Leland 2007), and a reasonably low estimate for power plant conversion efficiency of 0.25 was used to determine electricity generation offsets (Bain 1993). The equivalent emissions from a typical California grid electricity generation mix were considered to be displaced by the electricity produced from orchard biomass.

Each kilogram of biomass generates approximately 2.57 MJ of electricity after being dried in-field and at the power plant to approximately 30% moisture. A conservative value of approximately 25% energy conversion efficiency was assumed for California biomass power plants. When almond hulls are fed to cattle they are assumed to displace roughage, assumed to be silage corn, on a one-to-one mass basis. Displacement of electricity and silage corn production by use of orchard biomass co-products results in avoided GHG emissions, and is used to calculate GHG credits through system expansion to include energy generation and cattle feed production (Marland & Schlamadinger 1995). LCI data were obtained from EcoInvent and PE databases, accessed via GaBi software packages (Centre 2008; PE International 2009).

2.6. Temporary carbon storage

Temporary carbon in tree biomass is a function of marginal biomass accumulation on an annual basis as well as total storage time (orchard lifespan). Temporary carbon storage is a special case of emissions timing, where a removal of CO_2 from the atmosphere followed by an eventual emission occurs. Thus, to account for temporary carbon storage we use an alternative characterization method for GHG emissions, the Time Adjusted Warming Potential (TAWP) (Kendall 2012). The TAWP uses the relative cumulative radiative forcing (CRF) between an emission or removal of a GHG at a particular point in time (within the analytical time horizon of 100 years) and an emission of CO_2 today, resulting in units of CO_2 equivalents (CO_2e) *today*. The total kg ha^{-1} in CO_2e added per year in almond, walnut, and pistachio tree biomass was estimated using the logistic biomass model described above and in (Kendall et al. 2012), along with the total biogenic emissions from lost biomass at orchard clearing in order to calculate the TAWP of CO_2e drawn out of the atmosphere in tree growth. Storage in prunings, hulls, and shells is not considered in this calculation, as they are assumed to be mulched or otherwise disposed of in the same year that they are produced, resulting in a negligible contribution to carbon storage.

2.7. Scenarios

Two scenarios were examined: a typical or "business-as-usual" (BaU) scenario in which the best estimates of current co-product management practices and biomass fates was analyzed; and a maximum energy production scenario in which all available orchard biomass waste was utilized for energy production, including prunings, dead trees, shells, hulls, and cleared biomass at the end of the productive lifespan. Orchard clearing biomass was assumed to be directed to solid fuel power plants throughout the Central Valley as is the current practice, and prunings, shells, hulls, and individual removed trees were assumed to be combusted in modular biomass gasification-pyrolysis systems such as the Biomax system produced by Community Power Corporation (Overend 2004). Detailed discussion of the assumptions entailed in these two scenarios applied to almond production is offered in (Kendall et al. 2012), and the same assumptions applied for walnut and pistachio analysis in this study.

3. Results

Analyzed over a 61 year time horizon for a business-as-usual scenario, we find that the mean annual net GHG emissions of almond, walnut, and pistachio production are 1771, 2247, and 2986 kg CO_2e ha^{-1} respectively. These results include co-product credits of -1165, -159.8, and -137.9 kg CO_2e ha^{-1} and temporary storage credits of -187.4, -981.3, and -356.4 kg CO_2e ha^{-1} for almond, walnut, and pistachio respectively (Figure 5). Expressed per kilogram yield almond, walnut, and pistachio are responsible for 1.88, 0.89, and 2.17 kg CO_2e kg^{-1} kernel respectively (Figure 6).

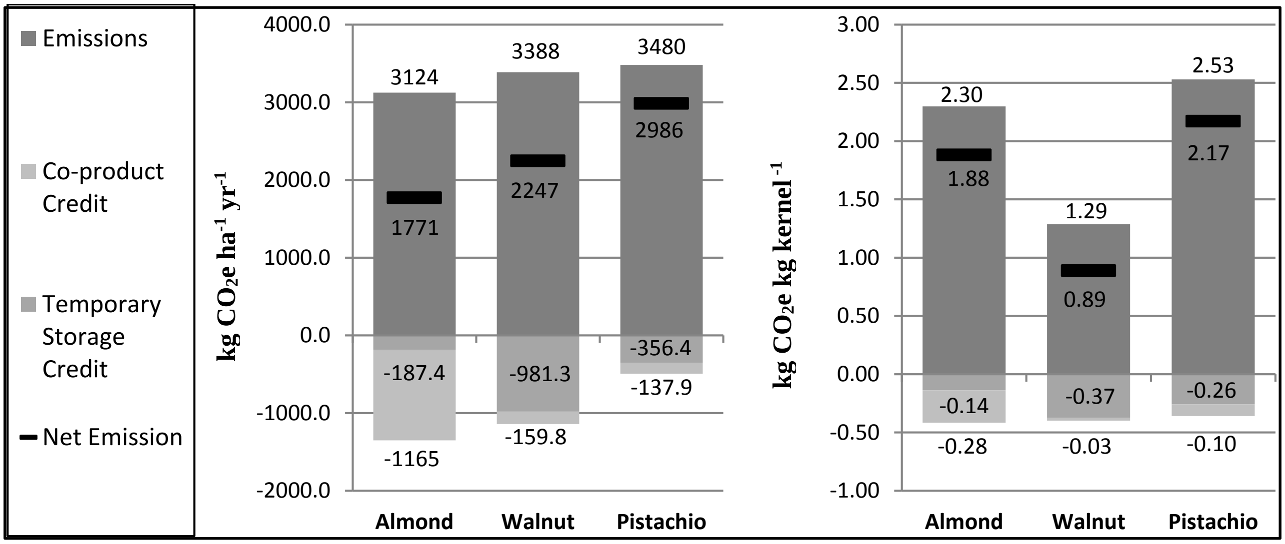

Figure 4. Mean annual GHG emissions and credits for nut orchards per hectare and per kilogram kernel under "business-as-usual" scenario.

The distribution of emissions among various management categories is roughly similar between almond, walnut, and pistachio, and is dominated by nutrient management at 38-43% total GHG emissions and irrigation at 16-34% total GHG emissions.

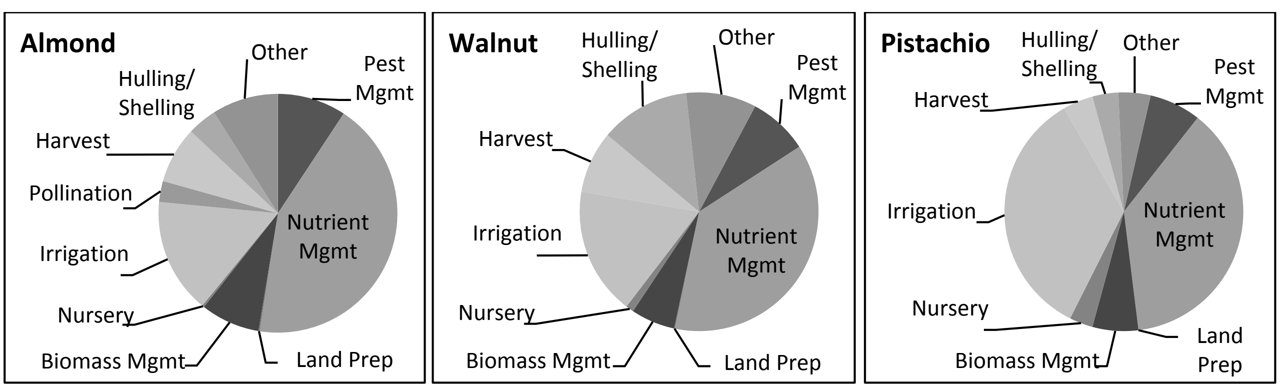

Figure 5. Breakdown of orchard emissions by management category for almond, walnut and pistachio.

The hypothetical maximum energy production scenario resulted in a substantial increase in potential co-product credits and a corresponding decrease in net emissions. Under this scenario net GHG emissions were calculated as -195.2, -981.3, and -84.67 kg CO_2e ha^{-1} and -0.14, -0.16, and -0.06 kg CO_2e kg^{-1} kernel for almond, walnut, and pistachio respectively (Figure 6).

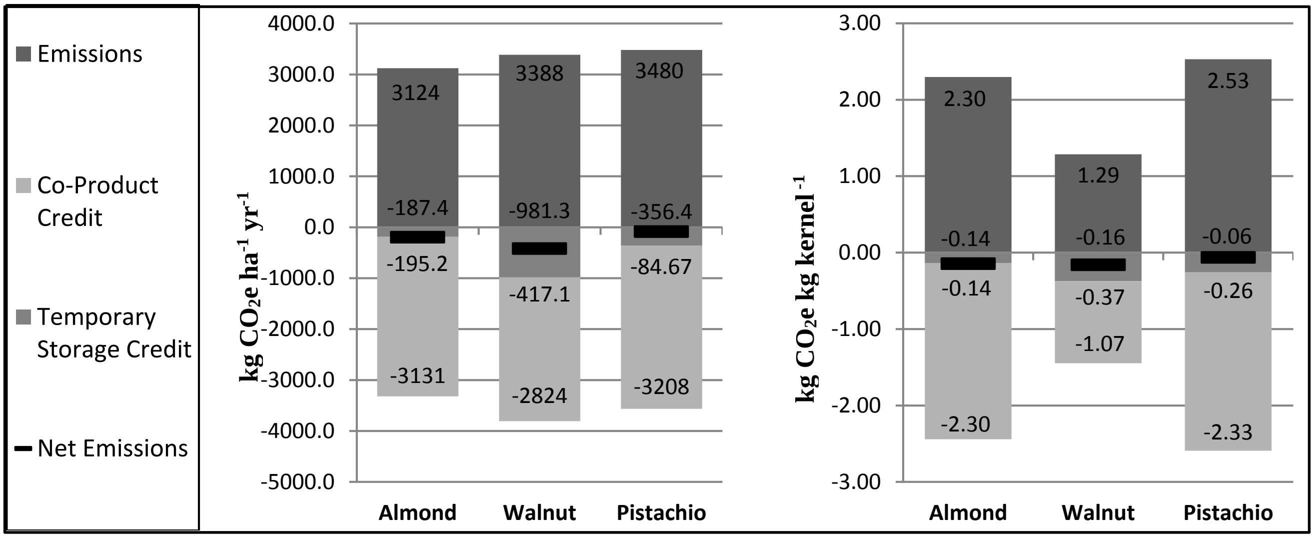

Figure 6. Mean annual GHG emissions and credits for nut orchards per hectare and per kilogram kernel under “maximum energy” scenario.

4. Discussion

The mean annual GHG burden, normalized to a 61 year time horizon, is similar among almond, walnut, and pistachio (Figure 4). This is due to the similarities in orchard management practices and to some extent, balances among inputs (Figure 5). For example, in wetter regions more frequent weed control and fungicide application is required, but less water is needed, whereas the opposite is true in dryer regions (Micke & Kester 1997). Somewhat greater differences in GHG footprint are observed when considering emissions per kilogram kernel (Figure 4) and when examining potential co-product and carbon storage credits. The former is due to variations in total yield and yield component ratios between these three crops (Table 2) while the latter is due to differences in co-product utilization (i.e., use of almond hulls as dairy cattle feed) and biomass accumulation characteristics (Figure 3). The scenario analysis highlights the variations between crops in potential to increase GHG credits through management practice – in particular, the expanded use of hull, shell, and waste biomass for energy production can generate significant GHG offsets (Figure 6).

5. Conclusion

This analysis examined typical almond, walnut and pistachio production in California using weighted-average data and consensus values for production inputs. As with all agricultural products, these nuts are subject to the inherent variability of region and climate which affects yields, biogeochemical emissions from orchard soils, and cultural practices of growers. This analysis highlights the critical importance of understanding the fate of co-products from orchard production including their utilization for energy production in order to determine true net GHG footprints of production, as well as the importance of maintaining high yields for increased GHG emissions “efficiency” of production (i.e., kg CO_2e kg^{-1} economic product).

The examination of a maximum energy scenario revealed the extremely high potential for California nut orchard systems to act as a net reducer of atmospheric GHG concentrations with the adoption of increased biomass co-product utilization practices and technologies. Indeed, due to lack of data, this analysis does not even consider the potential for carbon sequestration in orchard floor soils, which has been estimated as potentially highly significant (Kroodsma & Field 2006), nor does it consider the potential for increased management for biomass production (e.g., increased planting density coupled with periodic thinning, increased pruning frequency, cover cropping and no-till management, etc). Similarly, no scenarios accounting for potential GHG emission reduction through changes in inputs, management, or efficiency at the orchard field and production levels were examined. These represent additional potential sources for greenhouse gas reduction credits that will be explored in future analyses.

The results of this analysis suggest that combining the potential biomass management practices considered here with reductions in input intensity and alternative, low-GHG and energy intensive management practices could potentially allow California nut production to act as a significant GHG offset for the state. In order to promote and incentivize these practices, California's current GHG cap-and-trade legislation (Pavley & Nunez 2006) must properly credit orchard growers with the current beneficial results of perennial crop production, account for both co-product utilization and temporary carbon storage in standing biomass in calculation of net orchard emissions, and actively promote management practices that maximize the GHG benefits of these factors. Further research is needed to refine the walnut and pistachio LCA models and include more regionally specific data, as well as to elucidate the specifics of economic incentives that would be required to achieve optimum adoption of the GHG reducing management practices highlighted in this study.

ABSTRACT

Cattle milk production is strongly criticized for its impacts on the environment. For the first time an LCA approach was used to estimate them in southern Belgium. Based on a 9-farms survey, mean (SD) environmental impacts of 1 kg of fat-and-protein-corrected milk were estimated as 8.4 (4.5) g PO_4eq, 15.5 (2.8) g SO_2eq, 1.4 (0.2) kg CO_2eq, 3.0 (2.9) CTUe, 3.8 (1.2) MJ and 4.6 (0.7) m^2.yr for eutrophication, acidification, climate change, ecotoxicity, cumulative energy demand, and land occupation, respectively. Improved practices for manure application to land according to UNECE (2007) were simulated for 7 farms as an option to mitigate direct NH_3 emissions, with emphasis on mineral fertilization and machinery use. Maximum reductions of 10 and 13% were estimated for eutrophication and acidification respectively, with only marginal effects (from -1.3% to 4.2%) on the other impact categories. Inter-farm differences in impact per kg of protein produced and per m^2.yr of land occupation indicates that there are potential improvement possibilities to be investigated.

Keywords: milk, mitigation, farm gate, life cycle assessment

1. Introduction

Production of ruminant-based foods has been strongly criticized for its contribution to damaging emissions to the environment and resource use (Steinfeld et al. 2006). However at a global scale, it is expected that demand for these products will continue to increase (Alexandratos and Bruinsma 2012). Since resources are limited and damaging emissions have to be controlled, there is a need to improve cattle production systems. In Wallonia (southern Belgium), milk production is an important agricultural activity. Indeed, it accounts for 24% of the added value produced in Walloon agriculture (SPW-DAEA 2011). Walloon milk production tends to be intensive; specialized milk farms have a mean apparent N surplus of 189 kg/ha/y (CRA-W 2011).

Since agricultural activities are involved in most major environmental problems in Wallonia (e.g. acidification, surface water pollution, greenhouse gas (GHG) emissions; KIEW 2013), and to avoid transferring impacts between impact categories in mitigation proposals, a multi-criteria approach was used to estimate the environmental pressure exerted by dairy systems in southern Wallonia. Even though GHG emissions per unit of milk produced in Belgium are among the lowest in the world (Gerber et al. 2011), large variations are expected at a regional scale (Casey and Holden 2006), and it seems worthwhile to explore this variation to find mitigation opportunities at the farm level. Furthermore, the link between milk production, regional production potential, and sensitivity at the territory level has to be considered to optimize land occupation (e.g. use of non ploughable land for food production) and to avoid exceeding limits of local pressure on the environment.

Until now, multiple environmental impacts of milk production in southern Wallonia have not been estimated with life cycle assessment (LCA) methodology. LCA was applied using a tool called "Weden", adapted from van der Werf et al. (2009), to 9 commercial farms located in a small territory (Gaume), and individual mitigation options based on improved manure application were proposed.

2. Methods

2.1 Goal and scope

The purpose of this work was to estimate environmental impacts of milk production by dairy farms in the Gaume region using an approach similar to that described by van der Werf et al. (2009). It is a one-year attributional cradle-to-farm-gate LCA that estimates environmental impacts of producing milk. The functional unit was 1 kg of fat-and-protein-corrected milk (FPCM; IDF 2010). The environmental impact categories considered were climate change (excluding land use and land-use change; IPCC 2006), eutrophication, acidification (CML 2013), cumulative energy demand (Hischier et al. 2010), ecotoxicity (USEtox 2013) and total land occupation (Hischier et al. 2010). System boundaries included main inputs and farm processes up to the farm gate, except for buildings and veterinary or cleaning products (Fig. 1). Waste disposal, destruction, or recycling were excluded. It was considered that imported animals and manure had no environmental burden but they were included in nutrient balance calculation. For all farms, classic technical indicators, such as N surplus and milk production per cow were also calculated to investigate improvement possibilities and their relation to environmental impacts. The target public was (1) farmers, to whom LCA results were reported along with technical indicators to investigate mitigation options mainly based on better manure application to land and (2) farm advisors, to consider LCA approaches for benchmarking and mitigating environmental impacts of cattle-based products at a small-territory scale (Gaume).

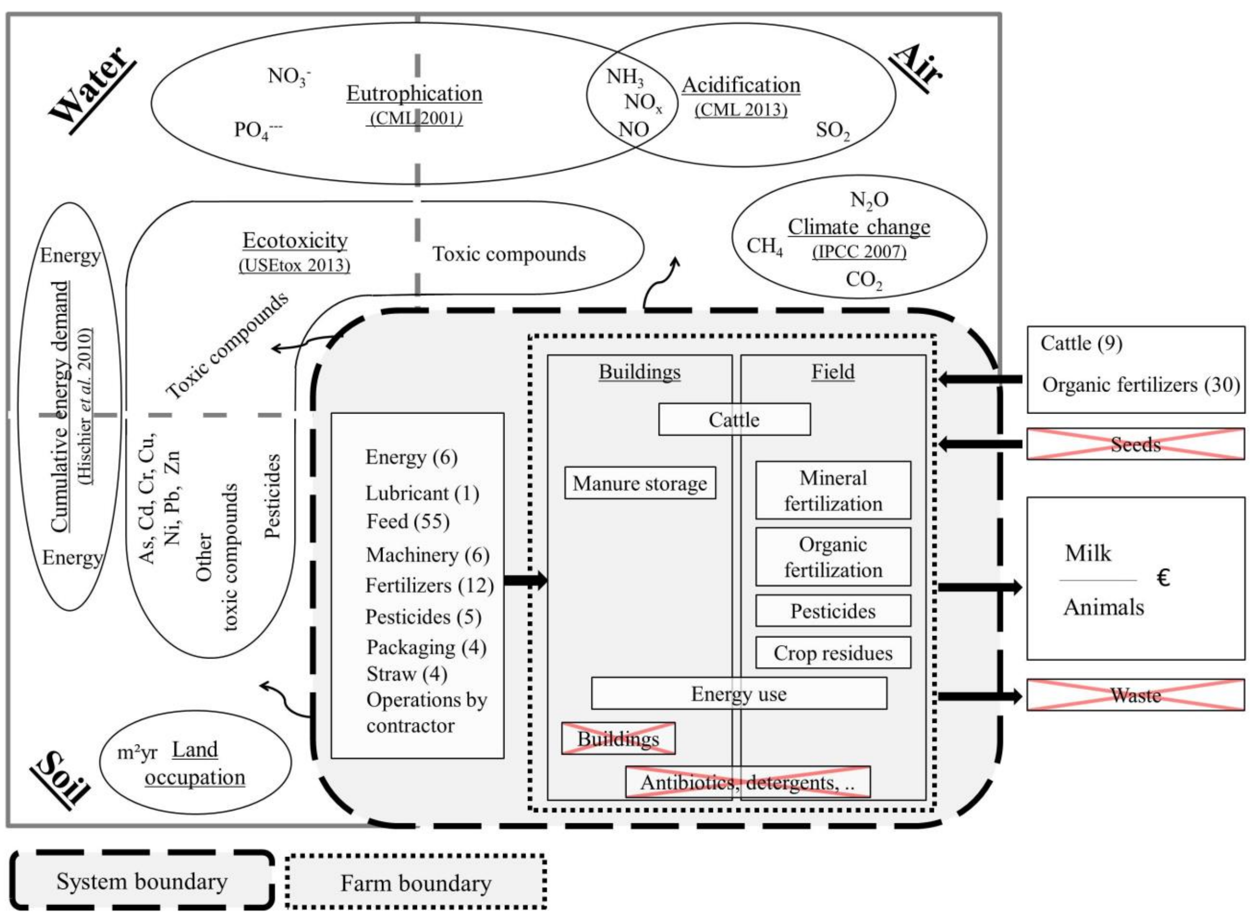

Figure 1. System description, impact categories and related damaging molecules and resources considered. Numbers in parentheses indicate the number of items considered in the inventory after aggregation (e.g., 63 machinery alternatives recorded on farms were aggregated into 6 groups).

2.2. Dairy production in Gaume, farm descriptions and technical indicators

The Gaume territory is a cultural sub-region that covers two-thirds of the Jurassic region of Belgium and includes 372 km² of usable agricultural area (UAA). It was chosen for this study because of its homogeneous soil and climate conditions, production practices, and cultural characteristics (to allow sociological analysis of production systems in the Qualaiter project). In 2010, in the Jurassic region 7271 dairy cows on 132 farms (25% of all farms) produced a mean of 5500 l of milk sold/cow/yr (CBL 2013). Only 39 of these farms were specialized dairy farms without a suckling herd. Despite the fact that mixed systems are dominant in this region, specialized dairy farms were mainly chosen to avoid problems of allocation or boundaries between dairy and beef or crop production in mixed farms. Nine farmers agreed to participate in this study, and 8 of them were exclusively dairy farmers (two of them organic), while the ninth had 32 suckler cows along with 120 dairy cows. Overall, the 9 farms held 895 dairy cows or 19% of dairy cows in the Gaume territory (Table 3). For the only mixed system, information was collected from the farmer to separate both systems. When no data were available to segregate crop- and animal-production systems (e.g. agricultural area used as pasture) an allocation between systems was done according to animal-feed dry-matter requirements. Data were collected on farms for the 2012 calendar year.

2.3. The Weden tool, inventory and impact assessment

The Weden tool consists of an Excel® spreadsheet split into three sections: input data, calculations, and reporting. Weden estimates emissions from the following farm processes:

- cattle: CH_4 emissions from enteric fermentation
- feed: emissions from production and importation of feed and straw
- induced emissions: N_2O emissions due to on-farm NH_3, NO_x and NO_3^- emissions
- machinery: emissions for machinery production
- mineral fertilizers off- and on-farm: emissions from production and importation and emissions from on-farm fertilization, respectively
- energy off- and on-farm: emissions from production and importation of energy and lubricants and emissions from on-farm energy and lubricant use, respectively
- organic fertilizers on-farm: emissions in the barn, during storage and at application
- pesticides and plastics off- and on-farm: emissions from production and importation of pesticides and plastics and on-farm emissions of pesticides to land, respectively
- others: on-farm emissions from crop residues and surpluses of trace metals, NO_3^- and PO_4^{---}

Table 1. Identification and explanation of modules/data sources of the IPCC and EMEP models adapted.

Domain	Adaptation	Variable used	Direct influence on
Herd management	Herd distribution among 4 periods: in barn, always on pasture (excluding milking time), intermediate periods (in barn at night, outside during the day) before and after winter	Duration of periods, duration of presence in the barn for milking and intermediate periods	Manure distribution, animal energy and protein requirements, animal diet
N fixation	Estimated according to legume species in grasslands	Mean proportion of legume species in grassland cover in June	N balance
Animal	Diet quality for each period and each animal category	Feed supplied (amount and quality[1]) and grazed grass quality	N and methane emissions
	Performances and characteristics	Weights, liveweight gains, proportion of pregnant cow, carcass yield, milk production, lactation period	Nutrient balances, cattle requirements, meat production, milk production
	Milk-production dynamics	Main periods of calving and milking duration	Dairy cow energy and protein requirements during the 4 periods of the year considered
Buildings	Barn type per animal category	Type of barn	Manure type and nutrient content
Manure management	Type of machinery and time before incorporation into soil	Machine type and duration before incorporation into soil	Ammonia emissions

[1] Digestibility and crude protein content

Models used for the on-farm inventory are based on element balances (N, P, K and trace metals) at the farm level (van der Werf et al. 2009). Methane (CH_4) and nitrous oxide (N_2O) emissions are modeled according to IPCC (2006) Tier 2 except for soil N_2O (Tier 1). Ammonia (NH_3), and nitrogen oxide (NO_2 and NO_x) emissions were calculated with EMEP/EEA (2009) equations. Phosphorus emissions to water were estimated according to Nemecek and Kägi (2007) while the nitrogen surplus at farm level was considered as lost to water as nitrate. Inventories were based on farm data collected from bookkeeping, other official documents related to the EU Nitrate Directive (AGW 2011) or common agricultural policy and farmer interviews (ca. 3 hours long) for farm management (cattle diet, barn type, manure management, etc.). This was done to increase model sensitivity to farm management and/or characteristics (Table 1).

The cattle module was divided into the ten animal categories used for national statistics and farm bookkeeping based on animal age and function (dairy vs. suckler cow). For each, animal requirements and excretion were calculated from IPCC Tier 2 (2006) based on diet quality, animal characteristics and management. If these were not available, data were taken from default values found in the literature (Table 2). Three manure types were considered: slurry, semi-solid manure and farmyard manure. Emission factors from IPCC (2006) used for semi-solid manure were those of solid storage and those for farmyard manure were those of storage below animals, according to emissions observed by Mathot et al. (2013). The Weden tool was also developed to take into account regional variability in machinery, barn types, manure management, pesticides, crop yield and characteristics, and organic and mineral fertilization (Table 2). Based on a detailed list of 279 machines (Mecacost tool: Rabier et al. 2008), details given by farmers about annual use (converted to kg machine equivalent), and the corresponding inventory, emissions of 6 categories of machines (general, tillage, harvester, tanks, tractors and trailers; Frischknecht et al. (2013)) were estimated. Consumption of fuel for operations by contractors was estimated according to Rabier et al. (2008) and expert opinion (F. Rabier, Pers.comm. 2013) for the choice of representative equipment and use. Inventories for the production of pesticides (5 types), mineral fertilizers (12 types), energy sources (6 types), lubricant (1 type), and plastics (4 types) were obtained from Frischknecht et al. (2013) and detailed data from farmer interviews and regional product lists and characteristics when necessary (Table 2). Inventories of feed and straw production were adapted mainly from Blonk et al. (2009), Frischknecht et al. (2013) and Piazzalunga et al. (2012).

Table 2. Main data sources for inventory and modeling of emissions

Item	Primary sources
Nutrient contents of slurry, semi-solid manure, farmyard manure and types of organic matter	AGW 2011; Godden et al. 2013;
Nitrogen fixation by legumes in grasslands	Limbourg et al. 2001
Machinery characteristics and fuel consumption	Rabier et al. 2008
Trace metal balance and content	Li et al. 2005; Piazzalunga et al. 2012
Cattle characteristics	INRA, 2007
Plant yield and characteristics; feed composition	CVB 2010; INRA 2007
Animal product characteristics	Mathot et al. 2012;
Mineral fertilizer characteristics	Piazzalunga et al. 2012
Pesticides	SPW-DAEA 2012
Packaging	van der Werf et al. 2009

Emission factors for eutrophication (PO_4eq), acidification (SO_2eq) and climate change (CO_2eq) were identical to those used by van der Werf et al. (2009). Cumulative energy demand (MJ) was calculated using characterization factors of Frischknecht et al. (2007). For ecotoxicity (CTUe), emissions of all toxic compounds included in the ecoinvent v2.2 inventory database (Frischknecht et al. 2007) were included for inputs, using USEtox characterization factors (USEtox 2013). On-farm emissions of trace metals, products of combustion and active ingredients of pesticides were included. A simplified approach was used for active ingredients of pesticides: we assumed that all active ingredients applied were emitted to soil. A list of currently applied products (467) and their active-ingredient concentrations (239) was obtained from SPW-DAEA (2012). When available (ca. 75% of pesticides), characterization factors from the USEtox database were used (not shown). When not known, the mean characterization factor of all active ingredients was used (486 CTUe/kg).

Per farm, one mitigation option to decrease NH_3 emission was simulated taking into account a better manure management by application of slurry with trailing hose instead of a splash plate and rapid incorporation of solid manure (UNECE 2007). A change in spreading equipment (tractor and tank/spreader) was included based on Rabier et al. (2008). Regardless of the mitigation option, and according to simulation with the Mecacost tool (Rabier et al. 2008), fuel consumption did not increase due to the use of more efficient spreading equipment (suitable power and faster operations). Mineral N fertilization was also reduced by assuming a ratio of 1 kg N per kg of N-NH_3 not lost during organic fertilizer spreading.

2.4 Uncertainty analysis and interpretation of results

Sensitivity to the type of allocation method used for co-products (meat and milk, no plant production was sold) was tested by comparing results from economic, biophysical (IDF 2010) and protein allocation. The latter two allocation methods were calculated using the change in animal numbers after subtracting imported animals, while for economic allocation, neither changes in animal numbers or purchases were included. Statistics were performed with R software (R Development Core Team 2011). For each farm, a summary of the results was produced, including comparison with those of other farms. The summary included results about the technical indicators, impact on the environment per kg of FPCM and per m^2 of UAA, and distribution of environmental impacts between on- and off-farm activities and within the farm. Furthermore, opportunities for mitigation were discussed based on manure management while using more efficient machinery to avoid NH_3 losses at spreading. Partial results and technical indicators (Table 3) were used to validate data collected and results. To investigate links between production efficiency and land-use intensity, the relation between impacts per m^2 of land occupation and impacts per kg of total protein produced was analyzed. Total protein was used as indicator to include meat production.

3. Results

Using economic allocation, mean (standard deviation (SD)) emissions per kg of FPCM for the 9 farms were 254 (116) g CO_2, 1.04 (0.2) g N_2O, 8.3 (1.71) g NH_3, 2.27 (0.38) g NO, 0.88 (0.36) g NO_x, 0.54 (0.2) g SO_2 and 32 (6) g CH_4 to air and 0.01 (0) g NH_3, 39 (39) g NO_3^-, 1.11 (0.83) g PO_4^{---} to water. Due to the large number of active ingredients involved in ecotoxicity, it was not possible to disaggregate them. Mean environmental impacts for the production of 1 kg of FPCM were 8.5 (4.5) g PO_4eq, 15.5 (2.8) g SO_2eq, 1.4 (0.2) kg CO_2eq, 3.0 (2.9) CTUe, 3.8 (1.2) MJ and 4.6 (0.7) m².y for eutrophication, acidification, climate change, ecotoxicity, CED and land occupation, respectively (Fig 2.1-2.6), with economic allocation between milk and meat production. High variability was observed for all impact categories (coefficient of variation = ca. 10-100 %, Fig. 2.1-2.6). Changing the allocation method to biophysical or protein-based allocation (Table 3) reduced impacts of milk production by 11% and 4%, respectively. However, there were no relations between economic and biophysical or protein allocations ($p>0.05$, $r=0.225$ and $r=0.178$, respectively), though protein and biophysical allocations were significantly correlated ($p<0.001$, $r= 0.997$).

For eutrophication, acidification, climate change and land occupation, on-farm emissions dominated (>70%), while for CED and ecotoxicity off-farm emissions dominated (>60%). Organic matter management (storage and application) was, on average, a main contributor to eutrophication (46% (30%)), acidification (84% (7%)) and climate change (22% (3%)). However, the main contributor to climate change was the herd, through CH_4 emissions from enteric fermentation (48% (8%)). For ecotoxicity, feed production contributed 65% (20%), while pesticide production and application contributed 9% (10%).

The main source of N fertilizer was organic manure. Indeed, 51.4% (17%), 8.6% (13%), 5.2% (10%) of N fertilized originated from slurry, farmyard manure and semi-solid manure, respectively, while the remaining 35% (26%) came from mineral fertilizers. On average, 87% (6%) of NH_3 emissions were due to organic manure management, with 34% (6%), 30% (4%) and 36% (10%) of them were emitted in the barn, during storage and spreading on the soil, respectively. Considering the equipment for and management of solid and liquid manure

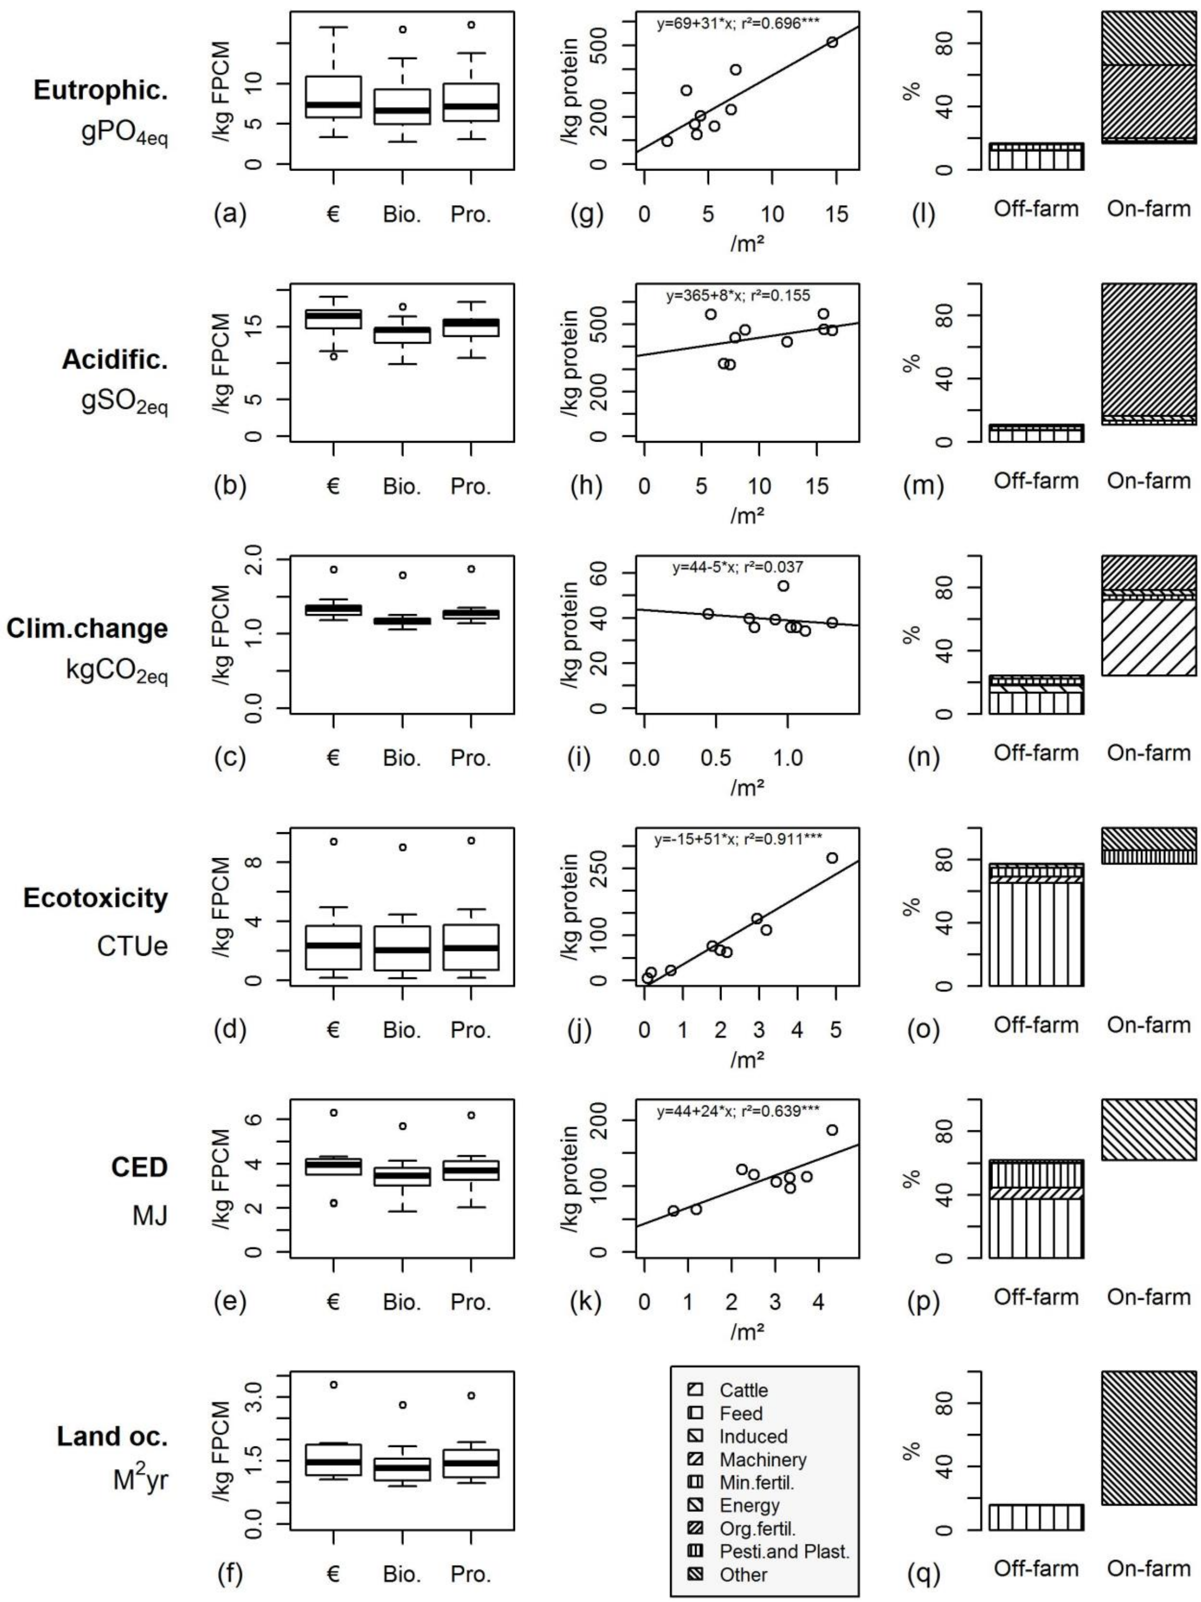

Figure 2. Potential environmental impacts per kg of fat-and-protein corrected milk (FPCM) as a function of allocation method (2.1-2.6): economic (€), biophysical (Bio.) and protein (Pro.), boxplots according default parameters. Relations between impact per m^2 of land occupation and that per kg protein produced for the 9 farms (2.7-2.11); *,** and *** indicate $p<0.05$, $p<0.01$, and $p<0.001$, respectively. Distribution (2.13-2.17) of the environ application to land, there was an opportunity to mitigate of NH_3 emissions and consequently N fertilizer use for

7 farms (Table 3). Simulation of these mitigations led to a decrease of 26% (6%) of NH_3 emission at application and, consequently, with a change in equipment and reduction of mineral fertilization, to reductions of 4.8% (3.6%) and 8.4% (2.6%) of eutrophication and acidification impact, respectively. Marginal positive effects were also observed for the other impact categories (climate change: 0.4% of CO_2eq, ecotoxicity: 6% CTUE and CED: 0.7% of MJ), but an increase was observed for the farms without mineral N fertilization (Table 3).mental burden: off- (left) and on-farm (right) and, within each, origin of the impact.

For eutrophication, ecotoxicity and CED, significant positive correlations were observed between impacts per kg of protein produced and per m².y used ($p<0.05$). No correlation was observed ($p>0.05$) for the other impact categories (Fig. 2.7-2.11).

Table 3. Mean characteristics, technical indicators, allocation factors and results of mitigation options for all 9 farms studied

Category	Item	Unit	Mean	SD	Max	Min
On-farm area	Total	Ha	94	41	159	55
	Grasslands	%	73	14	96	53

[1] According to Stilmant et al. (1998). [2] At the farm scale, related to the usable agricultural area of the farm. [3] Organic and mineral fertilization at spreading (before NH_3 losses from manure). [4] Percentage reduction for the 7 farms considered for mitigation.

4. Discussion

Although comparing results of this study with those from the literature is difficult because of methodological differences, we estimated higher values than those reported by Nguyen et al. (2013) for eutrophication (+60%) and acidification (+33%), similar values for climate change (-4%) and land occupation (+10%) but smaller values for CED (-14%). For eutrophication and acidification, differences could be explained in part (<10%) by high NH_3 emissions due to the low efficiency of equipment used in 7 of the farms. For eutrophication, 260 (300) g PO_4eq came from NO_3^{--} emissions of 14.1 (8.7) g N/m², higher than those in a similar study (8.1 g N/m²; van der Werf et al. 2009), which could help to explain the high eutrophication impact estimated. However, too little information was available for a full comparison with Nguyen et al. (2013), who did not calculate NO_3 emissions using farm-gate N balances. Furthermore, our small sample size means that extreme values can greatly influence mean values. When reporting results to farmers, environmental impact, technical information and mitigation possibilities (Table 3) were discussed with a particular attention to extreme values, like for nitrogen surplus, to investigate other mitigation options than those concerning manure management. As no environmental burden was attributed to imported animals, impacts are underestimated. However, for the 9 farms considered animals were imported on only one farm (2% of the herd), thus the underestimation is certainly relatively small.

The allocation method also influenced impacts of milk production, attributing fewer impacts to milk when shifting from economic to protein-based to biophysical allocation. Attributional LCA remains problematic due price fluctuations impact on economic allocation or more generally the choice of allocation methods that may change distribution of impacts between meat and milk. For product labeling, attributional approach seems necessary (e.g. IDF 2010); however, the use of functional units that require no allocation between co-products at the farm level, such as protein production (van Dooren et al. 2014), could be used to assess improvement in food production. Consequential LCA or system expansion could also be used.

Considering total protein production (milk and meat), improvement may be achieved by adopting the mitigation option of improving manure application to land or management. Simulation of the former, even though based on simple models, decreased environmental impacts (by 0.4-8.3%). The simulation assumed a reduction of N mineral fertilization directly proportional to the decrease in NH_3 emissions. This assumption is open to criticisms in the short term at least due to farmers' fears of quality or yield losses and higher costs due to change in machinery or energy purchase. Since NH_3 emissions from organic fertilization strongly influence eutrophication and acidification impacts, higher reductions could be expected if more efficient equipment was used (e.g. manure injection; EMEP/EEA 2009). This possibility was not tested because it would have involved major changes in equipment and energy use, reducing the chances that farmers would adopt the mitigation option. Furthermore, no reduction in mineral fertilization was possible in organic systems, which do not use it. Thus, only changes in machinery were taken into account, leading to marginally higher emissions for other impact categories (negative values in Table 3). This problem reflects difficulties in predicting changes in the quantity and quality of potentially available N for plant production and the related milk production, which was not predicted in simulations.

For mitigation associated with changes in farm management, even though only a few farms were considered, the positive relation between impact per kg FCPM and per m^2 of land occupation estimated for eutrophication, ecotoxicity and CED should be investigated further. Indeed, this relation indicates that it is feasible to have relatively low impact per unit of product and per unit of land occupied. Indirect emissions contributed strongly to ecotoxicity and CED, while direct emissions (N and P surpluses) contributed strongly to eutrophication (Fig 2.12, 2.15 and 2.16). Therefore, the relation between feed inputs and animal production (milk and meat) seems to be a key factor to adjust to reduce environmental impacts. However, on-farm land occupation is quite high (0.842 (0.098) m²/total m²), reflecting the importance of on-farm cattle feed production and of milk production linked to the territory, which is composed mainly of grasslands (0.731 (0.142) m²/m² of on-farm land occupation). Other mitigation options can be proposed based on technical indicators such milk production, herd composition or age at first calving. The complexity of production systems at the farm scale, however, makes it difficult to render good advice about practices. For example, to reduce the ratio of non-productive to productive animals, which varies widely between farms (coefficient of variation = 30%, Table 3), one could recommend reducing the age at first calving. However, one consequence of this change could be an increase in the amount of concentrated feed in the diet of young cattle, which could increase environmental impacts but also decrease veal production. Less veal production would have potential consequences, such as, in a consequential LCA approach, increased veal production in other systems to satisfy demand for veal.

Finally, the variability observed highlights the diversity and thus room for improvement in these production systems, even in a small and relatively homogeneous area. Methodological problems, however, such as errors in the inventory are still possible due to missing or incorrect data collection or modeling. Therefore, validating results and/or improving models are necessary. For example, in this study the complete causal chain recommended by IPCC (2007) and EMEP/EEA (2009) for cattle feeding was included, from feed ingestion to manure application to soil. However, the causal chain for N emissions probably depends greatly on the quality of the diet used in the inventory. Ideally, feed input, feed stock change and, when available, forage analysis in diets included in the study have to be validated. Results such as mean N (excretion – losses in the barn and storage) and CH_4 production by cattle (105 (21) kg N and 130 (13) kg CH_4 per dairy cow per year, respectively) have to be compared to regional recognized referential values. Furthermore, in the future, default values in causal chains should be replaced with better data, for example, by improving knowledge about cattle nutrition or estimating enteric CH_4 emissions at the farm scale with estimation based, for example, on milk analysis (Dehareng et al. 2012). However, this last approach will not solve the problem of modeling GHG emissions of non-milk-productive animals, which requires additional measurement (Mathot et al. 2012). Finally, beyond the normative approach, improvement and mitigation strategies have to be identified.

5. Conclusion

Despite the small number of farms studied, environmental impacts of milk production in the small territory of Gaume was highly variable. Implementing good practices such as using better manure spreading methods may mitigate eutrophication and acidification impacts. Further research is required to investigate and model differences in farm inputs and production, including both milk and meat co-products.

ABSTRACT

Uncertainties in environmental impacts of milk production related to model variables were investigated with Monte-Carlo simulation in a case study. Per kg of fat-and-protein-corrected milk produced, the 95% confidence interval of impacts was 6.2-10.4 g PO_4eq, 10.1-25.6 g SO_2eq, 1.1-1.9 kg CO_2eq, -7.6-19.2 CTUe, 4.3-4.9 MJ and 1.11-1.28 m²yr for eutrophication, acidification, climate change, ecotoxicity, CED and land occupation respectively. Expressed as coefficients of variation, uncertainties ranged from 3% to 2097% as a function of the impact category. The most influential variables changed with impact category, except those related to the functional unit. Monte-Carlo simulation and sensitivity analysis help to identify variables requiring more accuracy and detect errors implementing multiple-variables models in calculation tools.

Keywords: distribution, Monte-Carlo simulation, life cycle assessment, IPCC

1. Introduction

Uncertainty assessment in life cycle assessment (LCA; ISO 2006) of agricultural products, milk in particular, is a major concern, and relatively few studies have considered it (Yan et al. 2011). Flysjö et al. (2011) showed the importance of uncertainty in some emission factors, such as N_2O from soil used in relatively simple models, on the uncertainty in the carbon footprint of milk production. The influence of emission factors on nitrogen (N) compound emissions at the farm level compared to calculation with the N balance has also been highlighted (Payraudeau et al. 2007). Since agricultural activities are involved in most major environmental problems in Wallonia (e.g. acidification, surface water pollution, greenhouse gas (GHG) emissions; KIEW 2013), Belgium, a multiple environmental impact approach is necessary for milk production. To this end, a tool called “Weden” based on van der Werf et al. (2009) was built that included the ability to explore uncertainty in environmental impacts. This study aimed to investigate uncertainties in environmental impacts of milk production related to model variables and identification of the most influencing variables with a Monte-Carlo simulation approach based on a case study.

2. Methods

2.1. Weden tool

LCA of milk production on a farm was performed with a tool called Weden, consisting of an Excel® spreadsheet, described in Mathot et al. (2014). Models used for the on-farm inventory were based mainly on element balances (N, P, K and trace metals) at the farm level. Methane (CH_4) and nitrous oxide (N_2O) emissions were modeled with IPCC (2006), mainly Tier 2. Ammonia (NH_3) and N oxide (NO_2 and NO_x) emissions were calculated according to EMEP/EEA (2009), mainly Tier 2, approaches. For these two models, causality chains for calculation of N and CH_4 emissions from cattle feed ingestion to manure spreading were fully implemented. Phosphorus emissions to water were estimated according to Nemecek and Kägi (2007), and inputs at the farm level were adapted mainly from Frischknecht et al. (2007) using SimaPro software (PRé Consultants 2007). System boundaries, compound targets in the inventory and environmental impacts considered are summarized in Fig. 1. In the model used it is considered that imported animals and manures had no environmental burden but they are included in nutrient balance calculation. However, in this case study no manure or animal was imported into the farm.

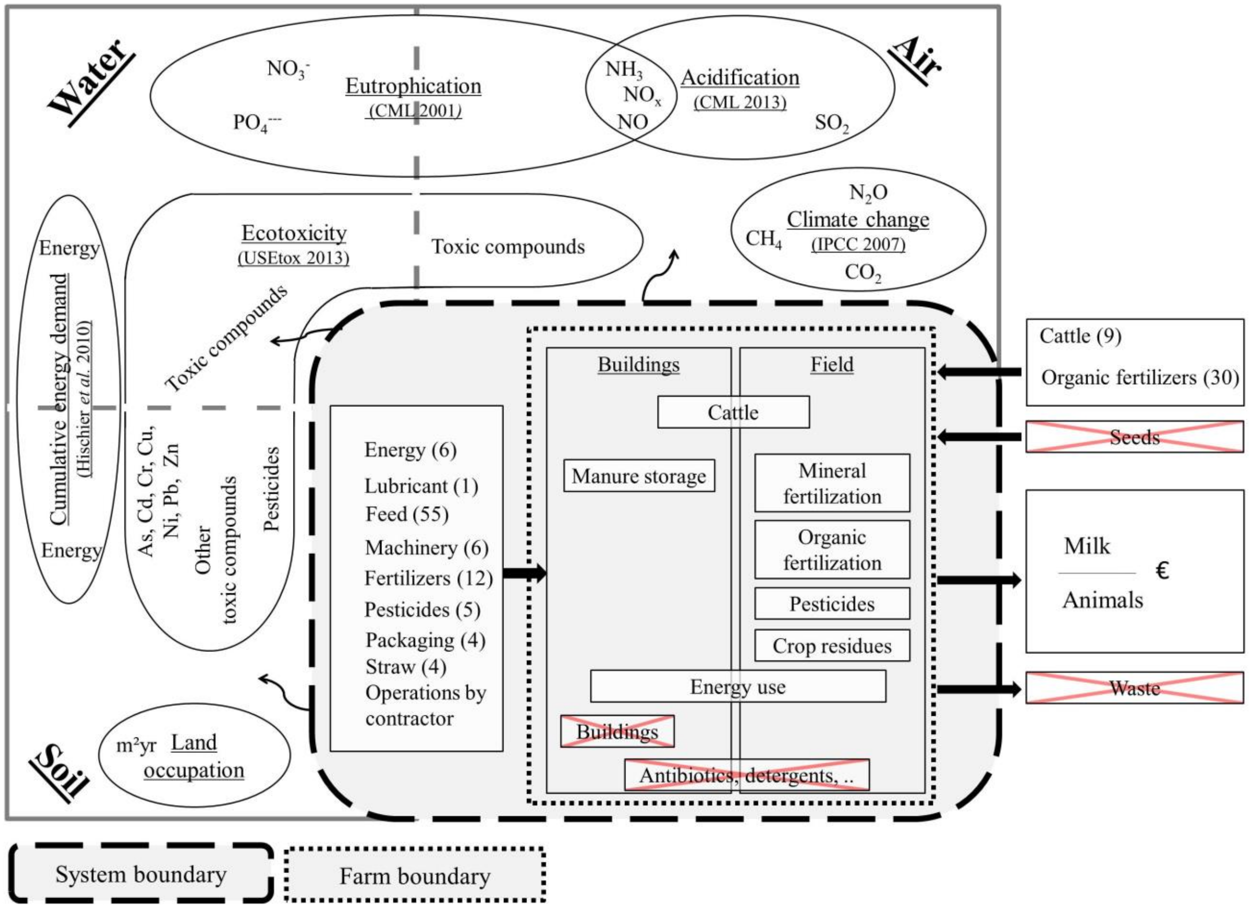

Figure 1. System description, impact categories and related damaging compounds and resources considered. Numbers in parentheses indicate the number of items considered in the inventory after aggregation (e.g., 63 machinery alternatives recorded on farms were aggregated into 6 groups).

2.2. Uncertainty calculation

Uncertainty analysis was performed with Monte-Carlo simulations and sensitivity analysis using three types of distribution: triangular, lognormal (with geometric mean) and normal (Weidema et al., 2013). Input variables supplied by farmer (Table 1) were excluded while model variables (e.g. mean cattle weight, N_2O emission factors, manure composition, feed N concentration) were varied in the uncertainty analysis. For each variable, a distribution was chosen based on characterization from available databases or literature data and a realistic range (e.g. nutrient concentration in slurry). When a variable's distribution was unknown, it was subjectively defined as normal with a coefficient of variation of 5% around the mean. Uncertainty in impact characterization factors was estimated only for ecotoxicity factors missing in USEtox (2013). Values for active ingredients used as plant protection products (PPPs) were considered to be lognormally distributed based on the geometric mean and standard deviation (SD) of the other PPPs in USEtox (2013) used. For some variables, Monte-Carlo simulation with not-well-characterized uncertainty parameters, as found in the literature, may lead to unrealistic variable values. For example, for dry matter content in certain manures, uncertainty parameters were arithmetic means and SDs, suggesting a normal distribution of the content. However, during Monte-Carlo simulation, it was possible to obtain negative values. If that occurred, the distribution was not changed; instead, the simulation was looped to consider only realistic minimum and maximum values. Monte-Carlo simulation was iterated 1000 times. A sensitivity analysis was also performed to investigate influence of variables with default uncertainty parameters and to identify major influencing variables. This operation consisted of recording changes in all impacts associated with a change in a single variable equal to the 75th percentile of its distribution. Two results were recorded: relative change in the impact, calculated as $Var=(Y_{0.75}-Y_{0,5})/Y_{0,5}$, and relative change in the impact divided by relative change in the variable, $Sen=Var/((X_{0.75}-X_{0,5})/X_{0,5})$, where Y is the impact value and X is the variable value. Indices indicate the percentile in the distribution corresponding to the value used.

Var indicates the proportion of change in the impact according to the change in the variable at its 75th-percentile value. It allows ranking variables according to their influence on results but relies strongly on the uncertainty parameters chosen for a given variable; therefore, it is not completely suitable for variables with default uncertainty parameters. Indeed, for these variables, strong underestimation or overestimation can be suspected. Sen indicates the relative sensitivity of the impact to the change in the variable. It is useful for identifying variables with default parameters whose precision has to be increased due to their potentially large influence on impacts.

Table 1: Input variables not considered in the uncertainty analysis.

Domain	Input variable
Cattle management	Head of cattle (in, out, losses, change in stock); milk production, consumption of veal, protein and fat concentrations; proportion of pregnant cows; lactation and non-lactation duration; distribution of calving period; grazing duration; diet composition
Crop management	Surface areas; amount and type of mineral and organic fertilizations; plant protection product amount and type used
Manure management	Amount produced and exchanged (in and out); type; treatment; application system
Revenue	From milk, from meat, from crops
Input	Amount of feed, straw, fertilizers, plant protection products, energy, plastics
Machinery	Type; amount and use
Operations by contractors	Type; amount

2.3. The case study

One of the farms analyzed by Mathot et al. (2014) was chosen as case study because of the supposed reliability of its input variables. This farm contained 77 dairy cows, for a total dairy herd of 168 head of cattle. Usable agricultural area was 67.4 ha, with 80% covered by grasslands, 12% by silage maize and 7% by other crops. Total milk produced in the year investigated, 2012, was 669.5 10^3 liters of milk, with a mean concentration of 42.4 g of fat and 33.5 g of protein per kg of milk produced. Inputs through feed and fertilization were 63.7 g N/m² and 1.43 g P/m². Of total revenue, 93.7% came from milk, and 6.3% came from meat.

3. Results

3.1. Distribution

According to the Shapiro normality test (R Development Core Team 2011) only the predicted values for CED were normally distributed. Per kg of fat-and-protein-corrected milk (FPCM) produced, impacts (95% confidence intervals) were 6.2-10.4 g PO_4eq, 10.1-25.6 g SO_2eq, 1.1-1.9 kg CO_2eq, -7.6-19.2 CTUe, 4.3-4.9 MJ and 1.11-1.28 m²yr for eutrophication, acidification, climate change, ecotoxicity, cumulative energy demand (CED) and land occupation respectively. Impact means (and CV) were, respectively, 8.2 g PO_4eq (13%), 16.3 (25%) g SO_2eq, 1.4 (14%) kg CO_2eq, 10.0 (2097%) CTUe, 4.6 (3%) MJ and 1.2 m²yr (3%) (Fig. 2).

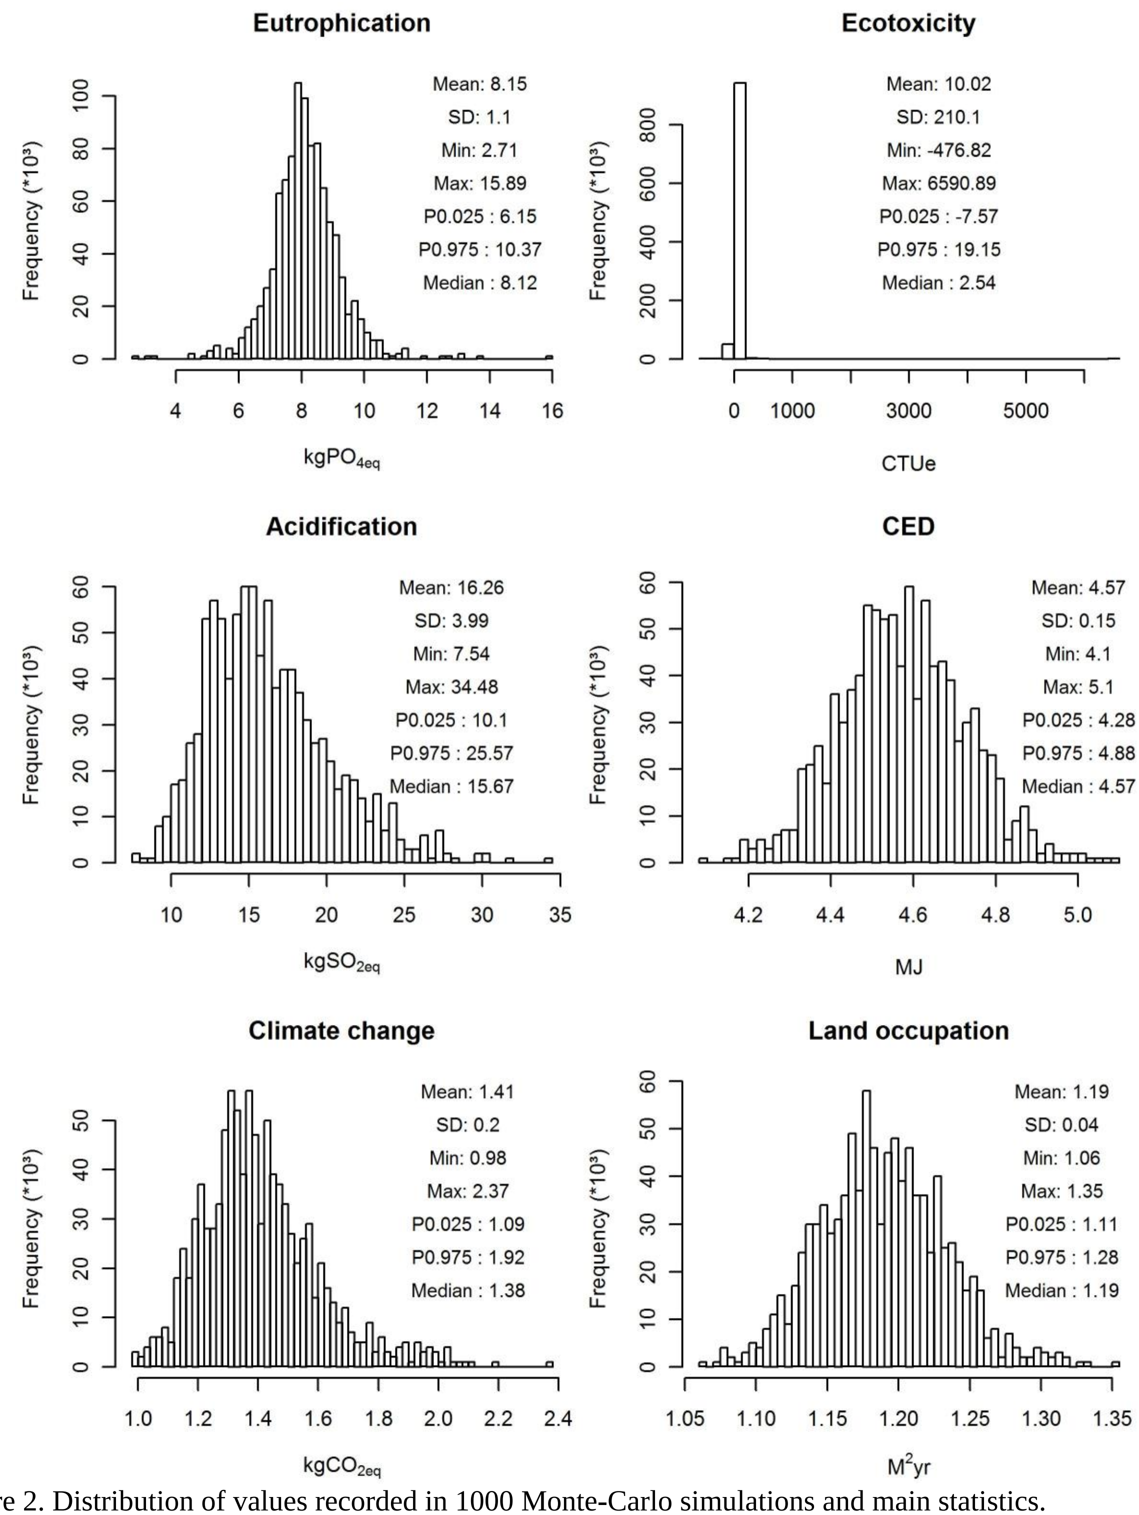

Figure 2. Distribution of values recorded in 1000 Monte-Carlo simulations and main statistics.

3.2. Variation and sensitivity

In total, 1084 variables influenced the results, all impact categories included. For 85% of the variables, the uncertainty in parameters was taken from literature, calculated or estimated. For the remaining 15%, uncertainty parameters were default values.

Table 2. Number (n) of variables influencing environmental impacts. The variable n indicates the number of variables influencing Var and Sen at more than |±1%| and |±10%|, respectively. Min and max are the values of the minimum and maximum influences observed. Moy<0 and Moy>0 are the means of negative and positive influences, respectively.

		Var						Sen

Table 3. Classification (number) of variables influencing the impacts more than |±1%| for Var and more than |±10%| for Sen. "Default parameters" is the number of variables using default parameters

	Eutrophication		Acidification		Climate change		Ecotoxicity		CED		Land occupation	
Variable	Var	Sen	Var	Sen	Var	Sen	Var	Sen	Var	Sen	Var	Sen
Feed and manure composition	0	0	4	11	2	5	1	0	0	0	0	0
Other input characteristics	1	1	0	0	0	0	3	0	0	4	0	0
Output characteristics	0	0	0	0	0	0	3	0	0	0	0	0
Fat-and-protein-corrected milk	1	3	1	3	1	3	1	3	1	3	1	3
Animal diet requirement	0	2	7	17	5	12	0	0	0	0	0	0
Emission factor	2	0	4	1	4	2	1	3	0	0	0	0
Other modeling	0	2	0	1	0	1	0	0	0	0	0	0
Conversion factor	0	4	2	4	2	6	0	1	0	2	0	1
Default parameters	1	8	14	33	10	26	1	3	1	3	1	3

3.2.1. Relative changes in impacts

CED and land occupation were influenced by relatively few variables (<60) while others were influenced by many more (141-341; Table 2). Eutrophication, acidification, climate change and ecotoxicity were subject to larger changes (greater than |±2%|) from the most influential variables than CED or land occupation (less than |±2%|). Regardless of the impact category, less than 10% of the variables changed the impact more than |±1%|.

3.2.2. Relative sensitivity of impacts

Climate change and acidification impacts were highly sensitive to certain variables. For more than 10 variables, the sensitivity was higher than |±10%|. Furthermore, these two impacts were highly sensitive to some variables (>|±100%|).

3.2.3. Influential variables

The most influential variables (>|±1%| for Var and |>±10%| for Sen) were identified and classified in 8 categories: Feed and manure composition; Other input characteristics (e.g. fuel CO_2 emissions on combustion); Output characteristics (e.g. protein content in animal live weight sold); FCPM (equation for calculation of functional unit); Animal diet requirement (model for estimation of cattle requirement and manure production), Emission factors (e.g.: N_2O emission from fertilization applied to soil); Other modeling (e.g., estimation of N fixation by plants) and Conversion factors (e.g., protein:N ratio of milk). For Var and Sen, the numbers of major (>|±1%| for Var and |±10%| for Sen) influencing variables were 4 and 12 for eutrophication, 18 and 37 for acidification, 14 and 29 for climate change, 9 and 7 for ecotoxicity, 1 and 9 for CED and 1 and 4 for land occupation, respectively (Tables 2 and 3). Among them, 1 and 8 for eutrophication, 14 and 33 for acidification, 10 and 35 for climate change, 1 and 3 for ecotoxicity, 1 and 3 for CED and 1 and 3 for land occupation were characterized with default parameters for Var and Sen, respectively. As expected, for all impact categories, conversion of milk production to FPCM influences the results, with the standardization of milk fat content as main contributor. Typically, results are sensitive to conversion factors but do not vary much because of them due to their low uncertainties, except for dry-matter-to-energy conversion and protein-to-N conversion, for which default parameters of distribution were attributed. Feed and manure composition and animal diet requirement variables influenced acidification and climate change impacts, while eutrophication impact was mainly influenced by emission factors in the model of N fixation by legumes. Ecotoxicity and CED were mainly influenced by other input characteristics and emission factors.

4. Discussion

Uncertainties in multiple environmental impacts of milk production were explored by considering mainly inventory model variables. Uncertainties, expressed as coefficients of variation, ranged from 3-2097% as a function of the impact category. The most influential variables changed with the impact category, except those used to calculate the functional unit. For this calculation, the most influential variable was milk fat content, which implies that accurate knowledge of milk fat content is necessary. Acidification and climate change impacts were influenced by many variables related to cattle requirements and feed composition. This reflects the impact of using IPCC and EMEP models, which consider the causal chain from feed ingestion to manure application and its input data through diet characteristics (digestible energy and protein content). When using these models, it is important to have good knowledge of diet composition. The influence of emission factors emphasizes the effect of a few generic values (e.g. N_2O emissions from soils). CED and ecotoxicity impacts were calculated with balance models; consequently, they were mainly influenced by input-output characteristics or emission factors attributed to input production. This is also partially the case for eutrophication, which is based on balance equations for some compounds, such as on-farm nitrate emission, but also on emission models, such as on-farm phosphate emission.

In this study, the influence of uncertainty in input variables was not included but would certainly add large uncertainty to the results. This work highlights the influence that different variables have on different impact categories, showing that impact can be sensitive to variables whose uncertainty is high or not well characterized. The procedure used to calculate uncertainty has some limits, however, such as not taking into account covariance between the variables of the same model. A global model approach would be interesting to improve the understanding of uncertainty. In the future, uncertainty related to the complexity of estimating emissions of damaging compounds should also be considered using model comparison and validation. Ultimately, performing Monte-Carlo simulations, as in this study, may help identify errors in implementation of models in calculation tools.

5. Conclusion

This approach helps to bound uncertainties related to model variables, which can be quite high, in environmental impacts of milk production. In the future, the identification of the most influential variables in emission models should help in decreasing uncertainties by improvement of their accuracy. Finally research is required to investigate influence of input variables.

Why Practice Life Cycle Management? Case Study of the New Zealand Wine Industry

Sarah J. McLaren[1,2,*], Elena Garnevska[1]

[1] Massey University, Palmerston North, NZ

ABSTRACT

The NZ wine sector is one of the most active NZ agribusiness sectors in terms of environmental sustainability initiatives and yet individual wineries vary widely in their commitment to environmental sustainability. The aim of this exploratory research, therefore, was to analyse why NZ wineries respond to the environmental sustainability agenda and to the Life Cycle Management (LCM) dimensions of this agenda. The results of this study indicate that adoption of a life cycle perspective in a certification programme is not a "selling point" for companies considering certification; however, the life cycle approach can lead to identification of new insights and related initiatives. Those advocating for adoption of LCM may wish to highlight these benefits as opposed to – or in addition to – expounding a narrative around expanded environmental responsibility along the supply chain.

Keywords: Life Cycle Management, New Zealand wine industry, environmental certification

1. Introduction

Environmental sustainability is increasingly relevant in the marketplace, and can provide a point of competitive advantage for companies that differentiate themselves on the basis of environmental credentials. However, there are marked differences between companies (as well as between economic sectors) in integration of environmental aspects into business activities.

New Zealand is a fast growing competitor on the New World wine map, and the New Zealand wine industry has recorded a strong expansion in both wine production and exports in the last decade (NZ Winegrowers 2013). The NZ wine sector is one of the most active NZ agribusiness sectors in terms of environmental sustainability initiatives and yet individual wineries vary widely in their commitment to environmental sustainability. The aim of this explorative research, therefore, was to analyse how and why (some) NZ wineries respond to the environmental sustainability agenda and to the Life Cycle Management dimensions of this agenda.

A prototype conceptual framework identifying the potential key factors explaining the attitudes and activities of companies regarding environmental sustainability was used to guide the research (see Section 2). Based on this framework, face-to-face interviews were undertaken with a small sample of NZ wineries (see Section 3). The results were then analysed against the framework (Section 4), and discussed in relation to the application of Life Cycle Management (Section 5).

2. Conceptual Framework

The need to explore linkages between business culture and sustainability is encouraging companies to reconsider their operations and strategies (Hall and Howe 2012).

Business culture is concerned with how involved parties (manufacturers, distributors, suppliers and retailers, government and shareholders) conduct their business (Bhaskaran and Sukumaran 2007; LaBahn and Harich 1997). Business culture is affected by many different external and internal factors including: social culture factors (religion, education, beliefs and attitudes, etc.); political, economic and technological factors; trade environment and globalisation; and business factors (size, ownership, management, etc.). The relationship between business culture and social culture, dynamic external factors, and business factors has been studied by a number of authors (e.g. Hofstede 1994; Wallace et al. 1999; Fang 2003; Fletcher and Fang 2006; Singh 2007). However, limited research has been undertaken on how business culture, shaped by different external (national and industry bodies, market and economic environment) and internal factors (company structure, management and marketing) affect a company's commitment to environmental sustainability (Packalen 2010). A prototype conceptual framework describing this relationship is shown diagrammatically in Figure 1.

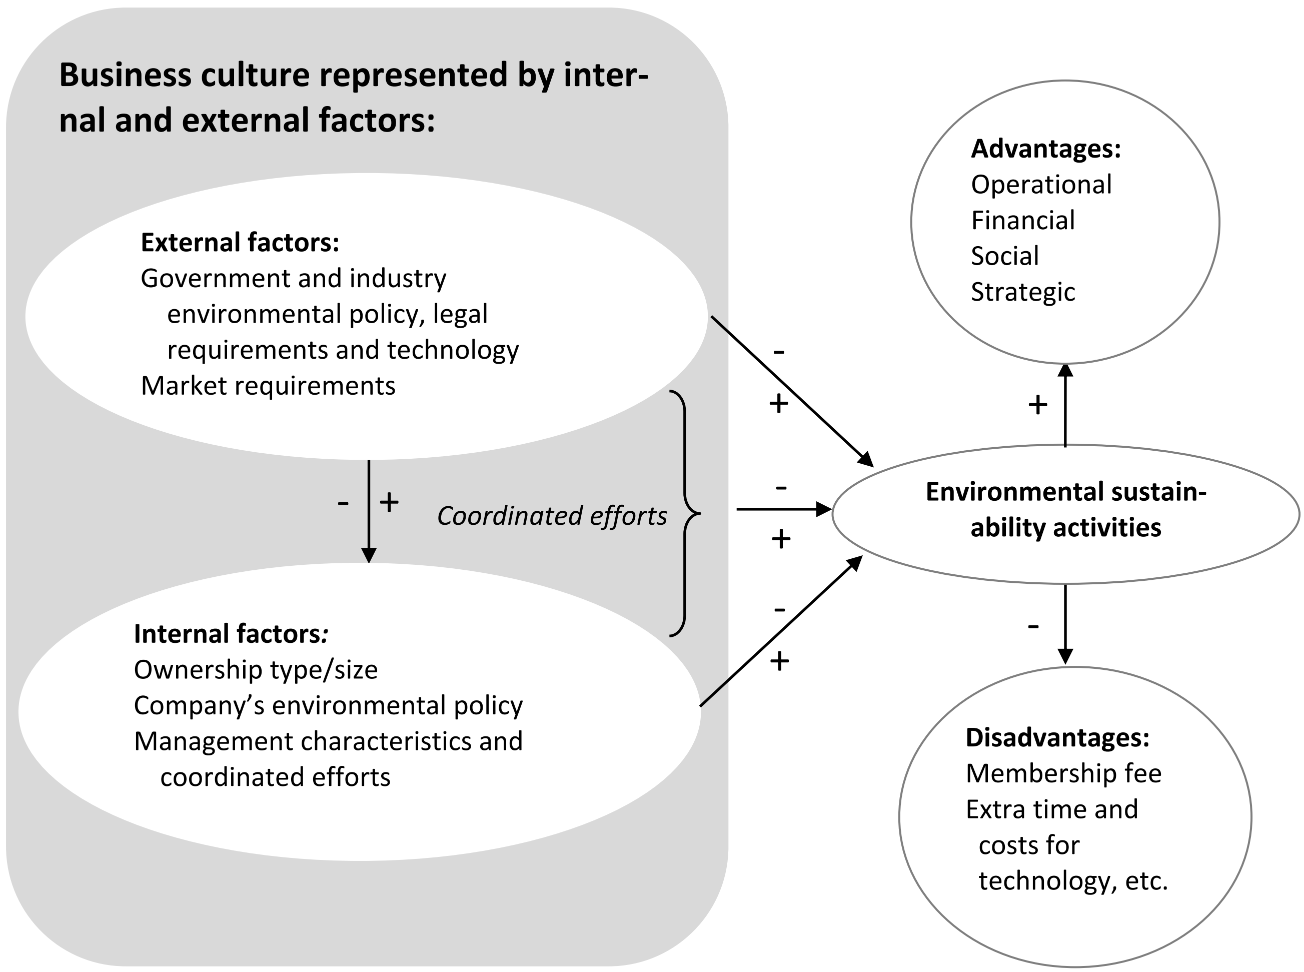

Figure 1. Conceptual framework describing relationships between business culture and environmental sustainability activities in companies.

In this study, environmental sustainability refers to the impacts of a company's activities on the natural (or modified natural) environment and to how these are managed. The environmental sustainability agenda comprises the issues that are considered relevant for management such as encouraging biodiversity, reducing greenhouse gas (GHG) emissions, and decreasing use of synthetic pesticides. This exploratory research analysed the influence of a number of specific external and internal factors/determinants on pro-active operations, management and strategies for environmental sustainability in NZ wine sector.

3. Methods

A qualitative methodology was employed in this study using semi-structured interviews. Ten New Zealand wineries were included in the study using snowball sampling. The interviewees were either the general/environmental managers or the owners of the wineries. All of the wineries included in this research had adopted some type of environmental sustainability certification. Seven wineries were members of the Sustainable Winegrowing New Zealand (SWNZ) programme, four had carboNZero/CEMARS certification, and three had organic BioGro certification. All interviews used open-ended questions and were recorded.

Qualitative data analysis was used for this research including the iterative process of describing, classifying and connection. Ethics issues were a high concern in this research relating to the participants' privacy and confidentiality.

4. Results

4.1. Summary of the NZ environmental sustainability programmes

Three key environmental sustainability certification programmes were used by the NZ wineries: Sustainable Winegrowing New Zealand (SWNZ), carboNZero (or CEMARS), and BioGro (organic certification scheme). In addition, one winery had ISO14001 certification and another one had had this certification in the past, and one winery had the UK's Carbon Trust's Carbon Footprint Label. Only the carboNZero and the Carbon Trust Carbon Footprint Label programmes use a Life Cycle Assessment (LCA) based approach i.e. they assess the greenhouse gas emissions associated with products along their full life cycles from extraction of raw materials, through manufacture, distribution, use and on to final waste management.

SWNZ (Sustainable Winegrowing New Zealand) was established in 1995 as an industry initiative, and was adopted by growers from all the grape growing regions in 1997. The SWNZ programme provides a framework for viticultural and winemaking practices. The seven focus areas in the SWNZ programme are: biodiversity; soil, water and air; energy; chemicals; byproducts; people; and business practices. Certified companies submit a report every year and are independently audited at least once every three years. Certified companies may put the logo on their products.

Established in 2001, **carboNZero** is an internationally accredited greenhouse gas certification programme. There are five key steps to attaining certification through the carboNZero programme: measure, manage, mitigate, verify, and market. The carboNZero programme may certify organisations, products, services, events, or individuals – and the carboNZero logo may be used on certified company websites, products and other publicity. Companies produce an annual report disclosing their greenhouse gas emissions and activities taken to reduce their carbon footprint, and are regularly audited by an independent auditor. CEMARS (Certified Emissions Measurement And Reduction Scheme) certification is an alternative certification option for organisations, also offered by the carboNZero programme, which focuses on the measurement and manage steps of the carboNZero programme.

BioGro is a New Zealand-based organic certification system that certifies producers, food processors, distributors and others to organic standards. Certified organisations are independently audited every year, and certified companies may put the BioGro logo on their products. The three organic wineries studied in this research also practiced biodynamic production techniques but had not opted for biodynamic certification.

4.2. External factors influencing environmental sustainability initiatives

Analysing the activities of the wineries against the external factors summarized in the conceptual framework (see Section 2), it was clear that "government and industry group environmental policy, legal requirements and technology" was a key driver for environmental sustainability activities for most of the wineries studied. In particular, in 2007 NZ Winegrowers launched its Sustainability Policy which stipulated that wines from vintage 2010 on must have been produced under one of a small number of recognised, independently audited, sustainability programmes in order to be included in NZ Winegrowers' national and international marketing, promotional and awards events. Effectively this meant that almost all NZ wine producers moved to achieve either SWNZ certification or organic/biodynamic certification by the end of 2012 (NZ Winegrowers, 2014a, 2014b).

Regarding market requirements, the interviewees did not identify any specific environmental requirements being demanded by their customers. At its most pronounced, the interviewees described "picking up signals" in their markets. For example, one interviewee said, *"Every time I went and did a wine tasting overseas, I'd always be asked how many sprays we use, do we use sprays in the vineyard ... So that was one reason for us to look more closely at what we were doing."* It also seemed that the economic environment (vis a vis the global economic crisis) had not made a significant difference to the way the wineries operated in their international markets with respect to responding (or not) to any change in demand for environmental sustainability credentials. However, a couple of the interviewees did mention that the international popularisation of the Food Miles concept in 2006/7 (see McLaren 2009) had created pressure for them to respond to that issue.

4.3. Internal factors influencing environmental sustainability initiatives

With respect to internal factors summarised in the conceptual framework, the type of ownership and/or size was not correlated with environmental sustainability activities: proactive environmental management was just as likely to be practised by a family-owned winery as by a business partnership, and by the smallest as by the biggest wineries. The existence of a company environmental policy/vision also appeared to be uncorrelated with environmental sustainability activities; in fact, only one of the wineries appeared to have formal procedures in place for monitoring and directing environmental sustainability performance (as far as this could be distinguished from the specific requirements of any of the certification programmes). On the other hand, "management characteristics and coordinated efforts" seemed to be important in determining the direction and scale of environmental sustainability activities. Particularly where a company had been founded by one or more current owner-managers, the environmental sustainability activities reflected their own beliefs; for example, one interviewee explained*, "The reason we had a lot of successes in that," referring to sustainability activities, "is because [X, the company founder] introduced it from before the winery was built."*

Regarding coordination amongst staff, differing perspectives were apparent. Some managers expressed frustration that staff did not spontaneously support environmental initiatives; for example, one remarked*, "... until you get your own vineyard managers and workers mindset into what they see, it is very hard for me to push it. And just say, right go and do this. Because you've got to have them on board as well."* However, in another winery many of the environmental initiatives were initiated, trialled and developed by staff throughout the company; the interviewee explained the context for this buy-in to environmental sustainability from staff:

> *"So, we are not a company that's been going for ten years and saying, "OK guys, from tomorrow we are going to have a sustainability focus," because everyone would think, "Oh yeah, that's another management thing they've come up with, it'll last a month and then be back to normal". So, whoever comes on board here know that that's part of what [X] is about. It's not that hard to keep that enthusiasm culture going, because that's just what we are."*

One interviewee identified the age of staff as a significant factor:

> *"I think it is the older people like me that have to think about it and think why are we doing this, or this is a waste of time separating all these out or doing this – and have to be convinced. I think the younger generation are much more inclined to just take it on just as part of what they are doing and they are the ones probably that come to us with more ideas about how we can change all the lights to energy saving lightbulbs or change the lights in rooms that we don't use very often so that they've got a sensor so that they come on and off as people come and go. But they are thinking about it just as a natural part of their life."*

4.4. Advantages of engaging in environmental sustainability initiatives

Turning to the perceived advantages and disadvantages of environmental sustainability activities, for most of the wineries the perceived advantages could be summarised as operational and strategic rather than financial or social. The biggest perceived advantage of environmental sustainability activities seemed to be the proactive strategic positioning of the company as indicated by this quote:

> *"If you were an importer and you were choosing between two or three different wineries, and the products were relatively the same, and the price was relatively the same, and someone was carbon neutral and if you had the option to put that on your brand, it is another thing that would lead them to maybe choose us ...*"

Regarding operational advantages, the main benefits expressed were related to the certification programmes and the need to regularly examine one's own processes as part of certification procedure (whether it was SWNZ, carboNZero or BioGro). As one interviewee remarked, *"It's a good way of especially, well in both the vineyard and the winery, of just keeping people accountable for what they do, making sure that record keeping is accurate and timely."* At another winery, the interviewee commented about the company's involvement in the carboNZero programme, "*Once we got all this measurement criteria, that helps us identify what projects we want to look at ... A lot of our projects we put in, to address the information we get from being part of carboNZero."*

Regarding financial benefits, the interviewees did not consider that they had received any price premiums for their wine products as a result of their activities. Furthermore, although the various certification processes had identified opportunities for more efficient energy use, freighting, etc., the cost savings were considered to be outweighed by the costs of the measurement and certification processes. Only three of the wineries were able to identify contracts where their environmental sustainability credentials had been a factor in winning the contracts; two of these wineries were only able to identify one contract each whilst the third winery (which was extremely proactive in publicising its sustainability credentials) considered that it was a (minor) factor in securing several contracts.

There was relatively little evidence of social advantages associated with environmental sustainability activities. Indeed, one interviewee mentioned how one member of staff complained about *"spending too much time and money on the gardens."* However, two interviewees did make the link between environmental initiatives and benefits for staff; as one said, "*I think it is good for the staff because if you can show them the benefits of it and get them behind it, it certainly makes a better work environment*."

For the organic wineries, the advantages of organic production concerned first and foremost the quality of the wine. As one interviewee responded when asked why their winery used organic practices, *"Because it improves the quality overall of the wine ... I know the quality is better …You can see the difference. If we couldn't see an improvement we wouldn't do it, we would go and do something else that gave us better quality. It is only done for quality reasons for us, it is not a marketing ploy."* For these wineries, organic or biodynamic production methods did not comprise a set of optional activities but were fundamental to the *raison d'être* of the wineries. Therefore a discussion about the advantages versus disadvantages of engaging in such activities was considered irrelevant.

4.5. Disadvantages of engaging in environmental sustainability initiatives

The interviewees did not identify any major disadvantages associated with engaging in environmental sustainability initiatives apart from the financial costs associated with the certification processes (charges for auditing, etc.) and staff time required to prepare certification documents. This is perhaps not surprising for the wineries certified to carboNZero given that they voluntarily chose to engage in that certification programme. However, for the SWNZ certification which is effectively compulsory (unless another approved scheme was chosen instead), several interviewees expressed the view that it was too easy *and "people looked at it and said you are not really telling me anything I don't know."* For both the carboNZero and SWNZ certification programmes, the interviewees considered that there should be more benchmarking so that they could identify how they were doing relative to the other wineries, and that the certification programmes should undertake more marketing to raise their profiles. The interviewees at the organic wineries certified to BioGro expressed frustration at the narrow focus of the carboNZero certification programme (i.e. the focus on carbon footprinting as opposed to a range of environmental impacts) and the lack of stretch in the SWNZ programme (i.e. they felt that the SWNZ programme could be more proactive in requiring wineries to demonstrate environmental improvements).

4.6. Interpretation from a Life Cycle Management perspective

Life Cycle Management (LCM) is a specific type of environmental management that focuses on managing the environmental impacts associated with products and services along their life cycles from extraction of raw materials, through manufacture, distribution, use and on to final waste management (Remmen et al., 2007). For wine products, obviously this includes managing the environmental impacts related to vineyard and winery activities as well as those associated with the upstream manufacture and delivery of inputs, and the downstream distribution and consumption of wine. The results in Sections 4.1 to 4.5 are therefore relevant to a discussion on uptake of LCM. However, in addition, it is worthwhile to consider evidence of, and attitudes to, activities that are particularly indicative of uptake of LCM. In this research, these activities were classified into three areas: (a) prioritisation of activities according to the magnitude of environmental impacts at different points in the cradle-to-grave life cycle of products and/or services; (b) vertical coordination with supply chain partners both upstream and downstream along the supply chain regarding environmental sustainability initiatives; and (c) changes to processes in order to close the loop for material and waste life cycles and to displace environmental impacts occurring at different life cycle stages.

Regarding (a), prioritisation of activities from a life cycle perspective, several Life Cycle Assessment (LCA) studies of wine have shown that the glass bottle makes one of, if not the, biggest contribution to a range of environmental impacts due to the energy-intensive glass manufacturing process and the weight of the packaging which must be transported from the glass bottle manufacturer to the winery and then on to markets (e.g. Amienyo et al. 2014; Barry 2011). Typical improvement activities include lightweighting of glass bottles, bulk shipment of wine prior to bottling, and use of alternative materials for wine containers (see, for example, Amienyo et al. 2014; Point et al. 2012; WRAP, 2007). All but one of the non-organic wineries mentioned lightweighting of their glass bottles as an environmental sustainability activity; however, this activity was not mentioned by any of the organic wineries. Only one winery had actually started to use plastic rather than glass bottles.

Other environmental hotspots are commonly identified at the vineyard production stage of the life cycle: toxicity impacts related to use of pesticides, and sometimes eutrophication and acidification impacts related to use of fertilisers (e.g. Barry 2011, p.20-21; Point et al. 2012). Activities in the vineyard that addressed these impacts were commonly mentioned in the interviews (e.g. planting wild flowers between vine rows, reducing use of pesticides). However, these actions focused on improvements and innovations within a single life cycle stage and therefore they did not constitute evidence of adoption of a life cycle perspective.

Regarding (b), vertical coordination along the supply chain, several interviewees mentioned discussions with suppliers about environmental initiatives, and in particular the glass bottle manufacturer regarding lightweighting of bottles. Regarding (c), closing the loop and displacing environmental impacts at different life cycle stages, this type of thinking was evident in the composting activities practised by all the wineries where waste organic matter from the winery was composted and applied out in the vineyards. However, only one winery had innovated to close the loop for other material and energy life cycles; at this winery, vine prunings were burned to generate heat that displaced use of liquid petroleum gas (LPG) in the winery, and a pilot project was underway to produce biochar from the vine prunings for application to the vineyard soils. In addition, this winery had also focused on displacing environmental impacts arising at different life cycle stages by, for example, installing wind turbines and solar panels, and grazing sheep in the vineyards (to displace the use of diesel for mowing).

5. Discussion and Conclusion

Perhaps the first point to note is that the organic wineries had a quite different motivation for engaging in environmental sustainability activities (assuming that organic practices are recognized as a subset of environmental sustainability practices). For them, it was necessary to be organic in order to produce wine of high quality. However, for the non-organic wineries, the key factors explaining their attitudes and activities regarding environmental sustainability were independent of the quality of the wine except in so far as quality was expressed through the brand story. One interviewee even hinted at a more definite distinction between organic and sustainable practices, saying, *"We are not organic. I think our main push is the sustainable thing."*

For the non-organic wineries, the factors that explained their attitudes and activities could be summarised as: a belief that environmental responsibility was "part of the story" about their products, that it would lead to more efficient business operations, and also that it placed them ahead of the competition in terms of environmental responsibility. For these wineries, they did not consider that they could achieve a price premium for demonstrating their environmental credentials; as one interviewee said, *"… for us it is a nice to have. It is part of what we do and we are not charging any more."*

Regarding enablers and barriers explaining adoption of environmental sustainability activities, external factors seemed to have a limited role apart from the industry sector requirement to be a member of SWNZ or another approved environmental certification programme. There was little evidence of demand for demonstration of environmental credentials in the marketplace, and instead the wineries regarded environmental sustainability initiatives as just a part of their brand story, and often not a particularly important part of that story. As one said *"No, it is not a strong part of our brand story at all."* However, it should be acknowledged the relative importance attached to this aspect did vary between the wineries. Only one internal factor appeared to be significant: the management characteristics and coordinated efforts.

Regarding the perceived advantages and disadvantages of engaging in environmental sustainability activities, the wineries considered that environmental sustainability activities enhanced their brand story, as noted above, and that the different certification schemes enabled them to "fine-tune" their operations. Some also considered that adoption of environmental sustainability activities created a better work environment for staff. The perceived disadvantages were related to the certification schemes rather than the environmental initiatives themselves; aspects that were mentioned included the costs of the schemes and the lack of awareness of the schemes amongst customers (which limited their usefulness as a marketing tool for the wineries).

Adoption of a life cycle perspective was evident in the decisions to undertake composting and to move to lightweight bottles; several of the wineries also mentioned discussions with suppliers regarding their environmental activities. However, only two of the wineries (which both had carboNZero certification) consciously articulated that they had taken a life cycle perspective in their environmental sustainability initiatives, and they both identified involvement in the carboNZero programme as a driver for new projects.

These results indicate that adoption of a life cycle perspective is not a “selling point” for companies considering environmental sustainability activities. Yet the life cycle approach can lead to identification of new insights and related initiatives with relatively significant environmental benefits in the life cycle of wine (such as a move to alternative packaging types). Such initiatives may assist the company in telling its brand story and attaining competitive advantage, being more efficient, and benefitting employees – factors that are recognised as advantageous by companies. Those advocating for adoption of Life Cycle Management may wish to highlight these benefits as opposed to – or in addition to – expounding a narrative around expanded environmental responsibility along the supply chain.

ABSTRACT

Simplified modeling of fertilizer N emissions in inventories of agricultural products may lead to considerable deviations of N emissions from actual N surpluses present in farming system. We compared impacts for global warming, eutrophication, and acidification of four crops either produced in organic or integrated (IP) production using ecoinvent inventories (v2.2). We remodeled N_2O, NO_3, and NH_3 emissions considering N input from fertilizers, N deposition, N fixation, management induced changes in the soil C-N-pool, and N withdrawal by yields. Global warming on a product basis of organic crops was up to 24% lower compared to IP after remodeling. Eutrophication of organic crops was comparable to IP crops and acidification initially up to 3.5 times higher in organic crops was only 1.9 times higher after remodeling. By taking total nitrogen turnover into account in the N modeling impacts of crops from different farming systems can be differentiated with higher accuracy.

Keywords: N emission modeling, fertilization, organic, conventional, total nitrogen turnover

1. Introduction

In the past 50 years agricultural intensification has led to a global increase in nitrogen fertilizer use by over 800%, which has led to a massive increase in food production (Foley et al., 2011). On a global scale food production and consumption contribute the highest share of reactive nitrogen compounds released to the environment (Leach *et al.*, 2012). This has environmental impacts on different levels: Nitrogen emissions contribute to global warming, eutrophication, acidification, and negatively impact biodiversity and human health (Galloway *et al.*, 2003). A more sustainable food production should therefore seek to reduce excessive fertilizer use and reduce nitrogen losses to the environment using a set of different strategies (Galloway *et al.*, 2008). One strategy often referred to in the scientific literature is the improvement of the N efficiency in animal and crop production (Galloway *et al.*, 2008; Foley *et al.*, 2011; Sutton *et al.*, 2011).

By prohibiting mineral nitrogen fertilization, organic agriculture is usually lower in its nitrogen intensity than conventional agriculture. In fact often in organic farming nitrogen is a yield limiting factor leading to lower N surpluses per ha. Analyses comparing N fluxes in different farming systems showed a higher N efficiency in organic crop rotations when taking into account the changes in soil organic nitrogen stocks (Küstermann *et al.*, 2010).

However, a recent review of comparative LCAs of organic and conventional products revealed often higher impacts for eutrophication, acidification and global warming for organic products (Meier *et al.*, 2014). A detailed analysis of several LCAs comparing organic with conventional products, though, showed that N emissions from fertilization as modelled in inventories may deviate considerably from the actual N-surplus present in the farming system. It was concluded that higher accuracy in N modeling would better differentiate between products from different farming systems.

A major problem in contemporary N emission modeling in LCA inventories of agricultural products seems to be that emissions models do not represent N emissions from organic fertilizers very well. This is particularly the case for soil born N_2O emissions and NO_3 leaching. Soil borne N_2O emissions from fertilizer input in LCA inventories are often modeled using the IPCC model (IPCC, 2006b), which estimates N_2O emissions based on the fertilizer N input only. By doing so the model considers the soil as black box not taking into account N fluxes in and out of the soil. However, especially for organic fertilizers where only a fraction of the total N is readily available for plants microbial processes within the soil are important for their mode of action (Gutser *et al.*, 2005) and in consequence determine their emission pattern. If high fractions of organic fertilizers are applied (as in organic farming were exclusively organic fertilizers are used) the amount of applied total ammoniacal nitrogen (TAN) is usually not enough to meet the crop plants' demand. The additional nitrogen needed for plant growth is supplied by readily available nitrogen mineralized from the soil C-N-pool. A simple N_2O emissions

model, which takes into account N mineralization from as well as N immobilization into the soil C-N-pool, has been proposed by Meier *et al.* (2012).
NO_3 leaching strongly depends on local climatic factors (rainfall), soil parameters and vegetation cover. Existing NO_3 emission models used in LCA inventories are usually too simplistic to cover the complex interactions between these factors. Accurate nitrate leaching requires the simulation of soil hydrological and biogeochemical processes (Li *et al.*, 2006). However, even with relatively complex models it is difficult to simulate nitrate dynamics accurate enough and a detailed parameterization is needed for satisfying results (Pedersen *et al.*, 2007). In part this is also due to the still poor understanding of the long-term fate of fertilizer-derived nitrogen in the plant-soil-water system (Sebilo *et al.*, 2013). Since NO_3 emissions from fertilization seem to be the most difficult ones to model an alternative solution is its calculation from the nitrogen balance by subtracting the modeled NH_3 and N_2O emissions from the N surplus. This in turn requires all N inputs and outputs such as fertilizer input, symbiotic N fixation, atmospheric N deposition, management induced changes in the soil C-N-pool and the N withdrawal by the yield. By doing so the law of mass conservation for N fertilization is satisfied, which is also the main requirement for calculating N use efficiencies (Godinot *et al.*, 2014).

The objectives of this study were to assess the chances in impact assessment for global warming, eutrophication, and acidification for four crops produced in different production systems when N emissions from fertilizers were remodeled on the inventory level using a N_2O model that also accounts for N turnover from the soil C-N-pool and adjusting NO_3 emissions to the actual N surplus.

2. Methods

In our analysis we considered the following ecoinvent v2.2 inventories for four different field crops representing Swiss organic and integrated (representing a less intensive conventional production) agricultural practices (Nemecek *et al.*, 2007):

- Wheat grains organic, at farm/CH
- Wheat grains IP, at farm/CH
- Barley grains organic, at farm/CH
- Barley grains IP, at farm/CH
- Soy beans organic, at farm/CH
- Soy beans IP, at farm/CH
- Potatoes organic, at farm/CH
- Potatoes IP, at farm/CH

Fertilizer based nitrogen inputs and fertilizer based N emissions as N_2O, NH_3, and NO_3 within the product related ecoinvent inventories were transformed to amounts of N input and N emissions per ha using the data in Nemecek *et al.* (2005) and Nemecek *et al.* (2007). In organic, slurry and solid manure were assumed to consist of cattle and pig slurry / solid manure respectively and in IP, of cattle slurry / solid manure respectively as described in Nemecek *et al.* (2005). Dilution of slurry was assumed as 1:1.5 (slurry : water) as in the ecoinvent processes. Based on the same fertilizer N inputs and crop yields assumed in the ecoinvent inventories we recalculated N_2O, NH_3, and NO_3 emissions from nitrogen fertilization as described in the following sections and changed these values in the original inventories.

2.1. NH_3 emissions

NH_3 emissions from slurry and solid manure were determined using an emission factor of 20% of applied total ammoniacal nitrogen (TAN). This factor was determined as the upper bound in a recent Swiss study measuring NH_3 emissions from slurry over cropland using improved analytical techniques (Sintermann *et al.*, 2011). TAN values assumed were 0.96 kg/m^3 of slurry and 1.32 kg/t of solid manure in the organic inventories and 0.92 kg/m^3 of slurry and 0.80 kg/t of solid manure in the IP inventories (Nemecek *et al.*, 2005). NH_3 emissions from urea were estimated as 15% and for all other mineral N-fertilizers as 2% from total applied nitrogen (Asman, 1992; ECETOC, 1994). These are the same emission factors as used in the original ecoinvent inventories (Nemecek *et al.*, 2007).

2.2. N_2O emissions

Soil borne N_2O emissions from nitrogen fertilization were estimated using the model by Meier *et al.* (2012), which was developed to better represent the mode of action of organic fertilizers by considering the N-flows in and out of the soil N pool using the IPCC emission factors (IPCC, 2006a). By considering the management induced N turnover processes in the soil the model also integrates nitrogen mineralized from or immobilized in the soil. Deviating from Meier *et al.* (2012) here the amount of management induced nitrogen mineralization from the soil organic N pool was determined by using the SOM-model by Brock *et al.* (2012), in particular by using Equation 1. In combination these models allow for a detailed calculation of the internal N flow based on the N inputs from fertilizers, N fixation, N deposition, and the management induced N turnover in the soil and on the N output by the yield.

$$SON_{MIM} = \frac{N_{PB} - N_{Fix} - N_{Dep} \times NUR_{NDep} - \sum_{i=1}^{n} N_{tot_{Fertilizer\ i}} \times NUR_{NFertilizer\ i}}{NUR_{SONMIM}} + \Delta N_{min} \qquad \text{Eq. 1}$$

SON_{MIM}	management induced nitrogen mineralization from the soil organic N pool [kg N];
N_{PB}	nitrogen in plant biomass [kg N];
N_{Fix}	nitrogen derived from the atmosphere by legumes via symbiotic fixation [kg N] (in case of the four crops analyzed only relevant for soy beans);
N_{Dep}	nitrogen from atmospheric deposition [kg N];
NUR_{NDep}	nitrogen utilization rate [%] of nitrogen from atmospheric deposition;
$NUR_{NFertilizer\ i}$	nitrogen utilization rate [%] of nitrogen from fertilizer i;
NUR_{SONMIM}	nitrogen utilization rate [%] of mineralized nitrogen from the soil;
ΔN_{min}	excessive nitrogen mineralization due to mechanical impact [kg N] (in case of the four crops analyzed only relevant for potatoes).

Equation 1 estimates the management induced N input from the C-N-pool by calculating the N balance between the amount of N built into plant biomass and the N input from fertilizers, atmospheric deposition, symbiotic N fixation, and excessive N mineralization due to intensive mechanical impact as it is the case in potato cultivation. The fact that only a fraction of the N coming from the various pools can be built into plant biomass is considered by pool specific nitrogen utilization rates (Equation 1).

Nitrogen in wheat biomass (straw and grains) was determined using data from a long term field trial comparing organic with conventional production (Gunst *et al.*, 2013). From this trial different N contents for organic wheat and wheat from integrated production were available. Nitrogen contents for the remaining three crops were taken from Flisch *et al.* (2009) not further differentiating between organic and conventional production.

For soy beans N_{Fix} was assumed to be 150 kg N/ha for integrated production and yield adjusted for organic resulting in 144 kg N/ha.

Atmospheric deposition was assumed to be 25 kg N/ha per year for all crops.

Values for the different nitrogen utilization rates and for the excessive nitrogen mineralization in the case of potatoes (50 kg N/ha for organic and IP) were taken from Brock *et al.* (2012). Since in the case of N from symbiotic fixation 100% of the nitrogen is built into plant the nitrogen utilization rate is 1.

Above and below ground residues were estimated on the basis of the formulas given in the IPCC Guidelines on N_2O emissions from managed soils (IPCC, 2006b).

2.3. NO_3 emissions

Emissions of NO_3 may occur from the nitrogen surplus during the cultivation period of a crop plant (NO_3-$N_{short\ term}$, see Equation 3) and after the cultivation period from the plant residues and excessive nitrogen from mineralization due to mechanical impact (NO_3-$N_{long\ term}$, see Equation 4). Total NO_3 emissions from the cultivation of a crop plant are obtained by Equation 2.

$$NO_3 - N_{tot} = NO_3 - N_{short\ term} + NO_3 - N_{long\ term} \quad \text{Eq. 2}$$

$$NO_3 - N_{short\ term} = \left(\sum_{i=1}^{n}\left(N_{tot_{Fertilizer\ i}} \times (1 - NUR_{NFertilizer\ i})\right) + (SON_{MIM} - \Delta N_{min}) \times (1 - NUR_{SONMIM}) + N_{Dep} \times (1 - NUR_{NDep})\right) - (NH_3 - N) - (N_2O_{direct} - N) \quad \text{Eq. 3}$$

$$NO_3 - N_{long\ term} = (N_{PR_{ag}} + N_{PR_{bg}} + \Delta N_{min}) \times Frac_{leach} \quad \text{Eq. 4}$$

NO_3-$N_{short\ term}$	amount of N [kg N] potentially being leached from the production of the crop plant;
NO_3-$N_{short\ term}$	amount of N [kg N] potentially being leached during the cultivation period of the crop plant;
NO_3-$N_{long\ term}$	amount of N [kg N] potentially being leached after the cultivation period of the crop plant by plant;
NH_3-N	ammonia N [kg N] determined as described in section 2.1;
N_2O_{direct}-N	N [kg N] from direct N_2O emissions determined as described in section 2.2.
N_{PRag}	amount of N [kg N] in above ground plant residues
N_{PRbg}	amount of N [kg N] in below ground plant residues
$Frac_{leach}$	fraction of N lost by leaching

We determined the amount of NO_3 leached during the cultivation period of the crop plant from the nitrogen surplus within the respective crop plant system as a proxy for potentially leached N using Equation 3. The nitrogen surplus is determined by the fractions of nitrogen not used by the crop plant from fertilizers, management induced soil-N mineralization (minus the amount of N from excessive mineralization due to mechanical impact (ΔN_{min})), and deposition. If the amount of nitrogen lost as NH_3 and N_2O is subtracted from the surplus, the nitrogen left is basically what can potentially be lost as NO_3. For the calculation of the amount of N potentially leaching from above and below ground plant residues and from N from excessive mineralization due to mechanical impact we used the IPCC (2006b) emission factor of 0.3 ($Frac_{leach}$).

2.4 Impact assessment

The remodeled N emissions per hectare from fertilizer applications were transformed to emission values per kg product again using the crop yields and allocation factors assumed in the ecoinvent inventories. Impacts of global warming, eutrophication and acidification were assessed for the former ecoinvent inventories as well as for the inventories with the remodeled N emissions from fertilizer applications. Impact assessment methods used were IPCC GWP 100a (IPCC, 2007) for global warming and EDIP2003 (Hauschild and Potting, 2003) for eutrophication (N only) and acidification. Relative differences between impacts of crops from organic and integrated production were calculated setting IP as the 100% basis.

3. Results

For all crops, irrespective of organic or IP production, the amount of N supplied by fertilizers was not sufficient to match the required N content in the plant biomass (Table 1). Thus, in most cases a substantial amount of N had to be supplied by the soil C-N-pool besides the inputs from fertilization, symbiotic fixation, and atmospheric deposition. Especially in the case of IP crops the amount of N mineralized from the soil C-N-pool seems fairly high. However, except for the harvested products all N in above and below ground biomass will be returned to the C-N-pool after harvest. The sum of the N inputs from fertilizers, fixation, deposition and soil C-N-pool always exceeded the N content in total plant biomass (Table 1) because – except for N from symbiotic fixation – never a 100% of the N from the inputs is built into plant biomass. Between 7% (soy beans) and 27% (barley) of the N from the inputs remained as surplus depending on the share of the different N input sources and their nitrogen utilization rates (see Eq. 1). Due to yield differences between the crops from organic production and IP the amount of N in plant biomass was 1.6 to 1.7 times lower in organic crops expect for soy beans where the N content in plant biomass was only 4% lower in organic soy bean which corresponded well with the yield gap of also 4%. For wheat, barley, and potatoes the amount of N mineralized from the soil C-N-pool to meet the plants N demand was approximately 4 to 12 times higher in IP production compared to organic. In contrast for the same crops amounts of N supplied by fertilizers were only 1.2 to 1.5 times higher in IP compared to organic (Table 1).

Table 1. N content in plant biomass vs. N inputs of the four crops analyzed.

	Wheat organic	**Wheat IP**	**Barley organic**	**Barley IP**	**Soy beans organic**	**Soy beans IP**	**Potatoes organic**	**Potatoes IP**
N content in plant biomass[1] [kg N/ha]	136	230	99	159	220	230	89	137
N input from fertilizers [kg N_{tot}/ha]	122	143	98	121	20	27	84	127
N input from fixation [kg N/ha]	0	0	0	0	144	150	0	0
N input from deposition [kg N/ha]	25	25	25	25	25	25	25	25
N mineralized from soil C-N-pool [kg N/ha] (without ΔN_{min})	35	134	13	69	49	48	2	23
N surplus [kg N/ha][2]	46	72	37	56	18	20	22	38

[2] N in plant biomass minus fertilizer N, minus N from fixation, minus N from deposition, minus N mineralized.
[3] N surplus minus NH_3-N, minus N_2O-N_{direct}, minus NO_3-$N_{short\ term}$.

The remodeled N emissions from fertilizer applications on a per ha basis showed the least differences for ‘Wheat IP’ (Table 2). In the case of ‘Barley IP’ NH_3 and N_2O emissions also differed only slightly whereas NO_3 emission were 1.6 times lower after remodeling. For ‘Potatoes IP’ NH_3 emissions were 2.3 times lower for the remodeled emissions whereas N_2O and NO_3 emissions changed only little after remodeling. Changes in the inventories of organic crops were generally higher than for the respective IP crops (Table 2).

Table 2. Fertilizer based N emissions per ha from the ecoinvent inventories and the remodeled values for the four crops analyzed.

	Wheat organic	**Wheat IP**	**Barley organic**	**Barley IP**	**Soy beans organic**	**Soy beans IP**	**Potatoes organic**	**Potatoes IP**
N emissions in ecoinvent inventories								
NH_3 [kg/ha]	33.93	9.06	29.22	9.63	3.45	5.70	15.71	18.31
N_2O [kg/ha]	4.93	6.07	4.69	4.29	6.96	7.34	3.40	4.07
NO_3 [kg/ha]	400.27	331.57	406.00	425.72	194.34	200.26	292.21	261.85
remodeled N emissions								
NH_3 [kg/ha]	13.41	7.79	10.78	6.99	1.41	2.55	5.03	7.80
N_2O [kg/ha]	2.93	4.47	2.24	3.41	1.40	1.55	2.10	3.12
NO_3 [kg/ha]	190.15	361.37	149.44	265.00	127.23	137.45	167.03	230.54

Comparing the crops from organic with the crops from IP production assessing the original ecoinvent inventories organic wheat and organic soy beans showed lower impacts for global warming (-9%, -12% respectively) than the respective crops from IP production (Figure 1). Impacts for global warming from organic barley and organic potatoes were higher (+17%, +16% respectively) than from IP crops. Impacts from eutrophication were higher for all organic crops (wheat: +108%; barley: +72%, potatoes: +39%) except for soy beans showing 26% lower impacts for eutrophication than IP soy beans. Impacts for acidification were manifold higher in organic cereals than in the respective cereals from IP production (wheat: +271%; barley: +241%). Also organic potatoes had higher impacts for acidification (+32%), whereas organic soy beans showed also lower impacts for acidification (-38%) than IP soy beans (Figure 1).

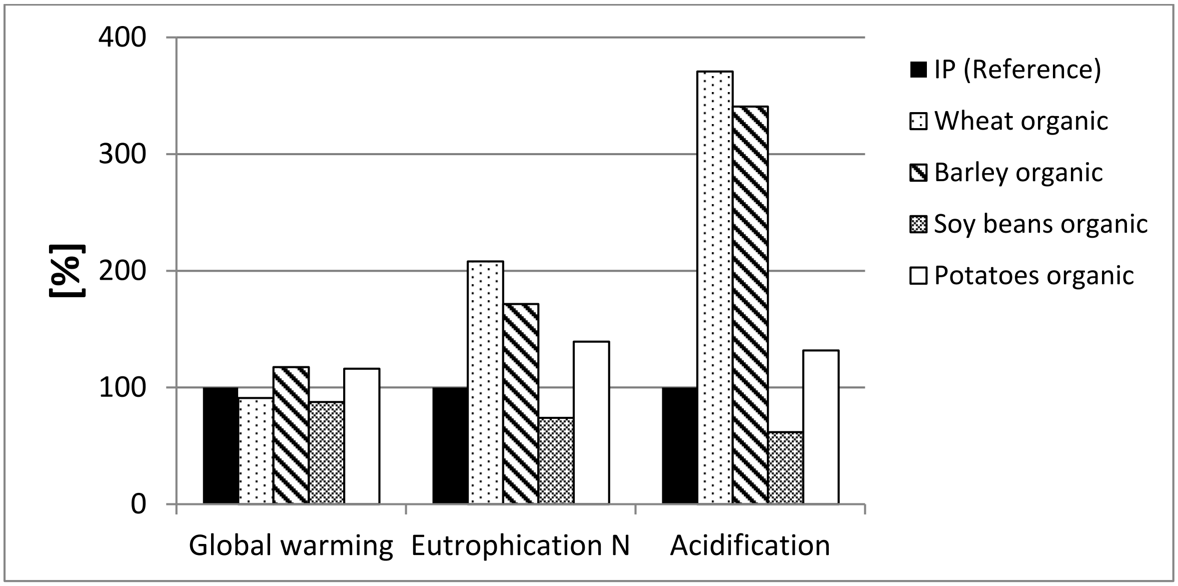

Figure 1. Relative differences between organic crops and the respective crops from IP production for global warming, eutrophication, and acidification per kg of grains, pulses and tubers respectively assessing the original ecoinvent inventories.

Comparing the four organic crops with their counterparts from IP production assessing the inventories with the remodeled N emissions from fertilizer applications all organic crops but potatoes showed lower impacts for global warming (wheat: -24%; barley: -17%; soy beans: -23%) (Figure 2). Impacts for global warming of organic potatoes were 8% higher than for the potatoes from IP production. Again impacts for eutrophication were lower (-40%) for organic soy beans. However, after remodeling N emissions, impacts for eutrophication of the other three organic crops were comparable to the impacts of the respective IP crops (wheat: -4%; barley: +6%; potatoes: +1%). Impacts for acidification of the organic cereals were still clearly higher than for the IP cereals (wheat: +89%; barley: +81%; Figure 2) but the difference became much smaller compared to the original ecoinvent inventories (Figure 1). Also the difference in the impacts for acidification of organic potatoes compared to IP potatoes became smaller in the remodeled inventory (+13%). Finally, impacts for acidification of organic soy beans were also lower (-40%) compared to IP soy beans in the inventory with the remodeled N emissions (Figure 2).

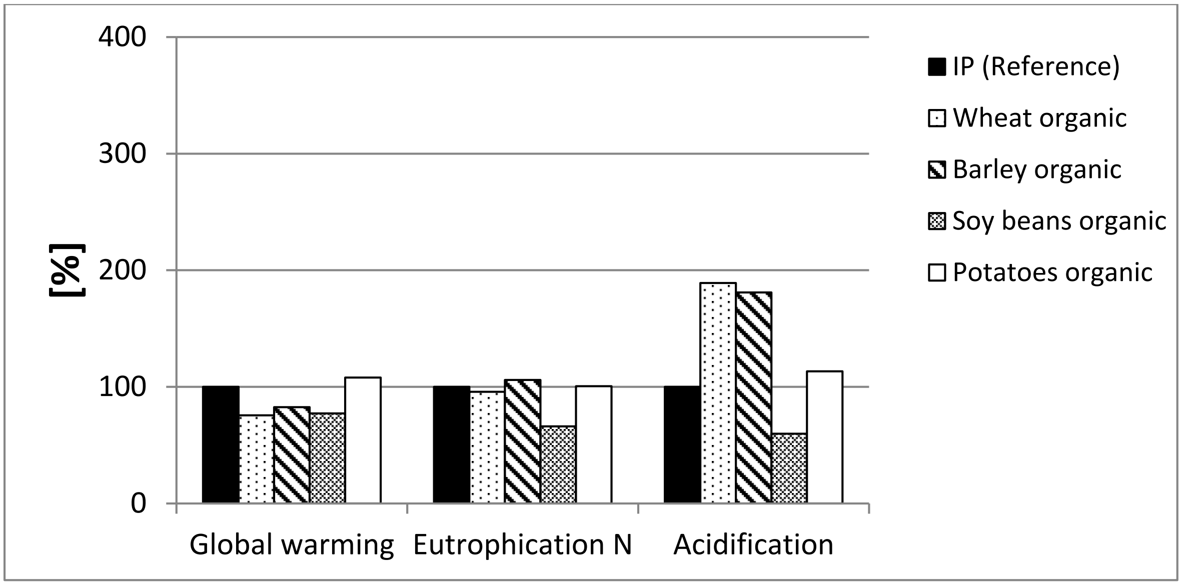

Figure 2. Relative differences between organic crops and the respective crops from IP production for global warming, eutrophication, and acidification per kg of grains, pulses and tubers respectively assessing the inventories with the remodeled N emissions from fertilizer applications.

4. Discussion

4.1. N emission modeling

The remodeled NH_3 emissions from fertilizer applications on a per ha basis were lower for all crops than the emissions in the original ecoinvent inventories. This can be explained by the different ammonia emission rates from slurry that were used in the estimations of the remodeled values and which are based on recent ammonia emission measurements from slurry application in Switzerland (Sintermann *et al.*, 2011). However, reductions in NH_3 emissions were always higher in organic crops after remodeling. This is because in organic crop production nitrogen is solely applied as organic fertilizers (slurry and solid manure for the crops analyzed in this study) having higher NH_3 emissions than mineral fertilizers whereas the crops in integrated production are mainly fertilized by mineral fertilizers.

After remodeling, N_2O emissions became less on a per ha basis for all organic crops except for potatoes. For the IP crops N_2O emissions increased after remodeling except for soy beans where the same decrease could be observed as for organic soy beans. For soy beans similar amounts of nitrogen fertilizers were applied, which explains the similar amounts of N_2O emissions. Further, in soy beans the greatest difference between N_2O emission values in the original ecoinvent inventory and the remodeled values could be observed. This can be explained by the modeling of the N_2O emissions according to IPCC guidelines 1996 in the original ecoinvent inventory (Nemecek *et al.*, 2007) where the amount of N from fixation was added to the amount of N from fertilizers. The higher N_2O emissions for organic potatoes after remodeling is due to the additional N from excessive nitrogen mineralization due to mechanical impact, which the model used here accounts for. The higher N_2O emissions after remodeling in wheat, barley, and potatoes from integrated production can be explained by inclusion of the management induced N mineralization from the soil C-N-pool by which the full N turnover in the modeling of N_2O emissions is considered. Relative to the N input from fertilizers the amount of N from the soil C-N-pool was larger in wheat, barley, and potatoes from integrated production than in the respective organic crops. This also explains why the differences in N_2O emissions between these organic and the respective IP crops became larger after remodeling.

Since NO_3 emissions are difficult to model reliably we estimated the total amount of leachable N on the basis of the nitrogen balance which resulted in lower NO_3 emissions per ha for all crops except potatoes irrespective of organic or IP. This indicates that in the original ecoinvent inventories NO_3 emissions are overestimated. Especially for organic fertilizers the NO_3 model used within the original ecoinvent inventories seems to produce values that are too high. In contrast the higher NO_3 emissions in potatoes after remodeling can again be explained by the additional N from excessive nitrogen mineralization due to mechanical impact which was considered for the remodeled values.

4.2 Impact assessment

In absolute terms impacts for global warming, eutrophication, and acidification became lower after remodeling for all crops irrespective of organic or IP with the exception of impacts for eutrophication in IP wheat resulting in higher absolute impacts after remodeling. The lower relative impacts for global warming per kg of organic wheat, barley and soy beans compared to the respective IP crops after assessing the inventories with the remodeled N emissions from fertilization can be explained by the considerably lower N_2O emissions. In the case of potatoes the relative difference in impacts for global warming between organic and IP potatoes became smaller after remodeling with still slightly higher impacts for global warming in organic.

Assessing the impacts for eutrophication on the amount of leachable N estimated on the basis of the N balance shows that impacts for eutrophication on a per kg of product basis of organic wheat, barley, and potatoes is comparable to the impacts for eutrophication of the corresponding crops from integrated production. Impacts for eutrophication of 1 kg of soy beans were already lower in the original ecoinvent inventories. However, the relative difference between organic and IP soy beans increased after remodeling because the relative difference of NO_3 emissions on the per ha basis increased.

Impacts for acidification on a per kg of product basis of organic crops decreased substantially when assessing the inventories with the remodeled N emissions. However, especially for organic wheat and barley impacts for acidification were still considerably higher than for the respective crops from integrated production. This is due to the sole use of organic fertilizers in organic crop production. Even after remodeling NH_3 emissions from organic wheat and barley were higher on a per ha basis than from the IP crops. Though, with improved slurry application techniques and management practices NH_3 emissions from organic fertilizers could be further reduced resulting in a further decrease in impacts for acidification from organic crops.

5. Conclusion

This analysis shows that N emissions from fertilization in LCA inventories of organic and conventional agricultural products are not well adapted to the respective farming system. In particular the crop specific changes in the soil C-N-pool need to be considered in the emission modeling to better represent N_2O emission from organic fertilizers and to take account of the total nitrogen turnover from crop production.

Calculating N emissions based on the actual N flow in the respective farming system leads to a more precise differentiation of impacts for global warming, eutrophication, and acidification between organic and conventional products. By that higher accuracy in N modeling from fertilization helps to improve the differentiation of environmental impacts of products from different agricultural systems such as organic and conventional agriculture and allows for conclusions on their N efficiency.

6. Acknowledgements

This study is part of the research project „Improving LCA methodology to comprehensively model organic farming“, which is funded by the Coop Sustainability Fund, Basel, Switzerland and the Federal Office for the Environment (FOEN), Switzerland. The goal is to develop LCA further to better differentiate between different agricultural systems.

A statistical approach to deal with uncertainty due to the choice of allocation methods in LCA

Unresolved debates on the application of allocation methods constitute a major source of uncertainty in Life Cycle Assessment (LCA) results. Some ways to deal with this issue are standardization, sensitivity analysis and scenario modeling. Standardization reduces uncertainty, while the latter two methods serve to analyze the system using one allocation at a time in order to show a range of possible outcomes. However, the full range of outcomes given all possible choices has never been shown. This can be misleading when evaluating the environmental impacts of a production system, particularly when comparing two systems. We investigate the use of Monte-Carlo simulations as a statistical approach for analyzing uncertainty propagation to the LCA outcomes, depending on the choice of allocation method. In this approach, a probability of occurrence is assigned to each allocation method, for each multi-functional process in the system. The allocation methods are sampled according to the probability of occurrence using Monte-Carlo simulations. The range and frequency of LCI outcomes was analyzed with and without this approach, including data uncertainty in both cases. The LCI results show the influence of many possible allocation choices and combinations in a system besides the influence of data uncertainty. Further implementation for more complex systems and broader LCI and LCIA outcomes is required.

Keywords: uncertainty in LCA, allocation, data, Monte-Carlo

1. Introduction

Methodological choices in all phases of Life Cycle Assessment (LCA) are unavoidable and are a potential source of uncertainty. A typical example of such choices is the choice between different methods to solve multi-functionality of unit processes. Generally, practitioners choose ambiguously between the following three types of methods to solve this issue: substitution (avoided burden), system expansion or partitioning, and within partitioning between different principles, e.g., mass, energy, or economic value[1]. This ambiguous choice could be a major source of uncertainty in LCA results since, as mentioned by Guinée et al. (2004): *"... it is impossible to have an ultimate best solution accepted by everybody for a problem that is an artefact of wishing to isolate one function out of many"*. In fact, several studies have shown the influence of the choice of allocation method in the dispersion of LCA results and e.g. policy implications (van der Voet et al. 2010; Wardenaar et al. 2012), and this is one of the reasons why ways to deal with uncertainty due to the choice of allocation method have been a key topic of discussion and development in the LCA arena in recent years.

Until today, the main approaches for accounting for uncertainty introduced to LCA results by the choice of allocation method include: standardization, critical reviews (peer review), sensitivity analysis, and scenario modelling (Björklund 2002). Standardization refers to consensus seeking on which allocation methods to use, and which procedures to follow if multi-functionality is encountered in LCA. Uncertainty due to allocation choices is reduced with standardization, but it does not explicitly lead to LCA results that account for uncertainty due to the choice made. In 1998, ISO (International Standardization Organization) provided guidelines to solve multi-functionality[2] (ISO 2006), which have become more widely applied by practitioners nowadays.

Another method to account for uncertainty due to the choice of allocation methods is sensitivity analysis. This method studies the influence that input parameters (independent) have on output parameters (dependent) (Björklund 2002). A sensitivity analysis that shows the influence of the choice of allocation method (independent parameter) on the LCA outcomes e.g. as Life Cycle Inventory (LCI) or as Life Cycle Impact Assessment (LCIA), is usually implemented by means of scenarios using different allocation methods. This type of sensitivity analysis approach is applied by most LCA practitioners and is referred to as scenario analysis (Björklund

[1] From this point on substitution, system expansion and partitioning (including different principles) are referred to as allocation methods

[2] ISO guidelines for allocation procedure are as follows: first, allocation should be avoided by substitution or system expansion where possible; second, where avoiding allocation is not possible physical partitioning should be applied and where this is not possible economic allocation should be applied. ISO also requires a sensitivity analysis where more than one allocation method seems applicable.

2002). Scenario analysis is still ambiguously defined in LCA because the scenarios design, i.e. which allocation methods to choose and for which multi-functional processes, remains vague and leaves room for debate.

Beside uncertainty introduced by methodological choices, other sources of uncertainty exist in LCA and perhaps the most recognized and addressed one is data uncertainty (Björklund 2002). Data uncertainty at the unit process level has three sources of uncertainty according to Henriksson et al. (2013): representativeness, inherent uncertainty and spread due to averaging of data. The authors developed a practical protocol quantifying the total dispersion of unit process data due to these three uncertainty sources. The explicit description of the input parameters, using distributions, mean values and standard deviations, is systematically facilitated by the protocol of Henriksson et al. (2013), which goes beyond the post-normal pedigree matrix based treatment of data uncertainty in LCA (Weidema & Wesnæs 1996; Funtowicz & Ravetz 1990).

Subsequently, a method has to be selected to propagate these data uncertainties into output uncertainties through the LCA model. For this, several methods exist and have been used in LCA (Heijungs & Lenzen 2014). Among the most popular ones are statistical methods, which include sampling methods such as Monte Carlo (MC) simulations. MC is becoming more and more commonly used in LCA, as it relies on computing capacity, which has increased in time (Heijungs & Huijbregts 2004). Other methods have also been studied, such as analytical uncertainty propagation using e.g. Taylor series expansions. Taylor expansions and analytical methods have been found to lead to similar results as MC simulations, while providing the contribution to uncertainty from each parameter and strongly reducing calculation time (Hong et al. (2010), Heijungs et al. (2005)). Nonetheless, more recently (Heijungs & Lenzen 2014) showed that both analytical and sampling methods are equally important and required for a good analysis, particularly sampling methods when uncertainties are large.

Analytical propagation of uncertainty for allocation factors was developed by Jung et al. (2013). The authors developed a method integrating allocation factors in matrix based LCA calculations and propagating the uncertainty in allocation factors to the LCA outcomes. In other words, the choice for an allocation method is made, but the factors themselves are described as uncertain input parameters leading to uncertainty in the LCA outputs. This method described by Jung et al. (2013) to address uncertainty in allocation factors and in data together is the most recent attempt in literature to deal with both sources of uncertainty together and uses an analytical method for propagation of uncertainty to LCI and LCIA results, i.e. a first-order approximation.

Despite these efforts to deal with data related and allocation related uncertainties, no statistical sampling method exists yet, to our knowledge, to simultaneously propagate through LCA, uncertainties due to data and to the choice of allocation methods. The aim of this study was to develop such a method, so that it can be used in LCA calculations and software. This study uses the CMLCA software as a testing software and implements an illustrative simple case study. Finally, we will simultaneously explore spread of LCI results when propagating uncertainty due to the choice of allocation method and due to unit process data uncertainties using MC simulations.

2. Methods

2.1. Uncertainty sources and propagation methods

Focusing on unit process and allocation uncertainties, we can distinguish the following sources of uncertainty: i. uncertainty in data at the unit process level (covering representativeness, inherent uncertainty and spread); ii. uncertain allocation factors per se (e.g. fluctuating prices lead to uncertain allocation factors for economic value allocation) and iii. choice of allocation methods (substitution, system expansion or partitioning). The main methods for propagating these uncertainty sources into LCA outcomes are: a) scenario analysis, b) analytical methods and c) sampling methods.

Table 1 shows the field of options that results from combining the previously described uncertainty sources and propagation methods. The table also shows some of the studies that have addressed particular sources with particular methods and combinations of both. Table 1 indicates that there are many studies that deal with allocation choices by applying scenario analysis, and that there are no studies that propagate uncertainty due to the choice of allocation method in an analytical way (perhaps because of its impossibility) and finally, that this study is the first one propagating uncertainties due to data and to the choice of allocation method in a simultaneous way.

Table 1. Field of options and examples of literature studies combining different propagation or analysis methods for addressing selected sources of uncertainty in LCA

Propagation / analysis method — Uncertainty source	a) Sensitivity Analysis / scenario Analysis	b) Analytical Methods	c) Sampling Methods
i. Unit process data	e.g. Middelaar et al. (2012) van der Harst & Potting (2014)	e.g. Heijungs et al. (2005) Hong et al. (2010) Imbeault-Tétreault et al. (2013) Jung et al. (2013)	e.g. Guo & Murphy, (2012) Gregory et al. (2013) Imbeault-Tétreault et al., (2013) Sonnemann et al. (2003) ***This Study (Option 2 and 3)***
ii. Allocation factors	e.g. Ardente & Cellura (2012) Huppes (1993)	e.g. Jung et al., (2013)	-
iii. Choice of allocation method + principles	e.g. Ardente & Cellura (2012) Ayer, N.W. et al. (2007) González-García et al. (2012) ***This study (Option 1 and 2)***	-	***This study (Option 3)***

The options we analyze in this study are the following:

Option 1: Scenario analysis for different allocation methods without statistical propagation for data uncertainty

This option consists of the classic scenario analysis to evaluate the influence of the allocation method on the LCA results. In this case, no data uncertainty is considered and only different allocation methods are applied to some multi-functional processes in the system, resulting in scenarios with punctual values for LCI outcomes given different allocation methods chosen for the calculations. For a large system with several multi-functional processes, it is unrealistic to analyze all the possible scenarios. The total number of scenarios is equal to a^n, where *n* is the number of multi-functional processes in the system and *a* is the number of allocation methods possible per process. Usually, LCA practitioners undertake a contribution analysis to help them decide which processes to analyze further and then they only create scenarios for the most important multifunctional processes, thereby significantly reducing the amount of scenarios. However, this approach can be misleading as the multi-functional process itself may have no direct emissions, but still have a big influence on the LCA results via upstream inputs.

Option 2: Scenario analysis for fixed allocation settings with statistical propagation for data uncertainty

Data at the process level is uncertain. In this option, we will apply the protocol of Henriksson et al. (2013) to quantify unit process data dispersions due to inherent uncertainty, unrepresentativeness and spread, and derive data distributions to be used as input parameters for the LCA model. Furthermore, we use MC simulations as a propagating method of the unit process data uncertainties and calculate LCI results based on the MC simulations outputs. For the choice of allocation method, fixed choices are specified, as is done in the scenario analysis.

Option 3: Statistical propagation for choice of allocation method and data uncertainty

This option propagates both data and choice of allocation uncertainties simultaneously, using MC simulations based on data distributions as in option 2 and probabilities of occurrence for the choice of allocation method as will be described in section 2.2. This option represents the novel contribution of this study. We will illustrate the possible advantages of this new method by showing the outcomes of the options described above for a simplified agricultural system i.e. rapeseed oil production in Northern Europe.

2.2. Implementation of a statistical propagation method for uncertainty due to the choice of allocation method in this study

For a multi-functional unit process, several *allocation methods* can be applied in order to solve multi-functionality. For partitioning-type of allocation methods, *allocation factors* are defined as the fraction that divides the non-functional economic and environmental flows to the functional flows (i.e. the co-products) of a multi-functional process (Guinée et al. 2004). For each *multi-functional unit process* in the system, allocation factors are defined to be able to solve the matrix algebra (Heijungs & Suh, 2002) behind LCA modeling. Typically, the sum of all allocation factors for each allocation method is equal to 1. This is, in very general terms, the normal parameter definition for partitioning type of methods using different principles such as mass, energy content and economic allocation. For substitution type of allocation, equivalent flows are found for the co-product to be substituted by another product(s), as well as the ratio of substitution.

In this study we introduce a parameter named the *probability of occurrence* (p) (as a percentage) for each allocation method which ranges from 0 to 100% and which sum for all p-values equals 100%. This means that for each multi-functional process, possible allocation methods are: method 1, 2, 3, 4 etc., which have an associated p_1, p_2, p_3, p_4 etc. percentage of occurrence between 0 and 100% and all together add up to 100%. Together they describe *ranges of occurrence* for each method i.e. from 0 to p_1 for method 1, from p_1 to $p_1 + p_2$ for method 2, from $p_1 + p_2$ to $p_1 + p_2 + p_3$ for method 3, until from $p_1 + p_2 + p_3 + p_a$ to 1 for method a.

In principle, to propagate the uncertainty due to the choice of allocation method through the LCA model into the LCA outcomes, a random real number R is taken from a continuous uniform distribution U (0,100), each time a multi-functional unit process is encountered in the calculation of the system, for every Monte Carlo simulation. This value (R) is evaluated for the ranges of occurrence, and this is how the allocation method and factors are defined for each individual simulation. If for example four allocation methods are defined for a specific multi-functional process*:*

$$
\begin{array}{cl}
 & R \sim U(0{,}100) \\
0 \le R \le p_1 & \Rightarrow \text{ use allocation method 1} \\
p_1 < R \le p_1 + p_2 & \Rightarrow \text{ use allocation method 2} \\
p_1 + p_2 < R \le p_1 + p_2 + p_3 & \Rightarrow \text{ use allocation method 3} \\
p_1 + p_2 + p_3 < R \le 100 & \Rightarrow \text{ use allocation method 4}
\end{array}
$$

By repeating the evaluation of R for a large number of runs, for example using MC simulations, several choices for an allocation method for each multi-functional process are taken into account, leading to the propagation of uncertainty due to the choice of allocation method to the LCA results. In each single MC simulation the allocation method for each unit process is selected using the ranges of occurrence for each method, and the results are calculated using such choice. The higher the sample the more combinations of allocation choices are taken into account in the results.

When analyzing a system with a relative large number of multi-functional processes the previously described propagation method becomes very powerful, as a large amount of scenarios can be reproduced minimizing the amount of inputs. For example, if the number of multi-functional processes is 10 and two allocation methods are possible for each process, then 1024 combinations exist if all allocation methods are combined for all multi-functional processes. A complete scenario analysis should show the outcomes for all the combinations. However, that is rarely the case in LCAs as it is a very time consuming process. With the proposed method 1024 combinations can be covered while defining the ranges of occurrence for each method per unit process only one time.

An example of the input parameters necessary for the method to propagate uncertainty due to the choice of allocation method as was described are shown in Table 2. For one multi-functional process four allocation methods are displayed in Table 2. These are the methods currently implemented in CMLCA. For each method the corresponding allocation factors for each co-product are shown. The sum of these factors for one method is equal to 1. For example, partitioning-2, has allocation factors 0.7 and 0.3 for co-product one and two of this example multi-functional unit process. Furthermore, the percentage of occurrence for each method is also defined. For the example, substitution occurs 2.5%, surplus 2.5%, partitioning-1 25% and partitioning-2 70%. Together the percentage of occurrence for the four allocation methods adds up to 100% as well. Thus, the ranges of occurrence for each allocation method in the example of Table 2 are: from 0 to 2.5% substitution, from 2.5% to 5% surplus, from 5% to 30% partitioning-1 and from 30% to 100% partitioning-2.

Table 2. Parameters for different allocation methods for a multi-functional unit process. This table displays the allocation methods implemented in the CMLCA software only

	One Multi-functional Unit Process			
Allocation Method	**Co-product**	**Allocation Example**	**% of occurrence (*p*)**	**Example**
1.Substitution	Co-product 1	1 kg rapeseed cake replaced by 1.5 kg peas	P_1	2.5%
	Co-product 2	-		
2.Surplus	Co-product 1	0	P_2	2.5%
	Co-product 2	1		
3.Partitioning-1	Co-product 1	0.55	P_3	25%
	Co-product 2	0.45		
4.Partitioning-2	Co-product 1	0.7	P_4	70%
	Co-product 2	0.3		
a. Allocation method	Co-product 1	C_1	P_a	P_a %
	Co-product 2	C_2		
	Co-product Y	$1-C_1-C_2$		

2.3. Illustrative case study

We have implemented in CMLCA version beta 5.2 a simple system: Rapeseed Oil production in Northern Europe, similar to Wardenaar et al., (2012). We focus on three key processes (1) cultivation, (2) transport to mill and (3) rapeseed oil extractions by cold pressing of rapeseed. Process one produces straw and rapeseed and process three rapeseed oil and rapeseed cake. Thus both processes are multi-functional and require allocation between the co-products. The system is described in Figure 1. The functional unit is 1 kg of rapeseed oil at mill and the system includes the production, storage and transport of the main inputs to these three key processes. For the description of the background processes, ecoinvent data from version 2.2 is used (http://www.ecoinvent.org/database/). Also, background processes are assumed to be allocated as done by the ecoinvent database and this assumption remain constant for all the options analyzed in this study.

For the two multi-functional processes, we assume two allocation methods are applicable i.e. surplus and mass for rapeseed cultivation and energy content and economic values for oil extraction. The allocation parameters defined for the case study are shown in Table 3. For *option 1* we use the four combinations possible using two multi-functional processes with two allocation methods each. This leads to four fixed allocation scenarios (Table 3) and the LCI results of this option are presented as point values given that no data uncertainty is assumed. For *option 2* we use the same fixed allocation scenarios as option 1, but in this case data uncertainties are propagated to LCI outcomes with MC simulations. We used a sample size of 700 simulations for the four fixed allocation scenarios. Table 3 shows that the percentage of occurrence assigned to each method is equal to 100, simply because choosing for one method corresponds to 100% probability of occurrence of that method, according to the method described in section 2.2. This holds for both options 1 and 2. Finally, for *option 3* we use 50% probability of occurrence of the allocation methods in both multi-functional processes, because this allows an equal chance of occurrence for all the methods. We ran option 3 for 2000 MC simulations which is different than the number of simulations in option 2 a choice made for practical reasons.

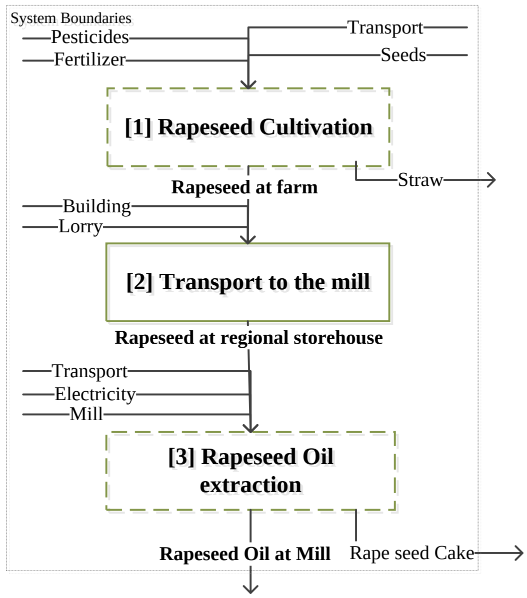

Figure 1. System for rapeseed oil production in Northern Europe. Boxes represent processes, dashed boxes are multi-functional.

Table 3. Allocation factors and probability of occurrence of each allocation methods for the two multi-functional processes in the rapeseed oil production system

	Multi-functional Process		Probability of occurrence p (%) for the different options				
	[1] Rapeseed cultivation		Option 1(no data uncertainty) and 2 (with data uncertainty, 700 MC)				Option 3 (data + choice of allocation method uncertainty)
Allocation Method	**Co-product**	**Allocation factor**	**Fixed Allocation1**	**Fixed Allocation2**	**Fixed Allocation3**	**Fixed Allocation4**	**2000 MC**
Surplus	Straw	0	100	0	0	100	50
	Rapeseed	1					
Mass	Straw	0.43	0	100	100	0	50
	Rapeseed	0.57					
	[3] Rapeseed oil extraction						
Energy Content	Rapeseed Oil	0.55	100	100	0	0	50
	Rapeseed Cake	0.45					
Economic value	Rapeseed Oil	0.7	0	0	100	100	50
	Rapeseed Cake	0.3					

3. Results

Results for option 1 are given in Table 4 and for option 2 and 3 in Figure 2. Option 1 shows the LCA results for a scenario analysis for different allocation methods without statistical propagation for data uncertainty. The results presented in Table 4 only show carbon dioxide emissions to air per kg of rapeseed oil at mill for the four fixed allocation scenarios. Emissions range from 0.7 to 1.19 kg CO_2 / kg of rapeseed oil depending on the allocation settings chosen for the two multi-functional processes under study. As expected, for those allocation scenarios in which rapeseed and rapeseed oil get a higher allocation factor (fixed allocation 1 and 4), the emissions per kg of rapeseed oil are higher.

Table 4. Carbon dioxide emissions to air per kg of rapeseed oil for fixed allocation (Table 3) and no data uncertainty propagation (Option 1)

Allocation Settings	CO_2 (kg CO_2 / kg of rapeseed)
FixedAllocation1	0,94
FixedAllocation2	0,70
FixedAllocation3	0,89
FixedAllocation4	1,19

Figure 2 shows a series of histograms that corresponds to the results for carbon dioxide emissions to air for option 2 and 3. The outcomes for option 2 correspond to the histograms for the four possible fixed allocation combinations with statistical propagation for data uncertainty (i.e. dashed lines in Figure 2). The outcomes for option 3 correspond to the histogram including statistical propagation of the choice of allocation method together with statistical propagation of data uncertainty (i.e. continuous line in Figure 2).

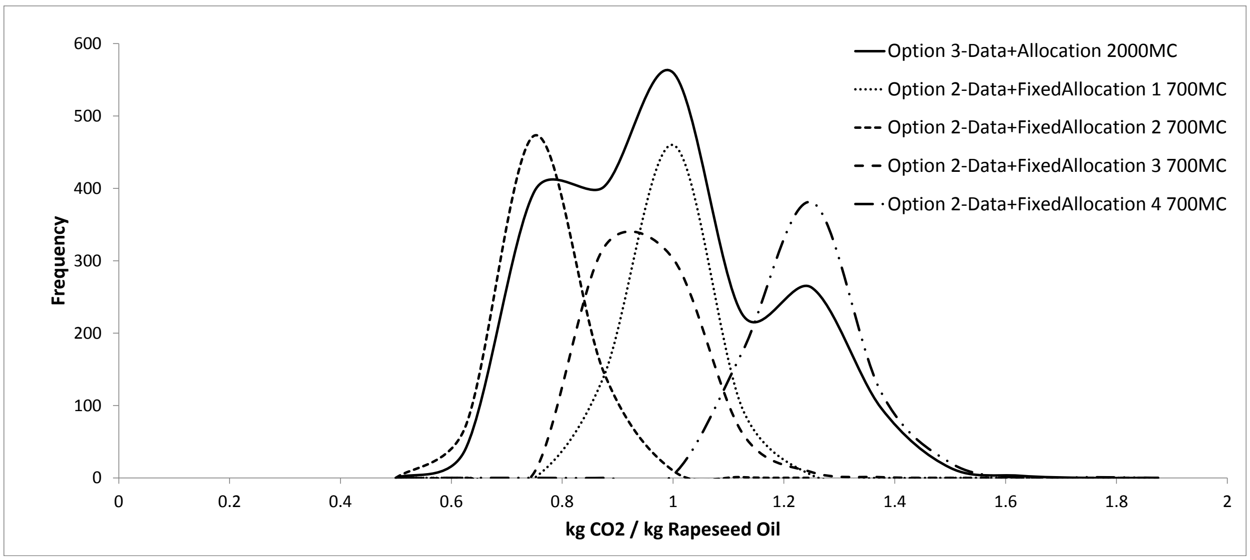

Figure 2. LCI results for carbon dioxide emissions to air per kg of rapeseed oil under four fixed allocation settings (Table 3) and for random allocation choice using MC simulations to propagate uncertainty

4. Discussion

The method presented here to simultaneously propagate uncertainties in data and due to the choice of allocation methods through an LCA, is based on the introduction of the probability of occurrence of each allocation method for a multi-functional process. This parameter can be used by assigning equal probability of occurrence to all allocation methods for a multi-functional process, as shown in the illustrative case of this study. Assuming this, helps to propagate, with equal chances, the uncertainty around the fact that one can choose for different allocation methods in different multi-functional processes. Therefore, assigning equal probability of occurrence to the allocation method per process, is expected to have an influence on the size of the peaks of the histograms i.e. the frequencies with which an outcome is observed, but not on the ranges of the outcomes. The shape of the histograms also depends on the sample size of the MC simulations which at the end determines the distributions of the LCI results.

Also, the use of this parameter allows a full statistical propagation of uncertainty with a large sample size to make sure all methods are sampled more or less equally. It can be argued, nevertheless, that this method could be intensive in terms of computing capacity requirements as it uses MC simulations as a propagating method. Analytical methods do not yet exist - despite recent efforts in the field -, which could be a less computing intensive alternative to MC simulations as proposed in this study, for propagation of the choice of allocation methods if possible at all.

The results showed how scenario analysis for allocating different multi-functional processes in order to explore the dispersion of the LCI outcomes i.e. option 2, leads to a similar range of outcomes for carbon dioxide emissions to air than option 3 which takes into account data uncertainty and allocation choice simultaneously in MC simulations. This is an indication of the strength of the method presented here that allows capturing in LCI results the influence of all possible allocation choices in a system next to the influence of data uncertainty without actually making an explicit choice for one or another method per process. Also, showing the likelihood for which an outcome can be expected given many possible combinations of input parameters and allocation methods for a specific system is another strength of the proposed method. Besides, both option 2 and 3, lead to a broader range of CO_2 emissions than when no data uncertainty is taken into account in the LCA, showing the importance of accounting for data uncertainty as emphatically pointed out by many other studies.

Further research is required to evaluate the method shown here for systems with a large number of multi-functional processes and broader LCI outcomes too. Finally, in the future, the method could be expanded to deal with uncertainties due to other sources not yet addressed in this study.

5. Conclusion

Unresolved debates on the application of allocation methods constitute a major source of uncertainty in LCA results. The full range of outcomes given all possible choices for allocation methods and combinations in a system with several multi-functional unit processes is hardly shown.

We propose the use of Monte-Carlo simulations as a statistical approach to simultaneously propagate uncertainties due to data and to the choice of allocation methods to LCA outcomes. For this purpose the probability of occurrence was introduced and assigned to each allocation method, for each multi-functional process in a system.

The distribution of LCI outcomes was analyzed with and without the previous approach and in both cases including data uncertainty and we conclude that the proposed method enables, in a relatively simple way i.e. with few additional parameters definition and modest computational calculation capacity, to propagate uncertainties due to the choice in allocation method and data uncertainty to the LCA results while not requiring an actual choice for one or another allocation method. Further implementation for more complex systems is required.

ABSTRACT

Integrated Multi-Trophic Aquaculture (IMTA) has been regarded as an environmental management concept that can minimize the environmental impacts of conventional monoculture aquaculture farms while expanding their economic base. These characteristics of IMTA systems hold as long as (1) there are no significant trade-offs between the discharge reduction and the life cycle environmental impacts of the IMTA infrastructure; and (2) the co-cultured species in the IMTA system constitute commercial species produced at scales that yield a profit. In this study we use Life Cycle Assessment (LCA) to analyze the environmental trade-offs between monoculture and IMTA systems. We do this by posing two questions: 1) what are the trade-offs for small and medium enterprises (SMEs) considering to move from monoculture aquaculture practice towards IMTA; and 2) what are the trade-offs comparing IMTA species with their conventional monoculture alternatives. Our hypothesis states that the level of integration of the productive activities of the co-cultured species (e.g., bivalves, echinoderms and algae) into the existing monoculture (e.g., finfish) productive activities will determine the magnitude of the trade-offs. Quantification of trade-offs is ongoing as part of the EU FP7 IDREEM (Increasing Industrial Resource Efficiency in European Mariculture) project. We here report our first conceptual results consisting of a scoping framework to be further applied in the project.

Keywords: Sustainable fish production, aquaculture, IMTA, LCA

1. Introduction

Aquaculture, which includes marine fish farming and in this paper refers exclusively to marine systems, faces increasing pressures as demand for seafood products grows while traditional wild fisheries are in decline (FAO, 2012). Integrated Multi-Trophic Aquaculture (IMTA) is the combined cultivation of multiple commercially farmed species that belong to different trophic levels in the food chain. In an IMTA system fish are farmed together with other species including bivalves (such as mussels and oysters), echinoderms (such as sea urchins) and algae or seaweed creating a more efficient, cleaner and less wasteful production system. IMTA allows nutrients from fish farms that are otherwise lost to the environment to be turned into useful products as they are utilized by these additionally grown species. IMTA is considered as one of the solutions to concerns about the future sustainability of aquaculture by increasing productivity and profitability while also reducing waste and over-reliance on raw materials from wild fish stocks.

The FP7 European research project IDREEM (Increasing Industrial Resource Efficiency in European Mariculture) aims to develop and demonstrate such IMTA technologies protecting the long-term sustainability of European aquaculture. The IDREEM project aims to demonstrate the benefits of IMTA through pilot commercial-scale testing, field research and modelling in collaboration with seven European small and medium enterprises (SMEs) paired to local Research and Technology Development (RTD) institutes (SME/RTD pairings). Interdisciplinary research within IDREEM will examine the obstacles and risks of using IMTA systems and apply and develop tools to overcome these constraints, whether they are economic, environmental, technical, social or regulatory. One of the tools applied is Life Cycle Assessment (LCA), which we use for answering two questions: 1) what are the environmental trade-offs for SMEs considering to move from monoculture aquaculture practice towards IMTA; and 2) what are the environmental trade-offs comparing IMTA species with their conventional monoculture alternatives.

The LCA work in IDREEM started with an LCA training of the different SME/RTD pairings. The goal of this workshop was to get the members of the pairings familiar with the main concepts of LCA and to familiarize them with the data collection needed for the LCAs. Following the LCA training the goal and scope definition and inventory analysis were started up. As a first step in the data collection, the present

finfish productive systems (monoculture, baseline or before IMTA systems) of all SMEs were described qualitatively. This included describing all relevant unit processes of each SME. As a second step, quantification of the inputs and outputs of the unit processes of the monoculture systems is currently taking place.

This paper presents first the methodology used to describe the SMEs monoculture and IMTA systems and second our first conceptual and qualitative results addressing the relation between questions posed, type of analysis needed and levels of integration achieved in IMTA. In the next 2 years of the IDREEM project quantitative LCA results will be produced and hopefully used in combination with the conceptual outcomes of this paper.

2. Methods

We started by qualitatively describing the current monoculture SME systems. As a first step in the qualitative description of the monoculture systems and keeping in mind the future comparison with the IMTA systems, the decision of assessing the SMEs monoculture systems in a detailed manner was made. The intention of this decision was to have as much data as possible available in an early stage of the project, including the SMEs' productive processes and activities, their material inputs and outputs and some ideas about their supply chain and waste treatment. A detailed description allows for a future aggregation while a "black box" type of description does not allow for disaggregation anymore neither for a detailed data collection in a later stage of the project. A detailed description was also expected to enable a better understanding of the true integration level of the IMTA species into the existing monoculture systems. Although the aim is to be as detailed as possible in the data collection the feasibility of this, of course, still depends on the availability of data within the SMEs.

The right part of Figure 1 shows a detailed scheme of an aquaculture production system, some general inputs and outputs but without showing the supply chain of materials for clarity of the graph. All inputs to individual processes are supplied by another productive system (upstream processes) or extracted from nature (environmental inputs). The left part of Figure 1 shows the "black box" aggregated type of description of the same system. The black box description is a simplified alternative to describe the monoculture systems, in which the material flows within the SME are not described.

As a second step in the process of qualitative data collection, pairings listed the activities (unit processes) performed and outsourced by each of them for their current monoculture production. A description of the practices used in each of the processes was also described as this helped in defining material inputs and outputs. The list of unit processes provided by each SME constitutes the foreground processes, for which data (primary data) will be collected by the pairings. All other economic activities in the supply chain of the SMEs i.e. upstream supply processes or downstream waste treatment processes will be described using literature or other secondary data sources. The monoculture LCAs consist of attributional cradle-to-gate analyses and do not include consumption of fish as part of the downstream processes. The boundary of the monoculture LCAs is thus at the gate of the SMEs, which depending on the activities of each SME, can be different. The right panel of Figure 1 shows common unit processes for all the SMEs, as well as possible boundaries and generic inputs and outputs to the monoculture productive processes.

Additionally to the monoculture activities, the pairings also described their preliminary plans for their IMTA systems. With respect to the level of integration of the planned IMTA systems (i.e. production activities and infrastructure) into the current monoculture systems, the proposed IMTAs are likely to move between two extremes.

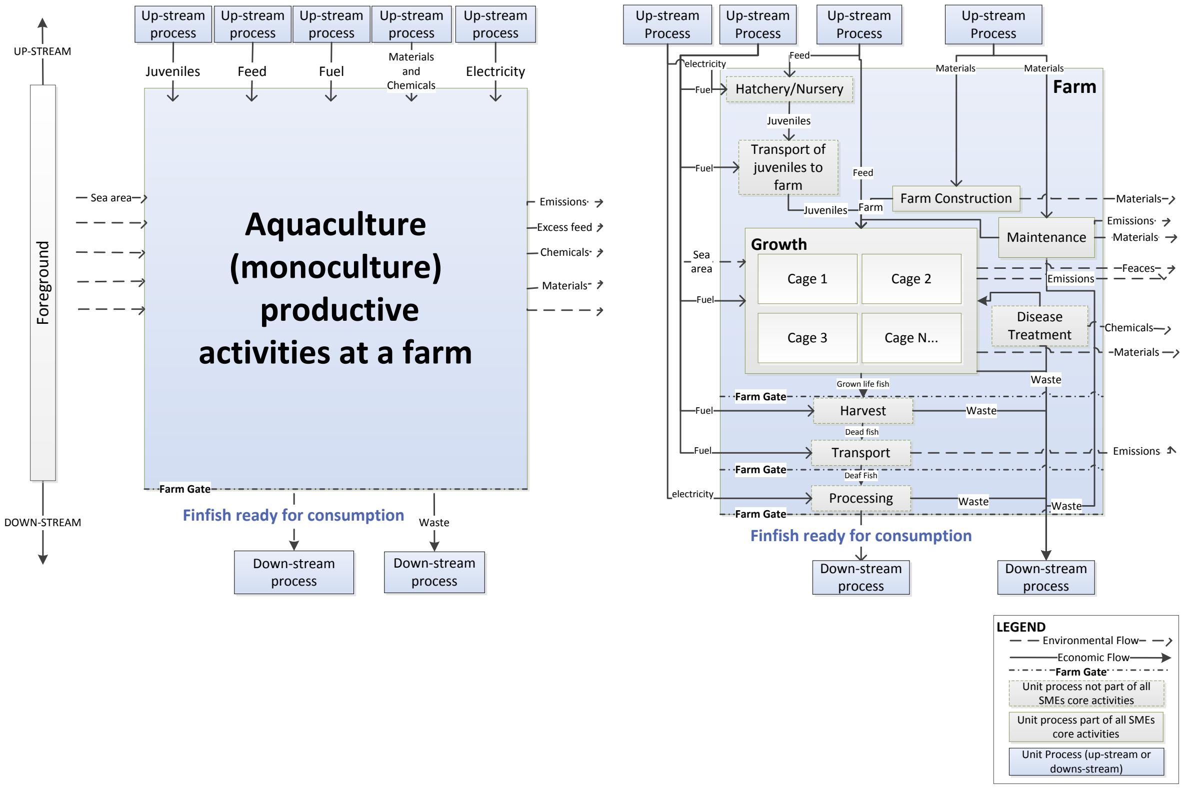

Figure 1. Left: "Black Box" aggregated and Right: Detailed disaggregated description of aquaculture farms

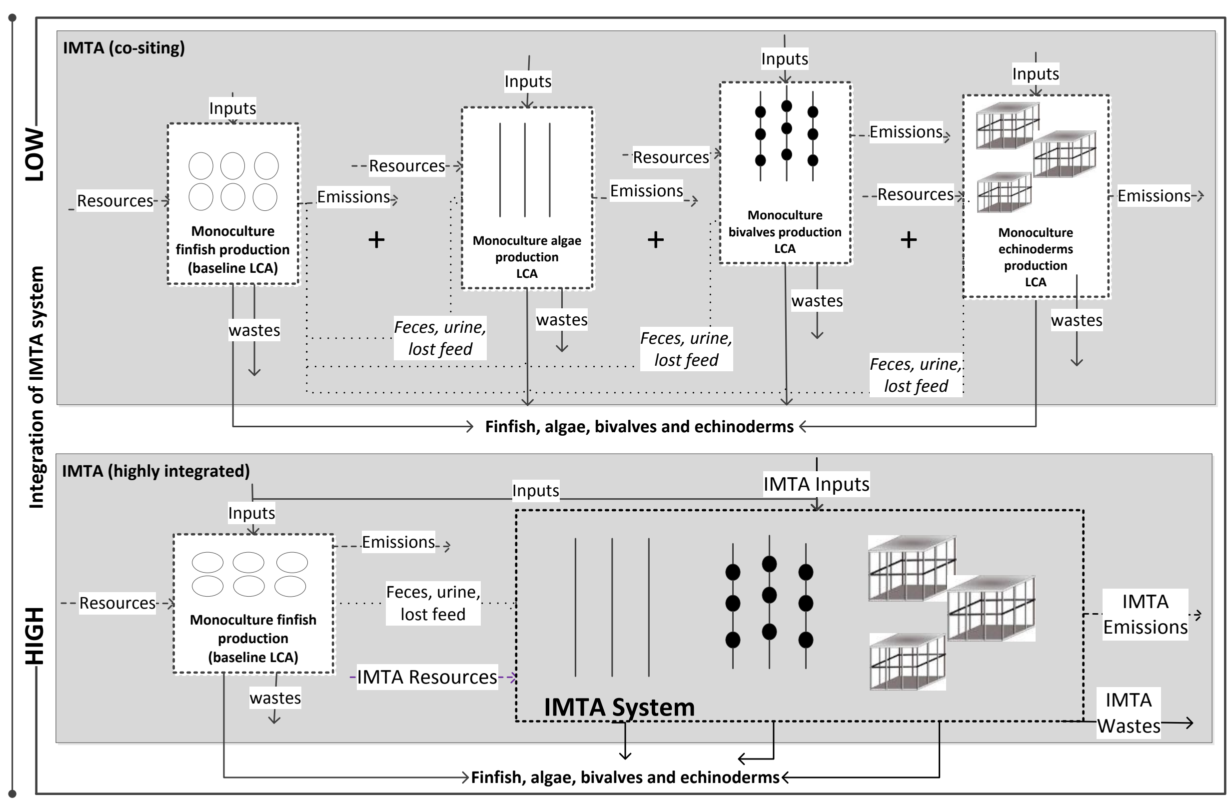

Figure 2. Level of integration of IMTA systems into the current production

On one side the IMTA system consists of a small add-on infrastructure and the operating activities (feeding, harvesting and related transport) are *highly integrated* into the current productive activities of the monoculture. In this case the IMTA system can be considered as highly integrated into the monoculture production system, and we refer to this extreme as the highly integrated type of IMTA.

On the other side the IMTA system corresponds to a relatively larger add-on infrastructure at sea constituting completely separate monoculture production lines for each co-cultured species, with its own inputs, resources, emissions and waste production. The latter extreme follows the description of IMTA by (Reid et al., 2009): "*Integrated aquaculture allows intensive management of several monocultures from different trophic levels within the same system, all connected by nutrient transfer through water"*. We refer to this extreme as the *co-siting* (or i*ndustrial symbiosis*) type of IMTA. We considered this extreme as *the low integration* extreme as only nutrient exchange in the water relates the different monocultures for the IMTA species.

Figure 2 represents schematically the two extreme levels of integration distinguished above: the upper part represents the lowest level of integration or co-siting (or industrial symbiosis) type of IMTA, the bottom part represents the highest level of integration.

Based on the descriptions of monoculture and IMTA systems, we now present our first conceptual and qualitative results addressing the relation between questions posed, type of analysis needed and levels of integration achieved in IMTA. These conceptual results consist of the scoping framework we intent to use further in the project once quantitative data becomes available for both monoculture and IMTA systems, in order to answer questions about the sustainability of IMTA as an environmental management concept that can minimize the environmental impacts of conventional monoculture aquaculture farms.

3. Results

In the methodology, we described how the monoculture and IMTA systems were qualitatively described by the pairings. Data to complete full attributional LCAs of the monoculture systems, are under collection by the parings and the IMTA systems are currently under pilot testing and are expected to achieve different levels of integration within the monoculture production activities and infrastructure. LCA will be used to answer two questions related to these systems: 1) what are the environmental trade-offs for SMEs considering to move from monoculture aquaculture practice towards IMTA (Q1: SME perspective); and 2) How do the environmental performance of IMTA species compare with their monoculture conventional alternatives (Q2: Product perspective).

Since the question determines the appropriate analysis and not the other way around, we present here the relation between these two questions, the type of analysis we will apply and the levels of integration achieved in IMTA systems. . We do so in order to determine the environmental trade-offs between the two systems that depend basically of three parameters: (1) the produce i.e. IMTA systems produce new co-cultured species next to finfish, (2) the nutrient discharge in the sea water due to lost feed and fish urine and feces, and (3) the life cycle impacts of the IMTA infrastructure e.g. upstream processes to produce inputs required to build and run the production of co-cultured species.

The flow diagram in Figure 3 shows the scoping framework for both Q1 and Q2. Q1 is a question from a company-perspective primarily, and is the main question for IDREEM. Companies are interested in increasing their eco-efficiency by cultivating economic species that grow on the nutrient discharge from the monoculture. This question is mainly addressed by a difference analysis which compares the environmental performance of the before and after IMTA system, taking into account differences in produce. In a difference analysis (Guinée et al., 2002) parts of the life cycle of the compared systems are expected to be quantitatively and qualitatively identical and are therefore omitted from the analysis to simplify it. The difference analysis can be performed for both extremes of integration and is thus independent of the level of integration as shown in Figure 3. However, the level of integration determines the magnitude of the trade-offs as in a low integration IMTA system the life cycle impacts of the IMTA infrastructure is expected to increase while in the high integration is expected to increase or perhaps decrease if inputs for the monoculture production are also used in the production of IMTA co-cultured species.

Moreover, full single-species LCAs can also be used to answer Q1. In this case, full attributional LCAs would be quantified for each monoculture species for all the co-cultured species in the IMTA systems and compared with the performance of the IMTA systems. Nonetheless, this would imply a change in the perspective for the question asked about the systems. In fact, we consider that full single-species LCAs leads to answer Q2, a question from a product-perspective, primarily comparing two ways of producing the same products (e.g., finfish, echinoderms, bivalves, algae, …): integrated in an IMTA system or by separate monoculture systems. In this case we will need to draft full single-species LCAs for each of the co-cultured species and compare these to the IMTA production of the same combination of species.

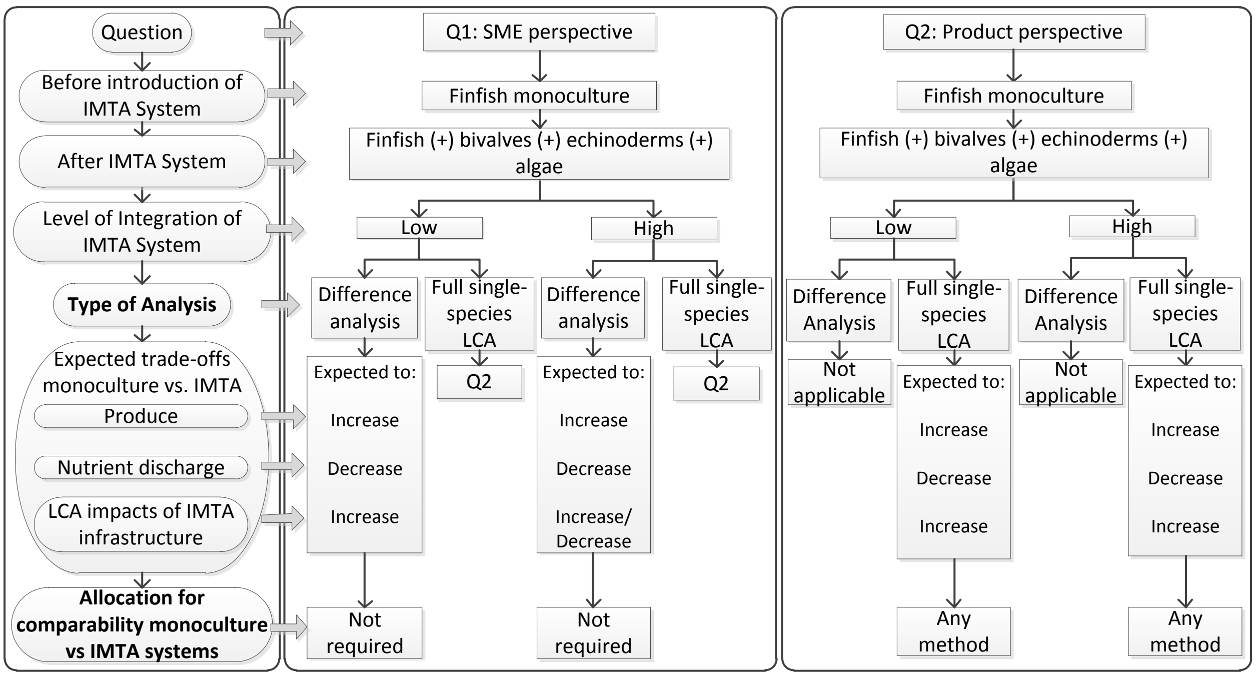

Figure 3. Scoping the IMTA systems LCAs starting from the question asked

The IDREEM SMEs currently produce only one species in their monoculture systems; as a consequence, we don't have a complete set of representative monoculture systems to compare the IMTA with. We will thus have to adopt existing LCA studies on these co-cultured species, adapt them to the SME conditions where possible, and take their results as second-best baseline system. The choice for separate, full single-species LCAs is again independent of the level of integration, but the more integrated the more challenging the allocation issues for the LCAs performed will become. To make the before and after IMTA systems comparable allocations is therefore required and any method, among which partitioning principles, substitution or system expansion should be applied. For Q2 we consider that difference analysis for any level of integration is not applicable as it would be very difficult to identify the equal parts of the before and after IMTA systems, and therefore full single-species LCAs would be the appropriate way to analyze such question.

4. Discussion

Our preliminary conceptual results show how questions determine the type of analysis to be applied. More particularly, the questions determine the scope of the LCAs to be performed, being a difference analysis omitting large parts of the systems compared or being a set of single, full LCAs for each species cultured. Focusing on the two starting question formulated different types of analysis can be used in order to calculate the life cycle environmental impacts of the IMTA systems implemented in the IDREEM project. The conceptual results also show that the type of analysis is independent of the level of integration of new species into the current monoculture system. Nevertheless, the level of integration of the productive activities of the co-cultured species (e.g., bivalves, echinoderms and algae) into the existing finfish monoculture system is expected to determine the magnitude of the trade-offs. The LCAs to be performed and the IMTA systems proposed by the involved SMEs with hopefully differences in levels of integrations will determine whether this expectation is correct or not. A complicating issue then is that the IMTA systems developed and tested within the IDREEM project will most likely not be in a stage beyond pilot-scale. This will be challenging for the LCA work as it implies that the LCAs can only deal with the pilot-scale on a more or less empirical data level. We will have to apply scenario and up-scaling techniques to estimate the LCA results for a full commercial exploitation of the IMTA plans.

5. Conclusion

IMTA is regarded as an environmental management concept that can minimize the environmental impacts of conventional monoculture aquaculture farms while expanding their economic base (Price & Morris, 2013). These characteristics of IMTA systems hold as long as 1) there are no significant trade-offs between the discharge reduction and the life cycle environmental impacts of the IMTA system and 2) the species to be used in the IMTA system are potentially commercial species produced at scales that yield sufficient additional profit.

In this paper we explored the relations between questions asked, levels of integration foreseen for the IMTA systems and the type of analysis to be performed to evaluate the environmental trade-offs between monoculture and IMTA systems, particularly those part of the EU FP7 IDREEM project. Our preliminary conceptual results show a scoping framework with some of the expected trade-offs and also shows that although the type of analysis to be used is independent of the level of integration of new species into the current monoculture system, the magnitude of the environmental trade-offs between the discharge reduction and the life cycle environmental impacts of the IMTA system can depend on the level of integration.

ABSTRACT

The UNEP SETAC Life Cycle Initiative has successfully provided a platform for consensus finding in the area of environmental indicators. A flagship project aims to provide global guidance and consensus on a few environmental indicators, including land use impacts on biodiversity. Land use and particularly land use change is one of the main drivers of biodiversity loss. However, no consensus exists yet on which indicators to use to quantify land use impacts on biodiversity within LCA. This is challenging for LCA on land-based products and production systems based in extensive land use, such as agriculture, forestry, open mining etc. The flagship project evaluates existing methods and models based on their ecological relevance, scientific robustness, transparency, reproducibility and applicability, among other criteria. The project is in progress with the ambition of delivering recommendations in 2015. This presentation focuses on identified methods and models to be included and review criteria for evaluation.

Keywords: Life Cycle Analysis, Life Cycle Impact Assessment, Biodiversity, Land Use, Ecological Indicators

1. Introduction

Environmental impacts of production and consumption are increasingly coming into the focus of companies and governments. Life Cycle Assessment (LCA) is one of the most important approaches to quantify environmental impacts of products from cradle to grave, in which the product system, process or service life cycle is mapped and environmental impacts are quantified. Applied as a decision-making tool and/or as a support to policy development, it makes use of indicators to consider different environmental aspects over a system's life cycle. Environmental indicators, i.e., quantified representations of impacts associated with specific impact categories, are required to measure the greening of the economy and of products. With increasing economic globalization, there has been a steadily growing need to create a worldwide consensus set of environmental indicators.

The UNEP/SETAC Life Cycle Initiative successfully provided the platform for consensus finding in the area of environmental indicators (USETox covering human and ecotoxicity) and LCA databases (Shonan Guidance Principles, UNEP/SETAC 2011). The work builds on previous experiences including the work on Product and Organization Environmental Footprints (PEF/OEF) of the European Commission and of the Water and Land Use working groups of the Life Cycle Initiative. A flagship project has now been established by the Life Cycle Initiative intended to run a global process aiming at global guidance and consensus building on a limited number of environmental indicators, including indicators those for assessing impacts from land use (LU) interventions, such as land use change (LUC), on biodiversity. The mandate of the taskforces started in early 2014 and will terminate in late 2015.

Biodiversity ranks high among the indicators of interest for the Initiative. An intensive transformation of natural areas over the past 50 years, mainly driven by economic growth and agricultural intensification and supported by technological development, have caused the loss of important environmental assets (MEA 2005). Land has been used for the production of goods and services along a global network of supply chains, often involving different temporal and spatial scales and various environmental pressures (UNEP 2012), which are mostly difficult to account for (Yu et al. 2013). These range from impacts on provisioning ecosystem services, with economic interest to humans, to the loss nature's intrinsic values and natural assets, such as biological diversity.

The increasing rates of land conversion in the last decades have led to a stronger engagement of different actors to enhance the sustainability of commodity supply chains (Newton et al. 2013) and the need to develop and implement tools to better understand the influence of supply chains on land use problems. In this context, the analysis of interconnected chains and linkage with specific policy are key steps on the assessment of impacts. Considering the manufacturing and production activities as some of the main drivers to land use and land use change, there is the need to focus on the prediction of potential impacts, such as biodiversity loss. There is also the need to assign responsibility for damages spread out across the supply chain, instead of focusing solely on final product providers.

However, despite these substantial contributions to address this issue in LCA, no clear consensus exists yet on the use of (a) specific impact indicator(s) to quantify land use impacts on biodiversity within LCA. This lack of agreement not only limits the application of correlated models, but also imposes constraints on the comparability of results of different studies evaluating land use impacts.

In this paper we establish the operational principles of the flagship project regarding biodiversity impacts from LU and LUC. We show how the taskforce in charge will assess current impact assessment methodologies and the process that will take place towards widespread consensus. We present briefly some preliminary and expected results and deliverables before the end of the mandate of the taskforce in late 2015.

2. Methods

2.1. Goal and scope of the taskforce

The objective of the taskforce is to conduct an overarching process aiming at global guidance and consensus regarding indicators and methods for the assessment of biodiversity impacts from LU (and, if possible, LUC) in LCA. An agreement will be pursued among experts, practitioners and stakeholders as to which methods respect a pre-established set of requisites. It is the task of the group to steer this process and collect all feedback in order to establish what are those requisites and in what cases, if any, those requisites are not met. It is beyond the scope of this taskforce to develop new methodologies, but it is expected that during its work the main aspects to tackle in future developments will be identified. Also, it might be suggested to combine existing proposals or to adapt and integrate existing methods from outside the LCA field (e.g. from recent research in ecology, conservation or other environmental sciences dealing with land use).

2.2. Participants and Process

To succeed in this task, this global effort involves world leading environmental and LCA scientists to develop scientifically robust indicators suitable for a global consensus. The taskforce includes not only experts in the LCA field, but also biologists, ecologists and experts in other disciplines relevant to the task.

The taskforce members contribute as part of one of two levels of engagement, namely:

- *Full members*, who have an active role in composing the deliverables. There are approximately 10 full members at present.
- *Agenda members*, who monitor the taskforce meetings and internal documents, providing comments when necessary. There are approximately 20 agenda members at present.
- *Stakeholders and interested parties*, who will lend their expertise to the group during specific stages (to be determined).

The workflow of the taskforce will take place according to the ensuing steps:

1. Identify domain experts, particularly beyond the LCA community, in order to engage with the top landscape ecologists and biodiversity scientists for a truly robust and internationally recognized indicator. Domain experts may engage directly with the taskforce or participate solely in consensus-building workshops.
2. Determine the relevant evaluation criteria for models of biodiversity change in LCA.
3. Identify impact indicators / models for land use impacts on biodiversity.
4. Assess models against the evaluation criteria, which may be expanded to include biodiversity-specific criteria deemed relevant during the assessment stage.
5. Collect feedback at the SETAC Europe Annual Meeting 2014 (http://basel.setac.eu/?contentid=636), an LCIA workshop, where the taskforce will share results of the method comparisons as well as the analysis and selection of models or model elements to represent the consensus.
6. Frame meetings (expected in autumn-winter 2014-15) to obtain inputs from specialized domain experts on the proposed assessment framework and indicators.
7. Build consensus and refine approaches during year 2, when the taskforce will prepare a report proposing the assessment framework, as well as the selected models and factors, as an input to a Pellston workshop.
8. Hold a Pellston or other technical workshop in 2015 for participants to analyze the inputs from the taskforce, establishing consensus on impact assessment approaches and factors.
9. Make recommendations and publish these in the scientific journals, as a follow-up from the technical workshop.

2.3. Deliverables and expected impact

The flagship project will deliver a global guidance publication with a supporting web system that may include ready to use datasets (impact assessment factors) for download. The publication will also include a critical review of the existing framework for land use impact assessment in LCA, accentuating key elements and shortcomings; plus a brief review of existing indicators and guidance on how to best establish regional impact indicators. In case global consensus on environmental indicators cannot be achieved, the publication will focus on crucial developments needed in order to steer impact assessment methods developers in the right direction.

These deliverables will confer international consensus and credibility to the quantification of environmental impacts on biodiversity generated by production systems in the context of e.g. product environmental footprinting, eco-labelling, etc. It is expected that the results and recommendations of this flagship project will be eventually incorporated into international and national initiatives in these areas.

The taskforce will also try to reinforce its mission by attempting to find connections with other existing similar initiatives. The consensus-finding process will end with a SETAC Pellston workshop, a one week workshop event in a remote location where invited experts and stakeholders discuss and agree on the recommended environmental indicators.

3. Preliminary results and discussion

3.1. Impact pathways

The assessment of LCA models is a necessary step before trying to build consensus in the community. As stated in point 2 of Section 2.2, to set up this assessment, one needs to commit to a set of principles to which the evaluation must conform.

The taskforce initiated this process by revisiting the impact pathways, originally proposed by Koellner et al. (2013a) that lead from LU and LUC to changes in the state of biodiversity. We completed the scheme with a comprehensive description of the main drivers of change and their consequences to variations in biodiversity indicators such as species richness and also ecosystem services provided by biodiversity. The result is shown in Figure 1. Impact assessment models will then be analyzed by assessing the inclusiveness of the pathways described in the figure.

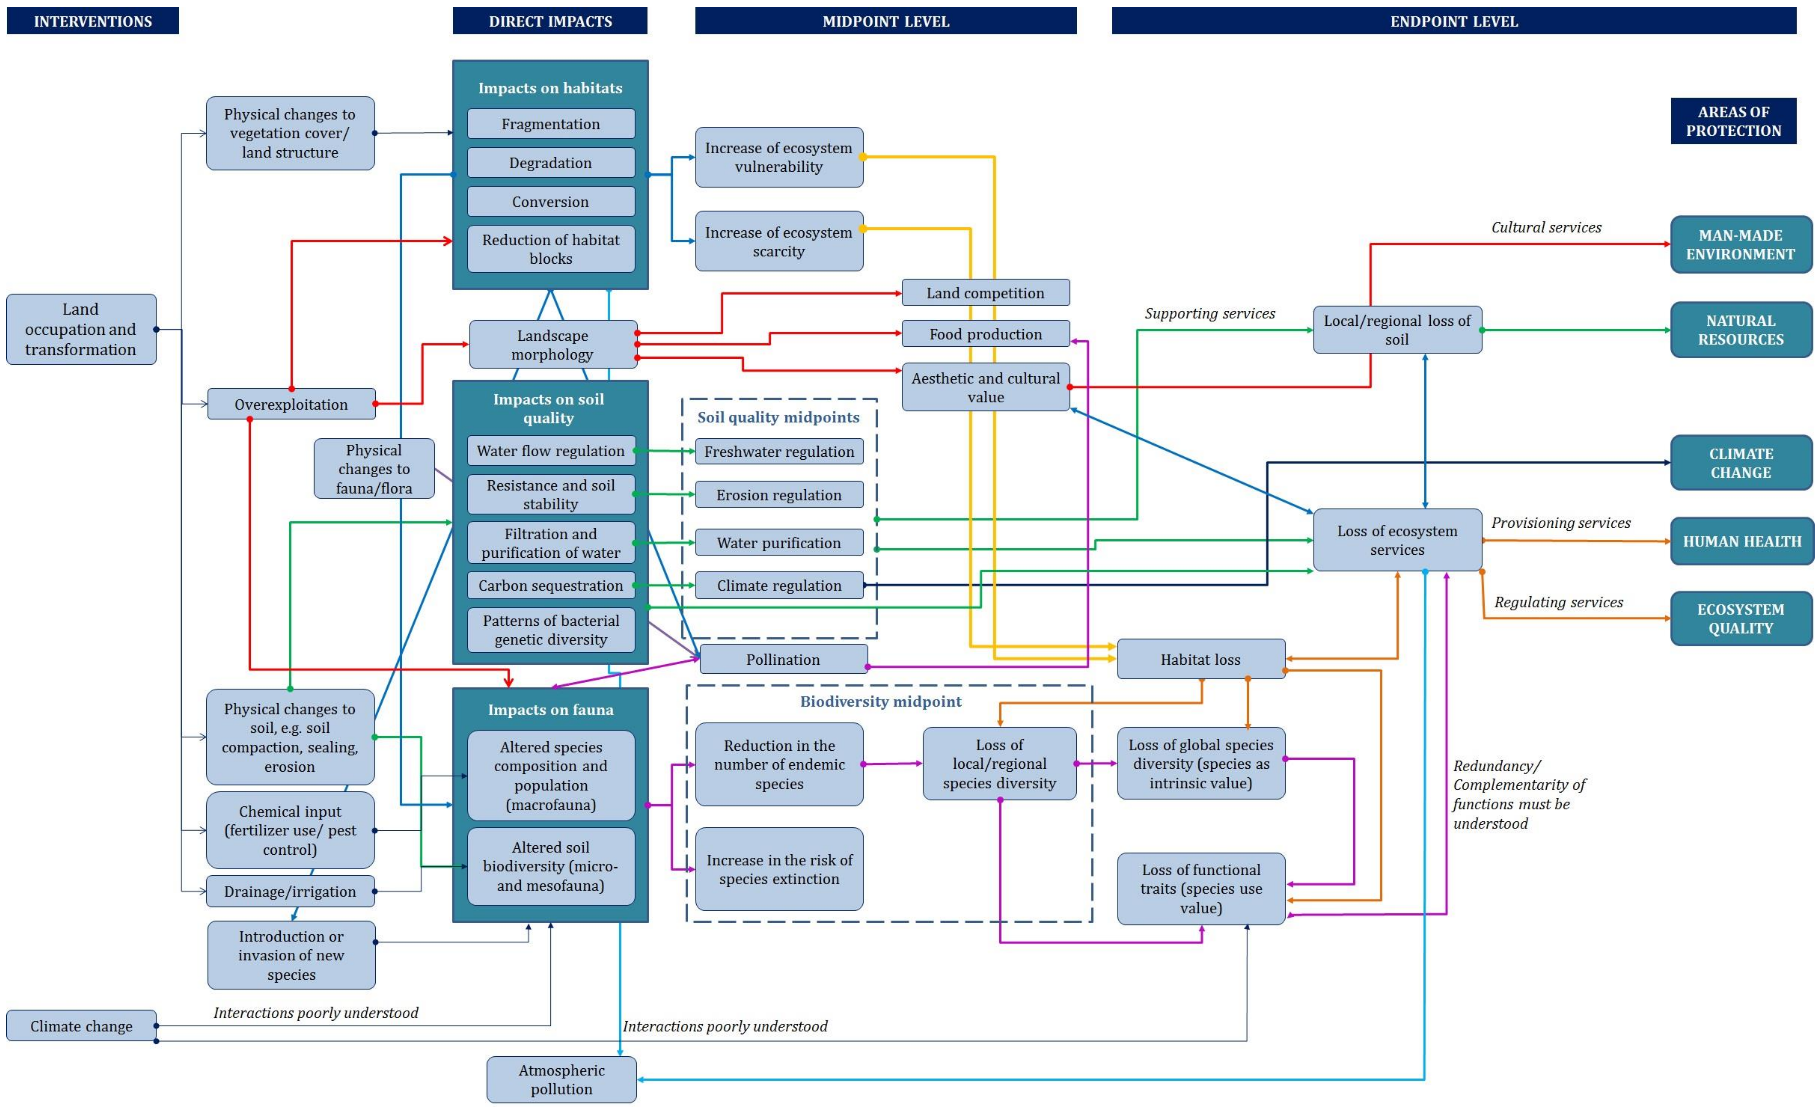

Figure 1. Major impact pathways leading from land use and land use change to changes in the state of biodiversity, and feedback loops that change the state of biodiversity and reinforce / counterbalance early drivers (adapted from Koellner et al. 2013a).

3.2. Review of LCA methods for biodiversity

After the main cause-effect pathways are determined, the taskforce reviews the methods for biodiversity assessment. While this work is still ongoing, some preliminary notes can be drawn from the effort.

Modelling efforts have yielded significant progress in the last two decades (Lindeijer 2000, Weidema and Lindeijer 2001, Brentrup et al. 2002, Koellner and Scholz 2007, Milà i Canals et al. 2007, Michelsen 2008, Schmidt 2008, Penman et al. 2010, de Baan et al. 2013a, de Baan et al. 2013b, Koellner et al. 2013a, Souza et al. 2013, Coelho and Michelsen 2014). These studies follow a systematic procedure that can be systematized in Figure 2.

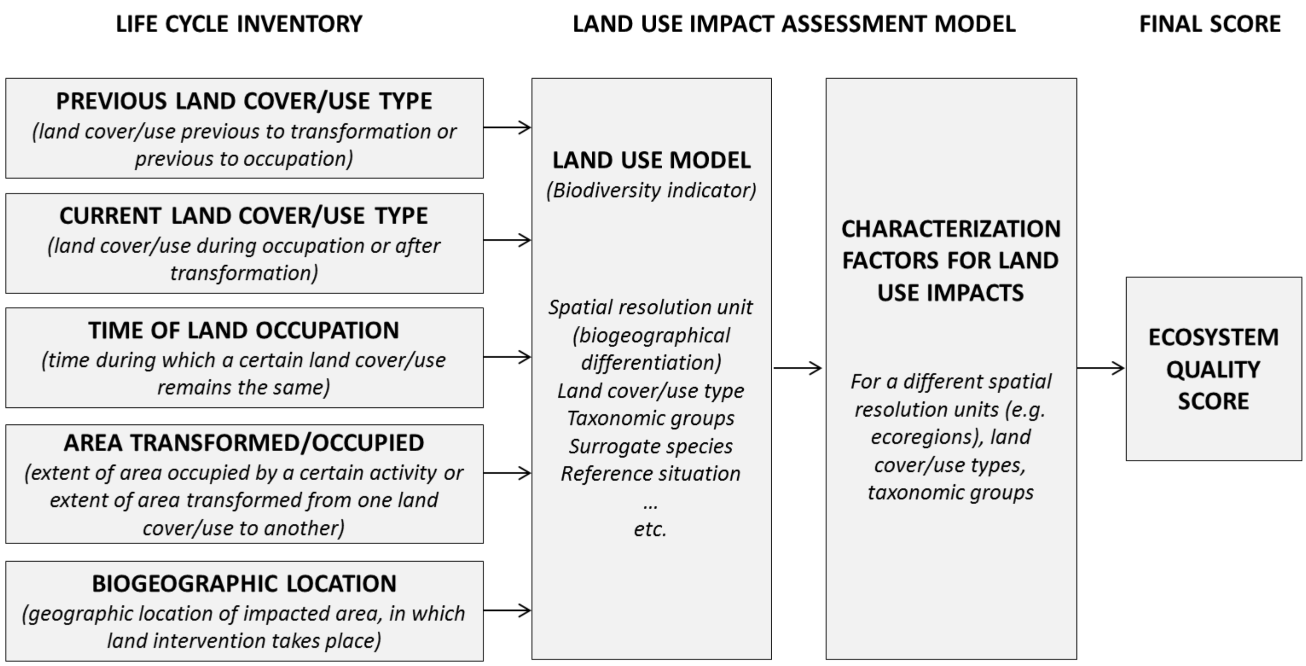

Figure 2. Key elements currently employed on the assessment of land use impacts in LCIA.

The group will extend the scope for identifying models, ideally including models from ecology that may be a good match for LCA even if they currently require some adaptation to fit in the scheme presented in Figure 2.

3.3. Systematic assessment of methods

The taskforce group also developed a systematic evaluation matrix based on the assessment of land use impact indicators performed for the ILCD in 2010. The current version of this matrix includes as relevant categories of assessment, for example, the following evaluation categories:

- *General completeness of scope*. What is the geographic and temporal scope of the assessment offered by the method? What is the reference state and the nature of the indicators (marginal or average impacts)? What is the taxonomic coverage? Are permanent impacts considered and double counting of impacts from different drivers avoided?
- *Compatibility and availability*. Is the method compatible with the established architecture of the overall LCA framework? If not, what would be required to make the method compatible? Are the underlying data and impact factors available for use by LCA practitioners?
- *Environmental relevance*. Does the method include the major impact pathways linking LU and LUC to biodiversity loss? Are the compositional, structural and functional attributes of biodiversity reflected in the midpoint and endpoint indicators? Are impacts across components (genes, species, ecosystems) reflected in the method? Is there a specific link to threatened or rare species and ecosystems?

- *Scientific robustness & certainty*. Are uncertainties quantified and presented in the method documentation? What recommendations can be made to deal with these uncertainties when assessing LU and LUC impacts? The taskforce's mandate includes the involvement of stakeholders, among which are policy-makers and other final users of the results obtained using the method(s) chosen. One crucial aspect is thus determining the usability of the indicator(s) that the group will recommend. This indicator must comply will all scientific requirements, and also provide useful information that practitioners can clearly interpret without being an overburden in the interpretation stage.

Tables 1 and 2 show selected evaluation criteria for the categories of "Completeness of scope" and "Environmental relevance", respectively. Descriptions of the type of questions and specific criteria to check against each method are shown in the third column.

Theme	Evaluation criterion	Description
1. General completeness of scope		
Indicator(s) and model(s)	Marginal (M) or average (A) damage, or not defined (ND)	Is the model based on average damage (A), marginal increase in damage (M), or is it not defined (ND)?
	Cause-effect relationships	The model based on a) best estimate or b) on precautionary cause-effect relationships
	Reference state	What is the reference state assumed by the method? Potential Natural Vegetation (PNV), Historical Reference Vegetation (Historic) or Average Current Vegetation (Average) or a mix depending on the context (Mix)
	Double counting	How are double counting problems when using empirical data addressed? Are they avoided, or not even mentioned? Describe any potential double counting (e.g. common impact attributed twice to interacting inventory flows causing joint effect).
	Number and description of land use/cover classes	Total number of individual land use/cover classes covered with specific characterization factors provided. Score system is based on reference to 33 land use/cover classes listed in Koellner et al. (2012) as a desirable goal, aggregated at a second order of detail (i.e. 1.2.1 = Forest, used, extensive). These are in turn drawn from EcoInvent, Alkemade et al. (2009) and Koellner and Scholz (2007a)
	Intensive/extensive LU class distinction	Do the impact/characterization factors differentiate between intensive and extensive land use classes? In terms of high/low-input agriculture, intensive/extensive pasture, clear-cut or selective forestry? Does it consider the cultural value of landscapes?
	Spillover effect (immigration credit and extinction debt)	Is the spillover effect between reference or original habitat dealt with in the method (or even assessed)? Immigration credit expresses a spatial effect of individual colonizing from nearby natural habitat. Extinction debt and immigration credit involve a time lag in biodiversity loss following conversion. Immigration credit could be, e.g., assessed using a proxy of distance to source habitat, extinction debt using a proxy of time since transformation.
Spatial and temporal characterization	Spatially and temporally explicit characterization	How can the method be applied to another spatial and temporal context? Is the characterization model adaptable to spatially and temporally explicit evaluation, and the input data needed clearly communicated?
	Permanent impacts	Does the method quantify irreversible, permanent impacts (species extinction, biotic or abiotic thresholds such as compaction, topsoil loss, extreme habitat isolation)? How are permanent impacts considered? Using what models and assumptions? Considering which scale?
	Geographic scope	For which geographic scope (regions) are the model and factors determined? What is the origin or scope of the data on which the method is based? List specific locations, single countries (list names), realms (list realm, AA: Australasia, AT: Afrotropic, IM: Indomalay, OC: Oceania, PA: Palaeoarctic, NA: Nearctic, NT: Neotropic), other (specify). Realms based on Olson et al. (2001).
	Spatial resolution	What is the level of spatial resolution of the method (generic/global, realm/continent, national, sub-national, pixel-based)?
	Taxonomic coverage	What is the taxonomic coverage of the method, in terms of the species groups used to develop the indicator: Soil fauna (SF), Herbaceous Plants (HP), Woody Plants (WP), Mosses (Mos), Lichens (Lic), Fungi (Fun), Mammals (Mam), Birds (Bir), Amphibians (Amp), Reptiles (Rep), Arthropods (Art) and other Invertebrates (Inv)

Table 1. Working version of selected criteria included in the method evaluation canvas shown for the category of "*General completeness of scope*". Adapted from ILCD land use method assessment 2010.

Theme	Evaluation criterion	Description
2. Environmental relevance		
General properties	Underlying biodiversity model(s)	Is there a specific underlying biodiversity model used (e.g. species area relationship, habitat suitability models)? Or are values based on an empirical pattern e.g. meta-study)?
	Land transformation framework	How is land transformation considered? E.g. LCIA framework: area x impact x recovery time
	Land occupation framework	How is land occupation considered? E.g. LCIA framework: area x impact x occupation time
Hierarchical components considered by method	Genetic level	Genetic indicators (e.g. allelic diversity, phylogenetic diversity)
	Single-species population level	Population indicators (e.g. population reductions, individually for species or averaged across species, or red list index of threatened species)
	Multi-speicies community level	Community indicators (e.g. richness loss or compositional change)
	Landscape/ecosystem level	Ecosystem indicators (e.g. habitat loss, SAR-based loss, fragmentation, isolation etc.)
Biological attributes considered by method	Composition diversity	Compositional indicators (e.g. relative abundance, presence and relative proportion of biodiversity features)
	Functional diversity	Functional indicators (e.g. ecological processes, nutrient turnover, immigration/emigration, NPP, functional group diversity)
	Structural diversity	Structural indicators (e.g. configuration of elements in space, habitat structure metrics, foliage density, topography, number of vegetation layers etc.)
Conservation relevance of indicator(s)	Quantitative change in species extinction risk	Does indicator measure a quantitative change in extinction risk?
	Vulnerable/red-list or rare/endemic species treated separately	Does the metric take into account threaten status, rare, endemic species distinctly (describe)
	General assemblage (all species) considered (e.g. richness, similarity)	Does it consider only (/in addition) overall assemblage change (i.e. not differentiating between species)?
	Vulnerable/red-list or rare/endemic ecosystems treated separately	Does the metric treat red list, threatened, rare, endemic ecosystems distinctly (describe)
Specific cause-effect pathways via interventions 1...N	Intervention 1: Ecosystem fragmentation and loss Intervention 2: Local vegetation cover modification Intervention 3: Landscape morphology change ...Intervention N	Which cause-effect chains for biodiversity loss are included with acceptable quality? Each environmental intervention has a corresponding cause-effect chain leading to direct impacts on biodiversity. Which indicators are used to assess impacts along the pathway?

Table 2. Working version of selected criteria included in the method evaluation canvas shown for the category of "*Environmental relevance*". Adapted from ILCD land use method assessment 2010.

3.4. Main questions to be addressed

The task force builds upon some key publications (Milà i Canals et al. 2007; Curran et al. 2011; Koellner et al. 2013a; Koellner et al. 2013b) that have experienced strong consensus among experts. These relevant publications, together with the work carried out by the group, allowed the taskforce to draw as early as the first trimester of work some intuitions about what particular aspects of the methodologies are stronger candidates for consensus and which will need more attention. These aspects, summarized next, will likely be the focus in the application of the evaluation criteria.

Three basic areas where there exists some form of preliminary implicit agreement can be highlighted:

- *Key elements in the assessment of land use impacts in LCA*. Occupation (area x time) and transformation (area) are the so called environmental interventions leading to land use impacts. In the current framework, the difference between land quality maintained (occupation) by the production system and a reference situation integrated over time and area is the measure of the impact. The measure of land quality requires agreed impact indicators (Figure 3).

- *Geographical differentiation*. The assessment requires some degree of spatial resolution.
- *Definition of land cover/use types*. A minimum distinction between land use/cover types is required (Koellner et al. 2013b).

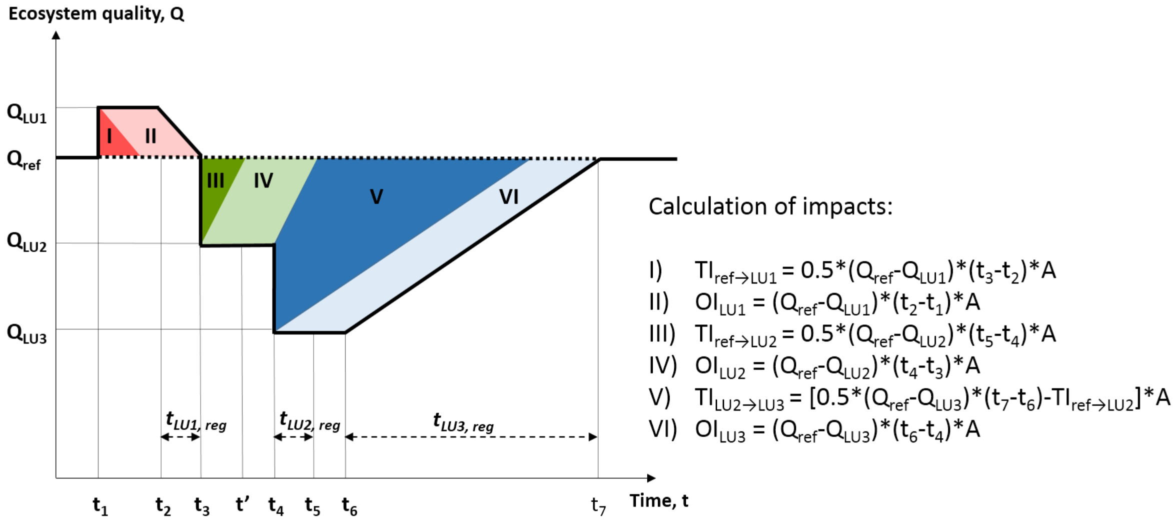

Figure 3. Simplified illustration of transformation impact (TI) and occupation impact (OI) for three land use types with different regeneration rates (tLUI, reg; tLU2, reg; and tLU3, reg). For simplicity, the area A of occupation and transformation, which would embrace the third dimension, is not shown in the graph, but in the equations.

The topics mentioned above will nevertheless be part of the review and eventually (if necessary) the group may recommend improved versions to the way they have thus far been operationalized in LCA.

Similarly, key areas of disagreement or generalized lack of satisfaction with the methods can be identified early and will be taken with care during the consensus-building exercise. These areas include, but may not be limited to:

- *Generic framework of land use impact assessment (Figure 3).* Although the framework in its abstract formulation is subject to widespread agreement, there are aspects in its operationalization that require careful consideration. As examples, there are several options for a reference state: historic, potential natural vegetation, natural climax, present state or others. It is also unrealistic to assume a null transformation time for most land use conversions. The taskforce will consider if it is acceptable, to facilitate consensus, to limit the assessment to occupation and exclude transformation impacts. The group will also equate the consequences of assuming full recovery vs. consideration of irreversibility of damages. We use this issue as an example of the analysis the group is currently performing in section 3.5.
- *Indicator(s) of biodiversity.* The taskforce will consider how best to represent biodiversity – as a single indicator (and in that case which) or in multi-indicator form; this is the main focus area for the task force. Species richness is commonly taken as a proxy to the state of biodiversity, but aspects such as species evenness or species functionality are equally crucial, as well as indicators at different levels (genetic diversity, population dynamics, ecosystem structure, vulnerability or scarcity, among others). Other types of indicators such as structural or pressure indicators are possible and will be assessed. Linked with the indicator(s) chosen, the group will define a set of ecological models used. If the strongest models involve species data, the group will attempt to assess which taxonomic groups should and can feasibly be included in the analysis, and assess current methodologies in face of their assumptions and data availability.
- *Spatial resolution.* The group will consider the scale at which impacts should be measured during impact assessment modelling. Since many ecological models are sensitive to data, it is not a trivial

issue to interpolate country-scale characterization factors from local ones and vice-versa, for example.

- *Impact assessment data requirements*. Linked to on-going data collection / reporting efforts, the taskforce will balance its thoroughness in terms of exhausting the ecological underpinnings of biodiversity change from land use and land use change with what is realistic to implement in LCA. Data limitations, as well as inventory limitations, together with the fact that LCA strives to calculate *potential* impacts, will necessarily require the taskforce to target feasible rather than exact modelling accuracy.

3.5. Example: review of the current framework

Land use impacts in LCA are typically associated with two inventory flows, land occupation and transformation (Lindeijer 2000, Koellner 2003, Milà i Canals 2007), which lead to a change in a defined quality indicator, Q, over a certain time period of time t. This is illustrated by Figure 3.

One crucial variable in this framework is the reference state, since its definition is a key element in the calculation of impacts in the temporal-spatial model. Currently, the so called Potential Natural Vegetation (PNV), as introduced by Tüxen (1956), is used as the reference. PNV concerns the vegetation that would develop in the absence of any human influences and in equilibrium with climatic conditions (Chiarucci et al. 2010). In LCA, land cover/use types are defined by Koellner et al. (2013a).

However, the recovery process of land is dynamic and the species present in the final state may be different – not meaning better or worse - to the original state (Curran et al. 2013). It is also questionable whether the resulting indicator is useful to policy-makers or fair to present-day interventions. Comparisons with, for example, land uses in the recent past could be easier to interpret than comparisons with idealized situations (see e.g. Milà i Canals et al. 2013). Further, although the framework technically allows improvements of ecosystem quality after LUC, the comparison with an idealized semi-natural system normally yields a loss of quality in the majority of situations. The framework also has a hard time dealing with dynamic effects such as temporal summation of impacts, since the past history of the field will have an influence in the ecosystem resilience (e.g. a highly fragmented plot is more likely to see higher quality drops), and thresholds, namely disturbance levels from which the ecosystem is no longer able to recover. To consider these effects one needs to build into the model the concepts of ecosystem resilience and resistance, which is impossible if the scale of the disturbance and the environmental quality of the ecosystem are not measured. This insight is relevant to evaluate biodiversity models.

One of the expected outputs of the task force will be to translate relevant criticisms (such as the reliance on PNV as the baseline for determination of impacts) into recommendations. Using this example, the group identified the baseline of the modeling framework as a limitation and will study alternatives and their consequences. Alternatives to PNV may be country-specific biodiversity targets, a LU mix at a reference year (e.g. 2000), or others.

4. Conclusion

Land use and particularly land use change from natural habitats to cropland and other human land uses is one of the main drivers of biodiversity loss and degradation of a broad range of ecosystem services (Sala et al. 2000, MEA 2005, Lenzen et al. 2009), by means of habitat conversion and/or fragmentation. However, land competition is very likely to increase in the future (UNEP, 2014) and the task to halt biodiversity loss became one of the top global priority issues.

LCA has a decisive word to say because of its nature as an aggregator of direct and indirect impacts allows producers and policy-makers to assign responsibility for damages to biodiversity. Given the importance of the environmental pressures on biodiversity and how much LCA can potentially contribute to conservation targets, it is imperative to align the LCA community around points of consensus, as well as point the way forward to better models that can service the community. The UNEP/SETAC taskforce intends to give a determinant contribution to this shared goal.

Multi-criteria decision analysis of feed formulation for laying hens

ABSTRACT

Increase awareness of environmentally sustainable food products and sustainability reporting in the food industry led to assessment of environmental performance of agri-food products using life cycle assessment (LCA). Feed production is mainly responsible for the overall environmental impact of egg and broiler production. In addition, feed cost accounts for a significant portion of the total cost of egg production. Feed formulation is a complex process of quantifying the amount of feed ingredients to satisfy nutritional requirement of layers. Traditional linear programming models can find least cost combination of feed ingredients that meet nutritional requirements. However, it has limitations of rigidity that cannot solve several conflicting objectives simultaneously. Alternatively, multi-criteria decision analysis (MCDA) can be used to find the optimal combination of feed ingredients that meet nutritional requirements at the lowest possible cost with the minimum carbon footprint. The results suggest that the carbon footprint of feed formulation could be reduced with a modest increase in cost.

Keywords: life cycle assessment (LCA), multi-criteria decision analysis (MCDA), carbon footprint, cost, feed formulation

1. Introduction

Consumer awareness of environmentally sustainable food products and sustainability reporting are responsible for a growing trend in sustainability of the food supply chain. Consumers are more conscious about how foods are produced and their consequential impacts on the environment. Many stakeholders in the food supply chain including producers, processors and retailers are adopting sustainable practices to address consumer demand for environmental friendly products and communicate the environmental profile of their products. Increasingly food retailers are integrating sustainable considerations into their supply chain to reduce cost, to enhance corporate reputation and to differentiate their products from competitors. In response to the demand and need for sustainability reporting, a life cycle assessment has been recently completed to assess the environmental performance of egg production in Alberta.

Key findings of LCA results identified feed production as the main contributor to greenhouse gas emissions (carbon footprint) (70%) of egg production in Alberta. The results were consistent with other LCA studies of egg and broiler production that identified feed production as a major contributor of greenhouse gas emissions (46-80%) from egg and broiler chicken production (Pelletier 2008; Sonesson et al. 2009; Wiedemann and McGahan 2011; Wiedemann et al. 2012). In addition, feed cost accounts for a significant portion (46-54%) of total cost of egg production (Martin et al. 1998). Improvement in the feed formulation can help to optimize feed efficiency.

Feed formulation is a complex process of assembling a blend of feed ingredients that meet the nutritional requirements of layers. Inadequate nutrition may lead to a reduction in egg size and production. Energy, protein and amino acid levels are major factors in feed formulation to achieve the best performance of egg production (Elliot 2012). Traditional linear programming has been used to formulate the least cost combination of feed ingredients that satisfies a specific level of nutritional requirements of layers. However, it has limitations of rigid assumptions that cannot solve several conflicting objectives such as cost minimization and reduction of environmental impact (Castrodeza et al. 2005; Rehman and Romero 1984). Compared to the linear programming, multi-criteria decision analysis (MCDA) is a more flexible method to solve several conflicting objectives simultaneously. Using MCDA, this study builds on the LCA study results to find the best compromise solution to the optimal combination of feed ingredients that satisfies economic, nutritional and environmental criteria.

2. Methods

2.1. LCA of feed ingredients

Carbon footprints of feed ingredients were assessed using ISO standards 14040/14044 (2006). This study included crop production on the farm, the subsequent drying, processing and the transport of feed grain to the farm. The functional unit used was 1 kg of feed ingredient at the gate of the feed mill. Background processes associated with input production (manufactured fertilizers, pesticides, agricultural machinery, and diesel), field operations and the transport of feed grains to the feed mill were adapted from the ecoinvent database (Nemecek and Kagi 2007). The electricity grid mix value was modified using Alberta data for energy sources and electricity importation from other provinces.

Life cycle inventory data for wheat, barley, peas and canola were developed using Alberta crop production data. Two farming systems (conventional and no tillage systems) were modeled for the four crops. Crop yield (2009-2011) and the proportion of each tillage system were used from the Alberta Agriculture Financial Service Corporation (AFSC – crop insurance). Corn, corn dry distiller grains (DDGS), soybean and soymeal were adopted from ecoinvent database using U.S Midwest data. Attributional LCA modelling was applied to the study because the main purpose of the study was to measure the total greenhouse gas emissions of feed ingredients based on average production data and the effects of any changes in level of output were beyond the scope of the study.

Economic allocation was used to allocate environmental impact of the by-products of feed ingredients such as soymeal, canola meal and corn DDGS because physical relationships of feed materials differed significantly from one feed type to another depending on nutritional contents such as energy, protein and essential amino acid (FAO 2014). Moreover, the prices of feed ingredients reflected their nutritional value. In this case, economic allocation was the best possible option to allocate environmental impacts of feed ingredients and their by-products in a consistent manner and on the basis of meaningful relationship between nutritional values and prices (FAO 2014). Limestone, dicalcium phosphate and salt were used from the ecoinvent database. Vitamin premix was used from Nguyen et al. (2012).

Global warming potential was considered as a single environmental impact indicator to analyze in the model because global warming potential was widely used as a standalone impact indicator using internationally recognized greenhouse gas quantification protocols such as ISO/TS 14067 and PAS 2050 to communicate the results to the public through carbon labelling schemes. For life cycle impact assessment method, IPCC 2007 GWP 100a was selected from SimaPro 7.3.3 to evaluate the global warming potential of feed ingredients (Goedkoop et al. 2008; Goedkoop et al. 2010).

2.2. Multi-criteria decision analysis (MCDA) for feed formulation

Multi-criteria decision analysis can be used to find the best comprise solution among several conflicting objectives. In order to model multiple objective programming, it needs to find target values for each of objectives (Tozer and Stokes 2001). This study focuses on two objectives – cost minimization and reduction of carbon footprint. Cost target (C*) and impact target (I*) are solved using traditional linear programming. C* is determined by a LP model of cost minimization as follow:

$$\min C = \sum_{i=1}^{I} \pi_i X_i \qquad 1$$

Subject to:

$$\sum_{i=1}^{I} a_{ij} X_i \geq b_{ij} \ \forall \ j = 1,2,..., J-1 \qquad 2$$

$$\sum_{i=1}^{I} a_{ij} X_i \leq b_j \qquad 3$$

The objective function specified by equation 1 describes the summation of the prices of the i feed ingredients (π_i) multiplied by its amount (X_i) used in the optimal feed formulation. Equation 2 and 3 are recommended nutritional lower and upper bound constraints. The coefficients a_{ij} measure the amount of the jth nutrient in the ith feed ingredients and b_j limit the allowable minimum or maximum amount of the jth nutrient in the feed formulation depending on the sign of inequality. Crude protein (%), metabolizable energy (kcal/kg), available phosphorus (%), calcium (%) and essential amino acids such as methionine (%), methionine + cystine (%), lysine (%), threonine (%), tryptophan (%) and isoleucine (%), are considered as the jth nutrient according to diet specification from commercial poultry nutrition (Leeson et al. 2008). Wheat, barley, corn, corn DDGS, soymeal, canola meal and peas were included as major feed grain crops. Other feed ingredients such as limestone, canola oil, dicalcium phosphate, salt and vitamin premix were also included in the feed formulation based on recommended diet specifications (Leeson et al. 2008).

Diet specifications for layers (60-70 weeks) were used based on guidelines for nutritional requirements of layers from commercial poultry nutrition (Leeson et al. 2008). Nutritional values of feed ingredients were collected from commercial poultry nutrition by Leeson et al. (2008). Price data (2013) for wheat, barley, corn, corn DDGS, soymeal and canola meal were collected from the Alberta Pulse Growers Association. Price of canola oil was used from the Canola Council of Canada. Prices of other minerals and feed supplements were from Masterfeeds - retail bulk price list of July 22, 2013. Nutritional values and prices of feed ingredients are presented in Table 1.

Table 1. Nutritional values and prices of major feed ingredients

Feed	ME (kcal)	C.P (%)	Ca (%)	P (%)	Methionine (%)	Lysine (%)	Threonine (%)	Methionine +Cystine (%)	Isoleucine (%)	Tryptop han (%)	$/tonne
Wheat	3150	13	0.05	0.2	0.2	0.49	0.42	0.41	0.3	0.21	258
Barley	2780	11.5	0.1	0.2	0.21	0.31	0.4	0.42	0.5	0.19	240
Soymeal	2550	48	0.2	0.37	0.72	3.22	1.96	1.51	2.6	0.71	569
Canola meal	2000	37.5	0.65	0.45	0.69	2.21	1.72	1.3	1.4	0.5	338
Corn	3330	8.5	0.01	0.13	0.2	0.2	0.41	0.31	0.29	0.1	290
Corn DDGS	2770	36.5	0.07	0.77	0.5	0.73	0.96	1.04	0.96	0.2	305
Peas	2550	23.5	0.1	0.3	0.3	1.6	0.9	0.5	1.1	0.23	287
Minimum requirement	2800	16	4.6	0.33	0.34	0.73	0.55	0.6	0.53	0.15	

Similar to the finding the minimum cost target, the impact target is solved using the following LP model:

$$\min I = \sum_{i=1}^{I} \pi_i X_i \qquad 4$$

Subject to:

$$\sum_{i=1}^{I} a_{ij} X_i \geq b_{ij} \;\forall\; j = 1,2,\ldots, J-1 \qquad 5$$

$$\sum_{i=1}^{I} a_{ij} X_i \leq b_j \qquad 6$$

The objective function in equation 4 describes the summation of the carbon footprint of the i feed ingredients (π_i) multiplied by its amount (X_i) used in the optimal feed formulation. Equation 5 and 6 are specified by similar procedures to equation 2 and 3.

When the target values (C* and I*) are solved, a multiple objective programming model is solved using the following MINIMAX formulation:

$$Min\ \lambda \tag{7}$$

Subject to:

$$\sum_{i=1}^{I} a_{ij} X_i \geq b_{ij}\ \forall\ j = 1,2,...,J-1 \tag{8}$$

$$\sum_{i=1}^{I} a_{ij} X_i \leq b_j \tag{9}$$

$$\sum_{i=1}^{I} \pi_i X_i = C \tag{10}$$

$$\sum_{i=1}^{I} \pi_i X_i = I \tag{11}$$

$$w_C (C - C^*)/C^* \leq \lambda \tag{12}$$

$$w_I (I - I^*)/I^* \leq \lambda \tag{13}$$

The objective function of the multiple objective model minimizes λ ,which is the weighted percentage deviations from the target values for each of the two objectives. The constraints specified by equation 12 and 13 measure percentage deviations from the target values when the weights for the goals $(W_C \text{ and } W_I)$ are equal to one. However, the model is flexible to adjust the weights that reflect a decision maker's priority over each objective.

3. Results

3.1. Carbon footprint of feed ingredients

Results of global warming potential (GWP 100a) ranged from 0.012 to 1.799 kg CO_2e/kg of feed ingredient (Table 2). Canola oil had the highest GWP while limestone had the lowest GWP. Among major feed crops, corn DDGS had the highest GWP, followed by wheat and corn which had greater GWP than barley, canola meal, peas and soymeal. For major protein feed ingredient, GWP of soymeal was higher than that of canola meal. Fertilizer production and its emissions from field application was a major contributor to GWP of feed crops. Transportation was mainly responsible for GWP of imported feed grains such as corn, corn DDGS and soymeal which accounted for 41, 33 and 19 % of total impact of GWP.

3.2. Least cost feed formulation

Least cost feed formulation had the lowest cost of $282/tonne and 562 kg CO_2e/tonne. The feed formulation contained wheat (18%), barley (25%), canola meal (8.7%), peas (19.7%), corn DDGS (17%), limestone (11%) and others[1] (1.3%). As energy and protein are essential for layer feed, unit cost/crude protein (%) and energy (1000 kcal) are calculated and presented in Figure 1. Wheat, barley and corn had the lower level of cost per unit energy while soymeal, canola meal, peas and corn DDGS had the lower cost per unit protein. Corn had the highest cost per protein content and soymeal had the highest cost per energy content. Both corn and soymeal had a huge gap of trade-off between energy and protein content. In terms of cost minimization, corn DDGS was more competitive than corn.

[1] Others included canola oil, dicalcium phosphate, salt and vitamin premix.

Table 2. Carbon footprint of feed ingredients (kg CO_2e/tonne)

Feed	kg CO_2e/tonne
Wheat	662
Barley	425
Soymeal	541
Canola meal	406
Corn	656
Corn DDGS	1153
Peas	435
Limestone	12
Canola oil	1799
Dicalcium phosphate	970
Salt	226
Vitamin premix	680

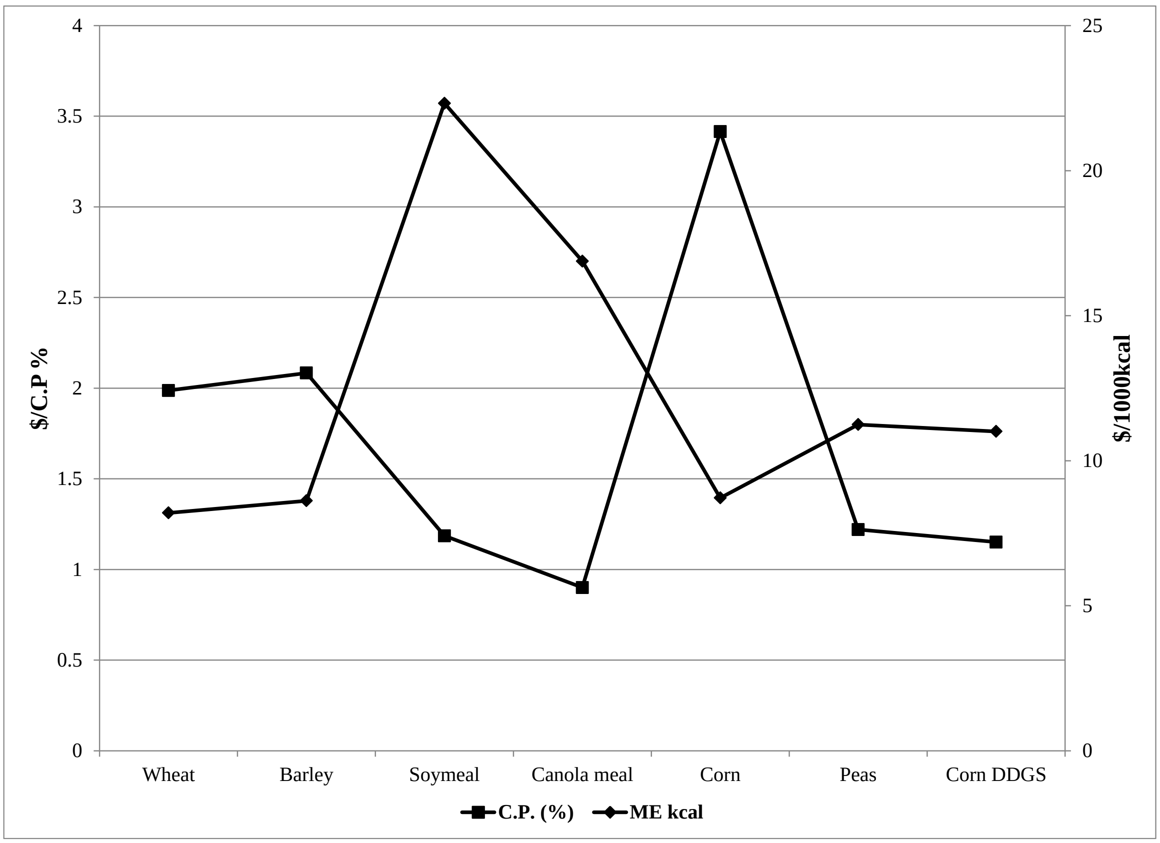

Figure 1. Unit cost per crude protein (%) and energy (1000 kcal) of major feed ingredients

3.3. Low-impact feed formulation

Low-impact feed formulation had the minimum level of 403 CO_2e/tonne and feed cost of $296/tonne. Low-impact feed reduced the carbon coefficient by 159 kg CO_2e/tonne (28%) at an increase cost of $13/tonne (4.5%). The feed formulation contained barley (59%), soymeal (9.5%), canola meal (8.5%), peas (12%), limestone (11%) and others (1.3%). Carbon footprint per crude protein (%) and energy (1000 kcal) are presented in Figure 2. Soymeal and canola meal were more competitive than peas and corn DDGS for crude protein. Wheat, corn and corn DDGS had a higher carbon footprint per unit crude protein and energy content. Barley, soymeal, canola meal and peas had the lower level of carbon footprint per both nutritional values.

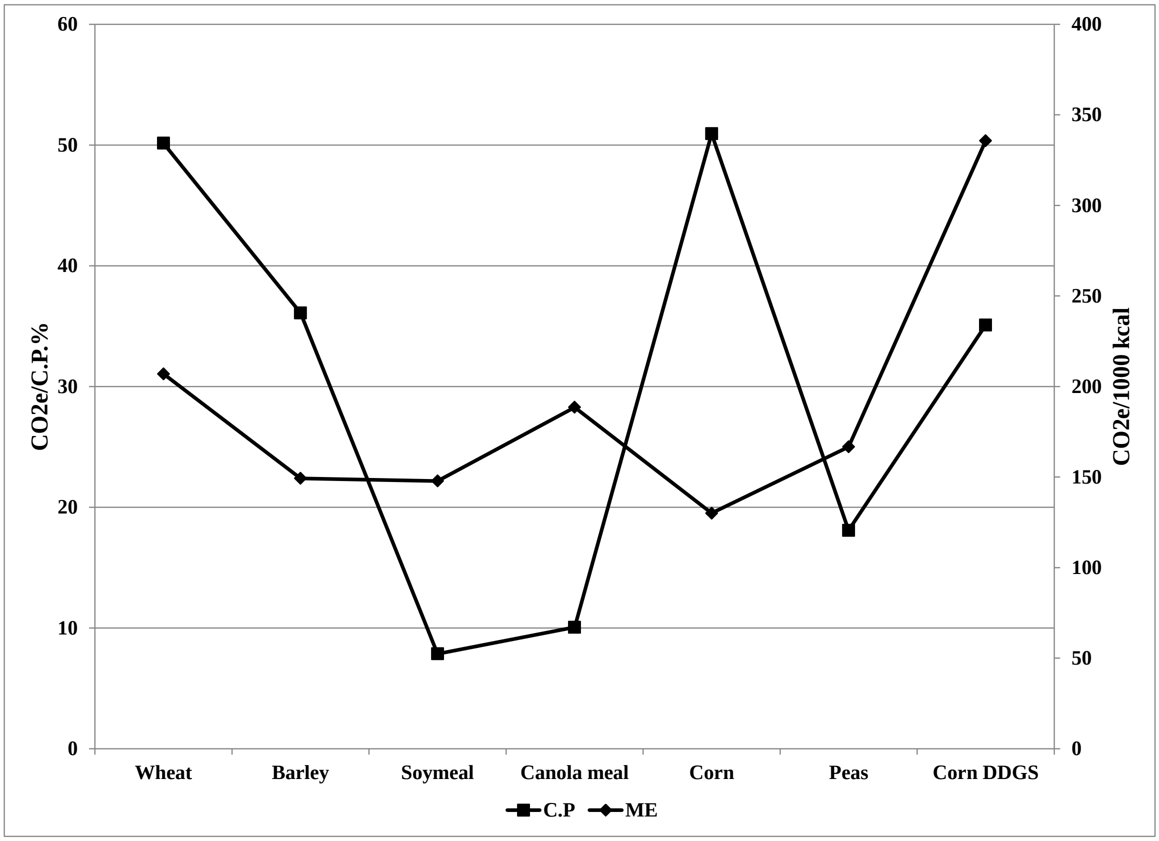

Figure 2. Carbon footprint per unit of crude protein (%) and metabolizable energy (1000 kcal) for seven major feed ingredients

3.4. Multiple objective solutions

The lowest cost ($282/tonne) from the least cost feed formulation and the minimum level of carbon footprint (403 CO_2e/tonne) from the low-impact feed formulation were used as the target levels of the two objectives – least-cost and low-impact. Multiple objective programming was solved under three different weighting scenarios for the two targets – equally weighted scenario (W_{LC} = W_{LI}= 1), cost heavily weighted scenario (W_{LC} = 2, W_{LI}= 1) and carbon footprint heavily weighted scenario (W_{LC} = 1, W_{LI}= 2).

The results of least cost, low-impact and three multiple objective solutions are presented in Figures 3 and 4. For the solution of equally weighted scenario (W_cW_i), the cost of feed formulation was $291/tonne, an increase over the least cost formulation of $9/tonne or 3% and, the carbon footprint was 411 kg CO_2e/tonne with a marginal decrease of 151kg CO_2e/tonne or 27% compared to the least cost formulation (LC). For the solution of the carbon footprint heavily weighted scenario ($1W_c2W_i$), the cost and carbon footprint of feed formulation were $296/tonne and 403 kg CO_2e/tonne that increased the cost by $14/tonne or 5% and decreased the footprint by 159 kg CO_2e/tonne or 28% compared to the least cost formulation. The results were almost the same as those of the low-impact (LI) feed formulation ($295/tonne and 403 kg CO_2e/tonne). Compared to the results of the equally weighted solution (a 3% cost increase and a 27% CO_2e reduction), the low-impact and the carbon footprint heavily weighted scenarios cost more (a 5% cost increase) but reduced relatively similar amount of the carbon footprint (a 28% CO_2e reduction). Therefore, both solutions are not optimal in terms of the marginal changes in cost and carbon footprint.

For the solution of the cost heavily weighted scenario ($2W_c1W_i$), the cost of feed formulation increased by only $1/tonne or 0.35% compared to the least cost formulation but the carbon footprint decreased by 105 kg CO_2e/tonne or 19%. The solution of the cost heavily weighted scenario was more feasible than that of the equally weighted scenario in terms of the marginal changes in cost and carbon footprint. Compared to the least cost formulation, a major change in these formulations was the substitution of wheat and corn DDGS by barley, peas and soymeal. The results indicated that wheat and corn DDGS had relatively higher carbon footprints with respect to crude protein and energy content in the diet than did other feed ingredients.

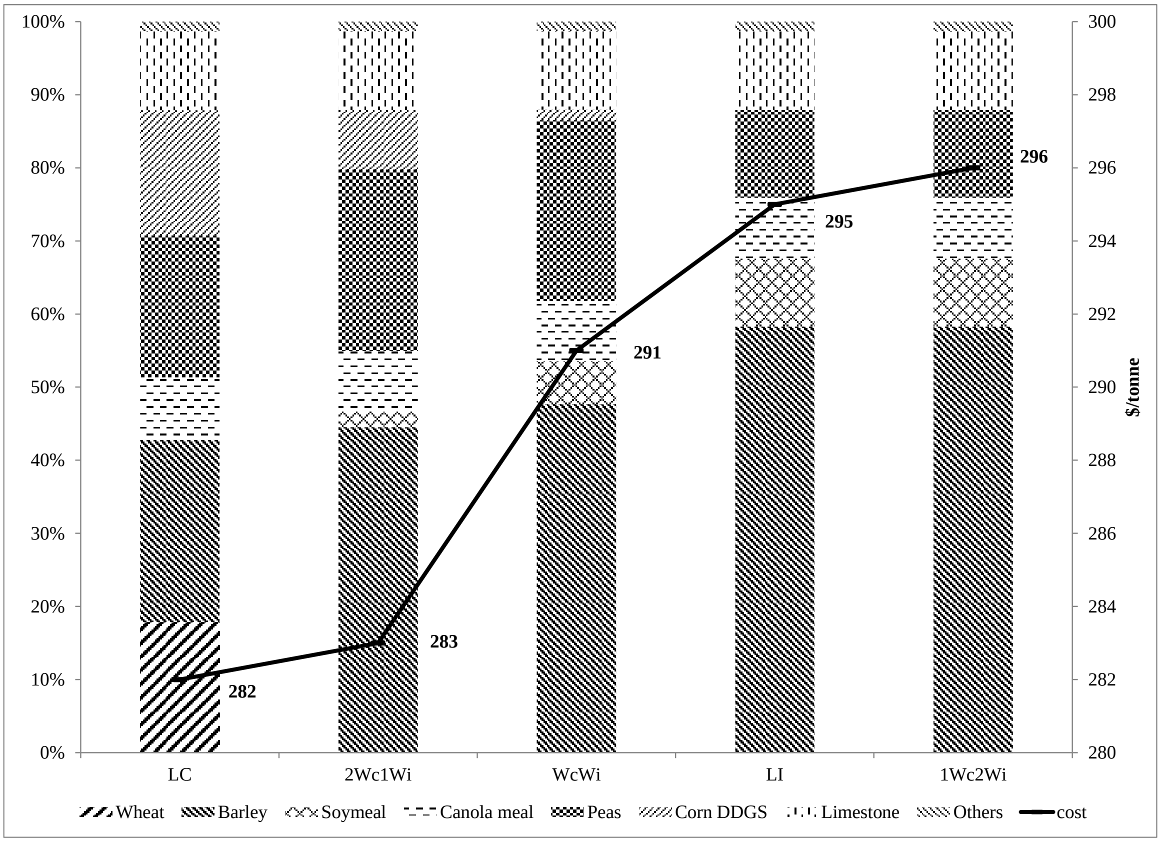

Figure 3 Optimal feed formulations and costs for five different scenarios

Note: LC, LI, W_cW_i, $2W_c1W_i$ and $1W_c2W_i$ stand for least cost scenario, low-impact scenario, equally weighted multiple objective scenario, cost heavily weighted multiple objective scenario and carbon footprint heavily weighted multiple objective scenario respectively.

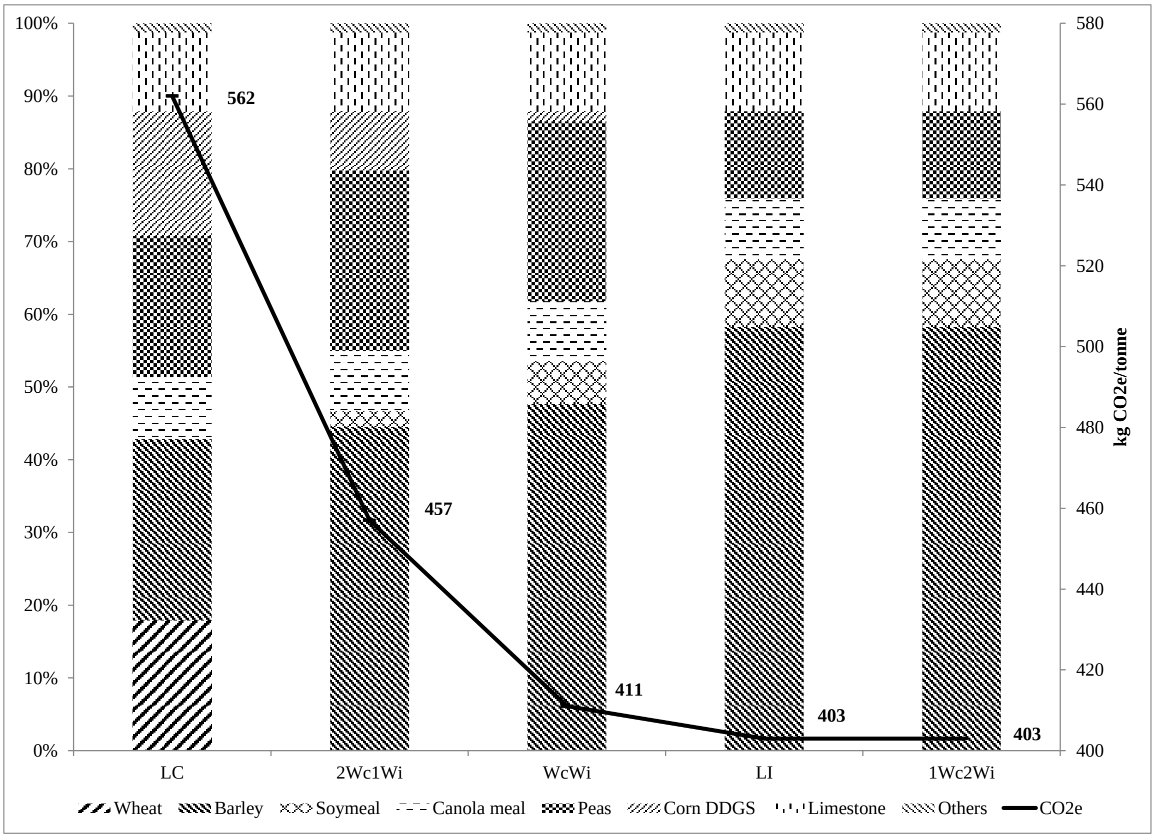

Figure 4 Optimal feed formulations and carbon footprints for five different scenarios

Note: LC, LI, W_cW_i, $2W_c1W_i$ and $1W_c2W_i$ stand for least cost scenario, low-impact scenario, equally weighted multiple objective scenario, cost heavily weighted multiple objective scenario and carbon footprint heavily weighted multiple objective scenario respectively.

4. Discussion

As feed production contributes to a large environmental impact of livestock production, feed has become a targeted environmental hotspot of attention in livestock production systems. The environmental impact of feed production could be reduced by supplementation with synthetic amino acids and inclusion of locally grown and low impact feed ingredients in feed formulations (Eriksson et al. 2005; Mosnier et al. 2011; Nguyen et al. 2012). Mosnier et al. (2011) found that the incorporation of synthetic amino acids in pig and broiler feeds could reduce the use of high impact Brazilian soymeal, resulting in a lower carbon footprint of feed formulations. Eriksson et al. (2005) investigated the impact of feed choice of pig production using three alternative scenarios of protein supply. The results indicated that feed formulation based on peas and rapeseed meal supplemented with synthetic amino acid was environmentally preferable because of the exclusion of high impact soymeal from the feed. Nguyen et al. (2012) confirmed that carbon footprint and eutrophication potential of poultry feeds could be reduced by the substitution of soymeal and cereals by rapeseed meal, grain legumes and co-products (wheat bran, gluten) with about a 2-8% increased cost.

Similar to the study of Nguyen et al. (2012), the results of this study suggest that carbon footprint of feed formulation could be reduced with a modest increase in the feed cost. Each feed ingredient has the strength and weakness in terms of cost and carbon footprint with respect to protein and energy content. Corn DDGS is more competitive than corn because corn DDGS contains a relatively high level of energy and protein compared to corn which contains more energy and less protein. Wheat is also a competitive feed ingredient because the unit cost per protein and energy is similar to that of barley. However, the low-impact formulation does not include wheat and corn DDGS because both feed crops have a higher carbon footprint. Barley, peas and canola meal have become major feed ingredients in terms of both cost minimization and reduction of carbon footprint. However, the inclusion of large proportion of barley in feed formulation requires adding non-starch polysaccharide (NSP) enzymes to layer feeds to enhance energy digestibility (Geraert and Dalibard 2003). Peas and canola have limitations of inclusion in formulations so that the amount of peas cannot exceed more than 30% and the amount of canola meal cannot exceed more than 10% (Hickling 2003; Newkirk 2009). Therefore, it is important to consult with poultry nutritionists about any suggested changes in feed formulations so that nutritional requirements and ingredient limitations are not compromised.

5. Conclusion

Carbon footprints of feed formulations could be reduced using low impact feed ingredients while satisfying nutritional requirement of laying hens. The feed cost will be higher in order to reduce carbon footprint of feed formulation. However, it is possible to find a lower carbon footprint of formulated feed at a reasonable cost. Barley, peas and canola meal play a major role to reduce the carbon footprint of feed formulation. Multi-criteria decision analysis could be used as a tool to achieve the best possible combination of feed ingredients at the lowest possible cost using multiple objective programming. This tool will help Alberta egg producers develop eco-efficient feed formulations that demonstrates industry's commitment to environmental sustainability.

ABSTRACT

Rising food demand, rapid urbanization, industrial development and climate change all lead to pressure on freshwater resources. Agriculture is one of the largest users of global freshwater resources, accounting for about 70% of freshwater withdrawals for irrigation. Irrigation accounts for 84% of the total surface water use in the South Saskatchewan River Basin (SSRB) in Alberta. A projection of 53% increase in freshwater use in the SSRB by 2030 could lead to additional pressure on freshwater resources in the region. This study assesses the impact of current and future freshwater use on regional water deprivation impact potential. The result suggests that the water stress index (WSI) and the blue water footprints for a future freshwater use scenario were three times higher than those for the current freshwater use scenario. A combination of increasing irrigation efficiency and improving crop water use efficiency will be an effective way to mitigate pressures of water stress.

Keywords: Water footprint, Water deprivation potential, Freshwater, Irrigated potato, Alberta

1. Introduction

Freshwater use has become a major social and environmental concern in the last two decades. This is due to rising food demand, rapid urbanization, industrial development and climate change which are significantly increasing pressure on freshwater resources (Ridoutt and Pfister 2010; Gheewala et al. 2013). Agriculture is one of the largest users of freshwater resources globally, accounting for about 70% of freshwater withdrawals for irrigation. Alberta has approximately 70% of the irrigated land in Canada. Alberta sources all of its irrigation water from rivers and reservoirs which accounts for 84% of the total freshwater use in the South Saskatchewan River Basin (SSRB) in Alberta (AMEC 2009). Irrigation water use is competing with other demands for freshwater such as urban and industrial consumption.

Global scenarios for future water demand and supply have identified major drivers of change in water demand in order to understand possible changes in the water footprint of production and consumption and to formulate alternative strategies for meeting increased demand for water (de Fraiture and Wichelns 2010; Ercin and Hoekstra 2014). The results of the scenario analyses suggested that future demand for freshwater use would increase significantly and it could exacerbate freshwater scarcity problems unless appropriate action was taken to improve irrigation efficiency and water use efficiency.

Similar to the global scenario analyses, a study of current and future water use in Alberta was conducted to establish a baseline assessment of current water use, to project future water use and to identify potential improvement strategies to meet future freshwater demand. A projection of water supply for the SSRB in Alberta forecasts that water use in the basin will increase 53% from the current 1.98 km^3 to about 3.04 km^3 by 2030 mainly due to expansion of irrigation districts (AMEC 2009). The water demand and supply study did not address a question of how future increased freshwater demand will impact the water footprint of primary agricultural production in Alberta. Therefore, this study assesses the impact of future freshwater use on the water footprint of irrigated potato production in Alberta and identifies potential mitigation strategies to alleviate future water deprivation potential. Potato production is chosen for the study because it is a high value crop, one of the major irrigated speciality crops in southern Alberta and processed potatoes are primarily dependent on irrigation water.

2. Methods

2.1. Water stress index

The water stress index (WSI) developed by Pfister et al. (2009) was used to calculate regional water stress characterization factor relevant to the SSRB in Alberta where most of the irrigated potato production exits. WSI is adjusted to a logistic function ranging from 0.01 to 1 (0.01=low water scarcity, 1= high stress) using a ratio of total annual freshwater withdrawal to hydrological availability (WTA) with modifications to account for monthly and annual variability of precipitation and corrections to account for watersheds with strongly regulated flows (Ridoutt and Pfister 2010).

AMEC (2009) assessed current and future water supply and demand in the SSRB with the Water Resource Management Model (WRMM). The model considered water supplies, natural water flows, precipitation, configuration of streams, canals and water management infrastructure, consumptive and in stream demands, water license priorities, water management policies and operating plans. The SSRB is comprised of four sub-basins: Red Deer, Bow, Oldman and South Saskatchewan. For future water use in 2030, it was assumed that there would be a 32% expansion of irrigation district areas in the Bow sub-basin and a 19% expansion in the Oldman sub-basin. Current water availability, current water use and future water use of the SSRB were taken from AMEC's Water Resource Management Model to calculate the withdrawals to hydrological availability (WTA).

The calculated WTA was adjusted by variation factors of monthly and annual precipitation of four sub-basins in the SSRB. Monthly and annual precipitation normals (1961-1990) were obtained from the AgroClimatic Information Service (ACIS) of Alberta Agriculture and Rural Development (ARD). Coefficients of variation of monthly and annual precipitation for each water sub-basin were calculated using 1600 township weather data[1]. The variation factor of the SSRB was calculated using a weighted average of variation factors and the mean annual precipitation of four sub-basins.

The water stress indices of the whole sub-basins in the SSRB were calculated for current water use and future water use scenarios by using the WTA for both scenarios and the variation factor. The WSI was used as a midpoint characterization factor to measure the water deprivation impact potential. As this study focuses on freshwater use and its impact on regional freshwater deprivation potential, the water deprivation potential is calculated by multiplying the blue water footprint with the WSI for the current and future use scenarios.

2.2. Water footprint

In terms of virtual water, water consumption is divided into three categories: green, blue and grey (Hoekstra et al. 2011). The green water consumption describes the evapotranspiration of rainwater during plant growth, which is especially relevant for agricultural products. Blue water consumption describes the volume of ground and surface water that evaporates during production, especially important for irrigated agriculture systems (Ridoutt and Pfister 2010). Grey water consumption describes the total amount of water required to dilute the used water until it reaches commonly agreed quality standards. Grey water consumption is excluded from this study because other LCA studies measure the impact of grey water as eutrophication and acidification potential in life cycle impact assessment (LCIA).

Crop water requirements of potato production for six locations from three irrigation districts (2011) were obtained from the Alberta Irrigation Management Model (AIMM, ARD 2014). The AIMM calculates daily evapotranspiration values over a growing season (May 15 to September 30) using daily climate data from the climate information network stations and crop coefficients and reference evapotranspiration of Penman-Monteith equations developed by Allen et al. (1998). Green and blue water footprints were calculated using the water footprint assessment method developed by Hoekstra et al. (2011). Irrigated potato yield for 2011 was obtained from Agriculture Financial Service Corporation (AFSC, 2012).

The US potato production data were adapted from ecoinvent database to estimate indirect blue water consumption for crop inputs and field operations (Nemecek and Kagi 2007). Data on field operations and

[1] Township weather data were calculated using a mathematical data interpolation method that weighted up to the 8 nearest station observations (ACIS 2013).

transportation was used from the US potato production because cultivation methods were similar across the North American commercial potato production system. Fertilizer production was modified using Alberta/Canada electricity grid mix. Fertilizer application rates were used from fertilizer recommendations for irrigated potato by Alberta Agriculture and Rural Development. Pesticide use was calculated from the 2011 Potato Crop Weed and Pest Control Guide, Prince Edward Island Department of Agriculture. Indirect blue water consumption of potato production was calculated by Impact 2002+ version 2.2 method in SimaPro 7.3.3 (Humbert et al. 2012; Goedkoop et al. 2010).

2.3. Sensitivity analysis

Sensitivity analyses of the future blue water footprint were conducted to identify potential mitigation strategies for alleviation of freshwater deprivation potential. Irrigation water conveyance efficiency, application efficiency and water use efficiency were also included in the analysis. The first sensitivity analysis included a combination of 4.3% increase in conveyance efficiency and 15% increase in application efficiency[2]. It is assumed that irrigation efficiency could be increased by improving irrigation infrastructure and adopting more efficient application equipment. The second and third sensitivity analyses included a 10% and 20% increase in potato yield (increased water use efficiency). It is assumed that potato yields could be increased by varietal and agronomic improvements.

3. Results

Water stress indices (WSI) of South Saskatchewan River Basin were 0.2078 for the current water use scenario and 0.5981 for the future water use scenario in 2030. An increase of 53% in future freshwater use could change from the current very mild water deprivation potential to a moderate severe water deprivation potential in the SSRB because a higher level of water withdrawal leads to a higher value of freshwater WTA, resulting in a higher value of WSI. The results of WSI for current and future freshwater use scenarios suggest that an expansion of irrigated areas in the SSRB would necessitate a determination of what is a sustainable level of irrigation withdrawals from the basin.

Irrigation water requirements of potato production ranged from 146 to 353 mm yr^{-1} depending on potato evapotranspiration (mm) and precipitation (mm) (Table 1). Grassy Lake required the lowest level of irrigation water because it had the highest level of precipitation. Conversely, Seven Persons required the highest level of irrigation water because of the lowest level of precipitation in the region. Both Grassy Lake and Seven Persons were located in the South Saskatchewan sub-basin. Total irrigation water requirement of potato production ranged from 179 to 433 mm after conveyance and application water losses were taken into account.

The total water footprint of potato production ranged from 133 to 158 L/kg (Table 2). As previously mentioned, the study focused on freshwater use and its impact on regional water deprivation potential so the water deprivation impact potential of blue water was calculated multiplying blue water with the water stress index (WSI) of the SSRB. The stress-adjusted blue water footprints are presented in Table 3. The results of the future freshwater use scenario in all regions were about three times greater than the current freshwater use scenario because the value of the WSI for future water use was about three times higher than those of current water use.

[2] Water conveyance efficiency is the ratio between the irrigation water that reaches a farm or field to that diverted from the water source. Water application efficiency is a measure of the fraction of the total volume of water delivered to the farm or field to that which is stored in the root zone to meet the crop evapotranspiration needs (Irmak et al. 2011).

Table 1. Parameters used for calculation of irrigation water requirement for irrigated potato production

Irrigation District	St. Mary	St. Mary	St. Mary	Taber	Taber	Bow River
Location	Seven Persons	Bow Island	Grassy Lake	Fincastle	Barnwell	Enchant
Potato yield (tonne/ha)	41	41	41	41	41	41
Conveyance efficiency (%)	93.7	93.7	93.7	93.7	93.7	93.7
Irrigation application efficiency (%)	80	80	80	80	80	80
Evapotranspiration (mm)	486	435	441	484	478	437
Precipitation (mm)	133	155	295	187	260	172
Irrigation water requirement (mm)	353	283	146	297	218	265
Conveyance loss (mm)	9	7	4	8	6	7
Irrigation application loss (mm)	71	56	29	59	44	53
Total irrigation water requirement (mm)	433	343	179	364	267	325

Table 2. Water footprint of irrigated potato (per hectare and per kg of potato)

Irrigation District	St. Mary	St. Mary	St. Mary	Taber	Taber	Bow River
Location	Seven Persons	Bow Island	Grassy Lake	Fincastle	Barnwell	Enchant
Green WF (m^3/ha)	1330	1550	2950	1870	2600	1720
Direct blue WF (m^3/ha)	4458	3536	1844	3751	2753	3347
Total WF (m^3/ha)	5788	5086	4794	5621	5353	5067
Green WF (L/kg)	33	38	73	46	64	42
Direct blue WF (L/kg)	110	87	45	92	68	82
Indirect blue WF (L/kg)	15	15	15	15	15	15
Total WF (L/kg)	158	140	133	153	147	139

Table 3. Water Stress Index-weighted blue water footprint of irrigated potato (L/kg) for two different water use scenarios

Irrigation District	St. Mary	St. Mary	St. Mary	Taber	Taber	Bow River
Location	Seven Persons	Bow Island	Grassy Lake	Fincastle	Barnwell	Enchant
WSI=0.2078 current water use	26	21	13	22	17	20
WSI=0.5981 future water use	75	61	36	64	50	58

Results of the sensitivity analyses are presented in Table 4. The results confirmed that an increase in irrigation efficiency and water use efficiency could alleviate future freshwater deprivation potential of potato production. Increased irrigation efficiency reduced about 11-13% in the blue water footprint. A 10% potato yield increase reduced the blue water footprint by 6-8%. And a 20% potato yield increase reduced about 22-25% of the blue water footprint.

Table 4. Sensitivity analyses for irrigation efficiency and potato water use efficiency (blue water footprint L/kg)

Irrigation District	St. Mary	St. Mary	St. Mary	Taber	Taber	Bow River
Location	Seven Persons	Bow Island	Grassy Lake	Fincastle	Barnwell	Enchant
Baseline	75	61	36	64	50	58
Increased irrigation efficiency	65	53	32	56	43	51
10% yield increase	69	56	34	59	46	54
20% yield increase	56	46	28	48	38	44

4. Discussion

An increase in irrigation freshwater use could lead to a moderate-severe level of regional freshwater scarcity. A projection of a 53% increase in freshwater demand by 2030 is not sustainable in terms of regional freshwater withdrawals to hydrological availability. However, sensitivity analyses indicate that increased irrigation efficiency and water use efficiency could alleviate the severity of regional freshwater scarcity.

In order to maintain sustainable consumption of freshwater resources in the region, it is necessary to develop strategies for sustainable freshwater resource management including improvement in irrigation efficiency, increased water use efficiency and the development of new drought resistant and short growing season varieties (Ridoutt and Pfister 2010; Gheewala et al. 2013). Although most potato growers already use efficient irrigation systems (low pressure pivot sprinkler systems) in the SSRB, there is still room for improvement in irrigation efficiency through adoption of new advanced irrigation systems such as LEPA (low energy precise application) sprinkler irrigation systems, variable rate irrigation systems (VRI) and, advanced management such as adequate irrigation scheduling.

Crop water use efficiency plays a major role in alleviating water scarcity because irrigation water requirements of crop production mainly depend on crop evapotranspiration (Gheewala et al. 2013). The development of drought resistant and high-yield crop varieties could potentially minimize the water footprint of crop production. Figure 1 illustrates that the average potato yields have increased by about 25% over the past the two decades due to varietal and agronomic improvements. Improvement in crop yield could lower the water footprint of agricultural products. An integrated management of freshwater resources combining strategies for increasing irrigation efficiency and improving crop water use efficiency will be an effective way of reducing the blue water footprint of irrigated crop production and alleviating the water deprivation potential in the region.

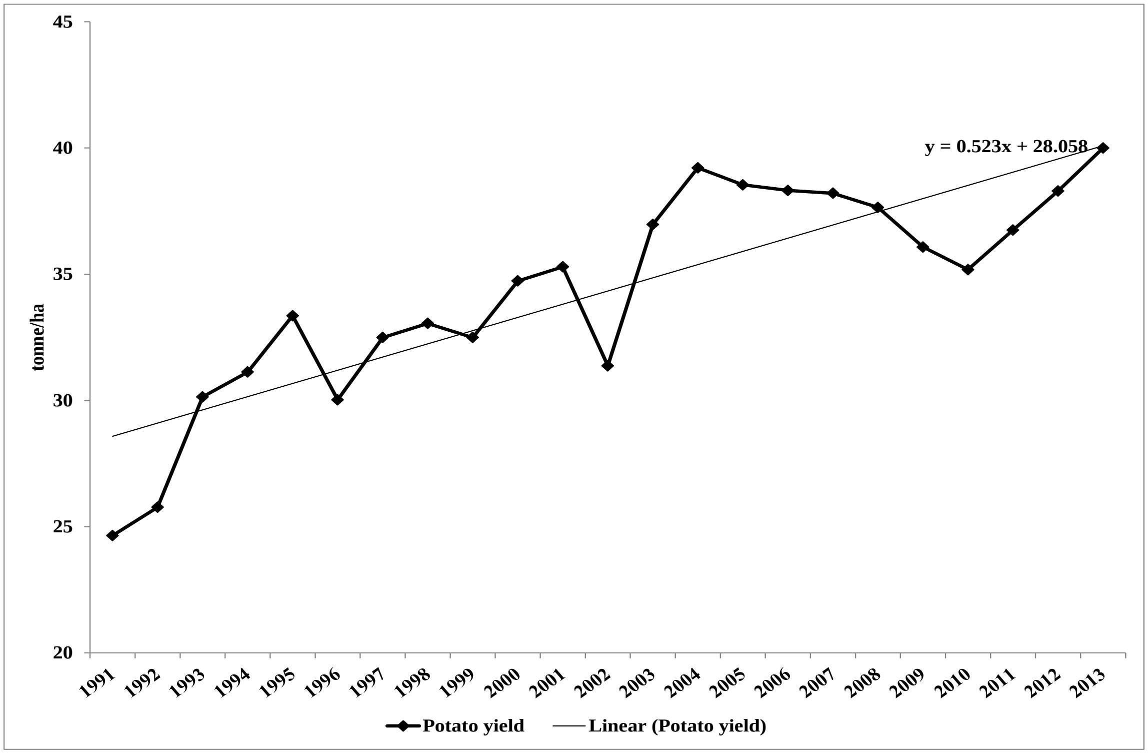

Figure 1. Average potato yield in Alberta (1991-2013)
Source: Statistics Canada, CANSIM Database (1991-2013)

5. Conclusion

Increased water use for irrigation could lead to additional pressure on freshwater resources and in a greater blue water footprint of irrigated potato production. A regional water stress index is a relevant characterization factor to measure local water scarcity in the particular region. Therefore, the WSI can be used to assess the impacts of different scenarios of water use and supply on regional water deprivation potential. A combination of increased irrigation efficiency and an improvement in crop water use efficiency will be essential to mitigate increase pressures of water stress.

ABSTRACT
Different methods have been used in LCAs to handle emissions related to livestock manure. Usually, the emissions from use of manure are attributed to the crop production. In this study, an alternative approach is suggested where manure is considered as a co-product from the livestock production. With this approach, the livestock production system 'pays' all environmental costs related to emissions from manure. However, the livestock system also gets credit for the fertilizer value of the manure corresponding to the amount of artificial fertiliser nitrogen that the farmer would otherwise have applied. As an example of using this approach, carbon footprint was calculated from four Danish steer production systems that only differ in housing system/type of manure produced. The steer production systems were: '100% outdoor/grazing', '100% indoor/deep litter', '100% indoor/slurry', or a mix as in the 'real system' from Danish herds.

Keywords: Carbon footprint, LCA methodology, Livestock manure production, Soil carbon changes,

1. Introduction

Different methods have been used in LCAs to handle emissions related to livestock manure, where the emissions from manure have been attributed to either crop production or livestock production. Usually, the emissions from the use of manure are attributed to crop production (van Zeijts et al., 1999). However, Dalgaard and Halberg (2007) suggested that the environmental burden of using manure should be considering as a co-product from the livestock production. This means that the livestock production system 'pays' all environmental costs related to emissions from manure. However, the livestock system also gets credit for the fertilizer value of the manure. This is also reflected in a new guideline from EU on methods for calculating the life cycle environmental performance of products (EU, 2013). The EU guideline suggests that when manure nitrogen is applied to agricultural land and directly substitutes an equivalent amount of the specific fertiliser nitrogen that the farmer would otherwise have applied, the animal husbandry system from which the manure is derived should be credited for the displaced fertiliser production (taking into account differences in transportation, handling, and emissions) (EU, 2013). The substitution rate of 'kg fertilizer N' per 'kg N in manure ex animal' is assumed to follow the Danish legislation (Anonymous, 2010).

The aim of the present study was to illustrate how an alternative approach, where manure is seen as a co-product from the livestock production, can be used to calculate environmental costs related to emissions from manure. This was illustrated by an example, where carbon footprint was calculated from four Danish steer production systems that only differ in housing system/type of manure produced.

2. Methods

To illustrate the suggested approach for including emissions related to manure production, carbon footprint was calculated from four Danish steer production systems that only differ in housing system and type of manure produced. The steer production systems were: 'a real system (1)' as found in private herds '100% outdoor/ grazing (2)', '100% indoor/deep litter (3)', and '100% indoor/slurry (4)'. In the 'real system' (data based on Nielsen, 2003), the steers were grazing for 143 days per year at semi-natural pasture resulting in a daily gain of 550 g. During winter, the youngest steers were housed at deep litter and afterwards in a slurry-based system and the feeding was based on grass clover silage and limited amount of concentrate, resulting in a growth rate of 900 g/d. For the last 45 days the steers were fed more intensively with more concentrate and were gaining 1,100 g/d before slaughtering at 25.4 months of age.

In the system '100% outdoor/ grazing', all manure was deposited at pasture. The system was similar to the 'real system', except that it was assumed that the steers were outdoor continuously, though feeding was similar to that in the 'real system'. In the '100% indoor systems', the steers were housed indoor and produced manure was either 'deep litter' or 'slurry'. Intake of fresh pasture was replaced by the same amount of energy from grass clover silage. Table 1 present the most important input and output from the steer production system. Smaller changes in the steer production exist due to the different housing/manure systems. These are mentioned in the footnotes of Table 1.

According to the new approach, manure is considered a co-product from the livestock system, in this case the steer production system. A process was defined for each of the three types of housing/manure production: 'slurry', 'deep litter', 'manure deposit at pasture'. A carbon footprint was calculated for each of the three types of housing/manure with a functional unit (FU) of '100 kg manure N ex animal' according to the method by Mogensen et al. (2014). In other words, the GHG emissions from '100 kg manure N ex animal' from different housing/manure systems was calculated. It was taken into account both the direct emissions from manure, but also that manure cause C and N sequestration, and therefore less leaching, and avoided fertilizer production. Manure N ex animal was calculated as N in animal feed minus N in gain (Nielsen & Kristensen, 2005).

The results of these three housing/manure production process were used in calculating carbon footprint of the four steer production systems, where FU was 1 kg carcass at farm gate. With the new approach, the steer production systems were treated as' landless systems' i.e. GHG contribution from feed production and livestock production was calculated independent of each other. Crops were assumed imported to the farm and grown with use of artificial fertilizer. However, this contribution was offset to a certain degree by including the fertilizer value of the co-product manure. For each of the feedstuff used (see Table 1), a carbon footprint was calculated according to the method by Mogensen et al. (2014).

GHG emissions from soil carbon changes were calculated as suggested by Petersen et al. (2013). The approach by Petersen et al. (2013) is based on a single year's addition of C (from crop residues, etc.) and the associated effect on atmospheric CO_2. Petersen et al. (2013) estimated that 10% of the C added to the soil will be sequestered in a 100-year perspective. The input of carbon to soil C was based on the input of above- and below-ground crop residues. In the present study, contribution to soil C changes was divided into the contribution from C input from crop residues and the contribution coming from C input from different types of manure.

Table 1. Input and output in the steer production system.

Per produced steer	
Input of a dairy calf (30 days), kg live weight	55
Input of feed, kg DM	
- Grass clover silage	1,690
- Straw	220
- Barley	360
- Rapeseed cake	80
- Grazing [1)]	1,440
- Milk powder	20
Total feed, kg DM	3,820
Straw for bedding, kg [2)]	1,160
Output of a steer, kg live weight	574
- Kg carcass	293

1) Grazing was used in steer system 1 and 2. In system 3 and 4 grass grazed was replaced by same amount of energy from grass clover silage
2) Amount of straw used in steer system 1, in system 2 and 3 with slatted floor and slurry produced no straw was used at all, and in system 4 2,482 kg straw per produced steer was used

Indirect land use change (iLUC) was calculated according to Audsley et al. (2009) where all use of land for crop production is assumed to increase the pressure on land use and thus causing land use change somewhere in the world. The indirect land use change causes a release of 8.5 Gt CO_2-eq per year, to which agriculture contributes 58%. This gives a contribution of 1.43 t CO_2-eq per ha when divided by the total agricultural area of 3,475 Mha (Audsley et al., 2009). In the present study, iLUC was included by multiplying land use (m^2/kg DM feed) by the iLUC factor of 143 g CO_2-eq /m^2.

3. Results and discussion

Table 2 shows the overall effect on GHG emissions of three different ways of housing/manure production; as ‘slurry’, ‘deep litter’, or as ‘manure deposit at pasture’. This overall effect of manure takes into account both the emissions from manure and the benefit from the avoided fertilized production. Contribution to GHG emission from direct and indirect emissions of N_2O and NH_3 from manure from housing, storage and application varied from 1,171 kg CO_2-eq per ‘100 kg N ex animal in a slurry-based system’ to 1,569 kg CO_2-eq per ’100 kg N ex animal in a deep litter-based system’.

Table 2. Greenhouse gas (GHG) emission from three different housing/manure systems, FU = 100 kg N ex-animal (Mod. after Mogensen et al., 2014)

Manure system [1]	**Deposit at pasture**	**Slurry**	**Deep litter**
Housing System	Outdoor	Indoor	Indoor
Emissions from manure:

N_2O-$N_{indirect}$, kg from NH3 and leaching	0.53	0.53	0.34
GHG from avoided fertilizer emission, kg CO_2-eq	**-574**	**-574**	**-370**
Total GHG from avoided fertilizer	**-992**	**-992**	**-736**
Total GHG from 100 kg N in manure (ex animal) , kg CO_2-eq [14]	**-69**	**-125**	**199**

1) CF from import of straw is not included in this calculation
2) Calculated according to IPCC, 2006
3) Calculated according to Mikkelsen et al., 2006
4) Leaching (NO_3-N) calculated as input minus other emission
5) Input to soil is the ‘100 kg N ex animal’ minus all losses.

6) In the deep litter system there is an extra N input from N content in straw. C:N in manure deposited at pasture and in slurry 8:1 (Wesnæs et al., 2009) and C:N in deep litter of 21:1 (Osda et al., 2001) both multiplied by a factor of 1.3 (Petersen, B pers comm., 2013)
7) According to the model by Petersen et al. (2013)
8) From C to CO_2 by factor multiplication 44/12
9) Per 10 kg C stored in soil, 1 kg N is stored in soil (Sundberg et al., 1999)
10) Anonymous, 2010
11) CF of N in fertilizer: 4,25 kg CO_2/kg N (Elsgaard, 2010)
12) CF of P in fertilizer: 4,63 kg CO_2/kg P (Ecoinvent, 2010)
13) CF of K in fertilizer: 0,596 kg CO_2/kg K (Ecoinvent, 2010)
14) Taking into account both the emissions from use of manure and the saved fertilized production

Table 3. Greenhouse gas (GHG) emission of animal feed, CO_2 g/kg DM feed (modified after Mogensen et al., 2014)

	Barley	**Barley Straw**	**Rape seed cake**	**Grass clover silage**	**Grass clover grazed**
Contribution to CF					
- Growing	484	49	390	404	453
- Processing	11	1	28	0	0
- Transport	18	18	75	0	0
Total CF	**512**	**68**	**494**	**404**	**453**
C sequestration 1)	86	8	-44	-61	-226
LUC	328	33	182	173	202
CF including soil C and LUC	**926**	**109**	**632**	**516**	**429**

1) For grazed crops contribution from C input from manure deposited is included in soil C changed.

Carbon footprint per kg carcass weight is shown in Table 4 for the four Danish steer production systems that only differ in housing/manure system. GHG from manure was calculated based on the values (Table 2) per ‘100 kg N ex animal’ corrected to actual amount of N ex animal in each steer production system and taking into account the distribution between the different housing/manure systems. Before including contribution from soil C and iLUC, CF per kg carcass was estimated to 16.6 kg CO_2/kg carcass in the ‘real steer system’, where the steers are grazing during summer and housed indoor during winter, i.e. manure system include a mixture of manure deposited at pasture, as slurry and as deep litter. Similar level of CF per kg carcass was estimated for the ‘100% outdoor system’. Here the steers are outdoor all year, but fed the same way, i.e. same contribution to CF from feed production. Lower emissions from manure from stable and storage in system 2, and lower CH_4 from manure deposited at pasture compared with as slurry was counterbalanced by less credit from substitution of fertilizer. CF per kg carcass was higher in steer system 3 with manure handled as deep litter compared with system 1 and 2. This was mainly due to higher contribution from enteric fermentation as the digestibility of grass clover silage is lower than that of fresh grass clover, which increases methane emission. Beside that there was a higher GHG contribution from production of straw for bedding. Before taking into account contribution from soil C and iLUC, steer system 4 has the lowest CF per kg carcass of all systems, even though GHG from enteric fermentation was at the same high level as in system 3, but total GHG from manure handling was lowest in the slurry-based system.

However, if GHG contribution from changes in soil carbon due to input to soil C from crop residues (‘soil C from feed’) and C from manure (‘soil C from manure’), steer system 1 ‘the real steer system’ has the lowest CF/kg carcass weight. Steer systems 4 and 2 have almost similar CF and system 3; the ‘deep litter system’ has the highest CF per kg meat even though manure as deep litter has a huge positive effect due to soil C sequestration. Including contribution from LUC did not change the ranking of the four steer production systems.

Table 4. Carbon footprint (CF) in four steer production systems that only differ in the way of housing/type of manure, CO_2 kg/kg carcass

Steer system	**1 The real system**	**2 100% outdoor**	**3 100% indoor Deep litter**	**4 100% indoor Slurry**
N in feed, kg N [4)]	117	117	107	107
N in gain, kg N	14	14	14	14
N ex animal, kg N	103	103	93	93
Manure system, % of N ex animal				
- deposited at pasture	**39**	**100**	**0**	**0**
- slurry	**15**	**0**	**0**	**100**
- deep litter	**45**	**0**	**100**	**0**
GHG from feed production, kg CO_2/kg carcass				
- growing, processing, transport	6.1	6.1	6.3	6.3
- soil C	-1.4	-1.4	-0.6	-0.6
Total GHG from feed, kg CO_2	4.7	4.7	5.7	5.7
GHG from manure, kg CO_2				
- Emissions	3.4	2.8	4.1	2.4
- Saved fertilizer production [2)]	-1.0	-0.7	-0.6	-1.1
- Effect on soil C	-1.3	-0.8	-2.5	-1.0
Total GHG from manure	1.1	1.3	1.0	0.3
GHG from CH4 enteric, kg CO_2/kg carcass	7.2	7.2	7.7	7.7
GHG from input of calf	0.6	0.6	0.6	0.6
Others, straw, minerals [3)]	0.3	0.1	0.6	0.1
CF, kg CO_2/kg Carcass	**16.6**	**16.6**	**18.6**	**15.9**
CF incl. soil C from feed, kg CO_2 [1)]	15.2	15.2	18.0	15.3
CF incl. soil C from feed and manure kg CO_2	13.9	14.4	15.5	14.3
CF incl. soil C and LUC	**16.4**	**16.9**	**18.0**	**16.8**

1) For grazed crops contribution from C input from manure deposited is included in soil C change of the crop ‘grazed grass’.
2) In system 2 only 50% of manure deposited at pasture is assumed utilized for grass production, for the other 50% no fertilizer value was assumed, however this manure contribute to soil C input (included in ‘GHG from manure’
3) No straw was used in system 2,
4) In system 3 and 4 intake of pasture is replaced by same energy form intake of grass clover silage, which lower N intake

5. Conclusion

The present paper has illustrated an approach, where the environmental burden of manure could be handled by considering it as a co-product from the livestock production. That means that the livestock production system ‘pays’ all environmental costs related to emissions from manure, and on the other hand that the livestock system also gets credit for the fertilizer value of the produced manure. Thereby, the calculated carbon footprint of feed crops is independent by use of manure or not.

The total GHG emissions from three types of manure when taking into account both the emissions from manure handling, the positive effect of soil C sequestration and reduced N leaching due to use of manure and the benefit from the avoided fertilized production, was investigated. Production and use of manure as either slurry or deposited at pasture generated a positive effect for the environment compared with use of fertilizer, whereas the opposite was seen for producing and use of manure in a deep litter system. It was found that the total GHG emission from using manure in term of ‘slurry’ will cause a reduction in GHG emission of 125 kg CO_2-eq per 100 kg N ex animal. Similar, the overall effect was a saved GHG emission of 69 kg CO_2-eq/100 kg N ex animal if manure was deposited at pasture. Whereas there was an overall GHG release of 199 kg CO_2-eq per 100 kg N ex animal as deep litter. There estimates are under the assumption that the manure was used in a way that it will be utilized to substitute use of fertilizer. Due to that, carbon footprint of identical steer production system that only differ in the type of housing/manure system, came out with a lower CF in a steer production systems, where the type of manure was ‘slurry’ or ‘deposited at pasture’ compared with CF of a steer production system on deep litter.

ABSTRACT
The increasing demand for livestock products will intensify the claim on land. To use land efficiently, we need a method to determine the efficiency of land use to produce animal-source food. Life cycle assessment (LCA) has been used to assess the land use and shows that land required to produce, for example, 1 kg of protein is in the same range for eggs and milk. Methods used, however, do not take into account that laying hen diets contain more human-edible plant products than dairy cow diets. Furthermore, the suitability of land to grow human-edible plant products is not taken into account, as all land is counted equal. The aim of this study, therefore, was to develop a method to determine the efficiency of land use by livestock for human food production. We illustrated our novel approach for the case of egg and milk production systems in the Netherlands.

Keywords: animal production, land use efficiency, egg, milk, food

1. Introduction

For decades, the livestock sector has focussed on improving the feed efficiency at animal level, i.e., the ratio of kg product output over kg resource input. This focus increased global production of animal-source food, but also the demand for land by the livestock sector. The current livestock sector uses about 70% of all agricultural land in the world (Steinfeld et al., 2006). The demand for especially animal-source food will further increase, and, therefore, intensify the claim on agricultural land, implying that land use efficiency (LUE) will become increasingly important for livestock production.

Life cycle assessment (LCA) is most commonly used to assess LUE of animal-source food products along the entire chain. A generally accepted indicator is land occupation. Current LCA results show that land occupation is in the same range for eggs (35-48 m^2/kg protein) and milk (33-59 m^2/kg protein) (De Vries and De Boer, 2010). They, however, also concluded that interpretation of current LCA results is hindered, because they do not include the environmental consequences of competition for land between humans and animals. Compared to diets of ruminants, for example, diets of laying hens, generally, contain more products, such as cereal grains, that humans could consume directly. Direct consumption of these cereal grains by humans is more efficient from a land use perspective than consumption of milk or eggs produced by animals fed with these cereal grains, because energy is lost during conversion from plant to animal product (Goodland, 1997).

One way to gain insight into the efficiency of land use by livestock, while correcting for this competition between humans and livestock, is to compute human-edible energy or protein conversion ratios (Wilkinson, 2011; Dijkstra et al., 2013). This protein conversion ratio, for example, represents the amount of protein in animal feed that is potentially edible for humans over the amount of protein in the animal product that is edible for humans. Wilkinson (2011) computed human-edible protein conversion ratios above 1, except for milk and suckler-beef production. Ratios above 1 are not sustainable because animals produce less human-edible protein than they consume (De Boer, 2012).

Another limitation of the land occupation indicator is that it does not account for the suitability of occupied land to cultivate food crops. Conversion ratios, as presented by Wilkinson (2011), do not include the fact that, for example, grass fed to dairy cows can be produced on land suitable for the cultivation of food crops. Some LUE indicators were proposed that correct occupied land for its production capacity, like the net primary productivity of potential biomass (NPP_0) (Ridoutt et al., 2012) and the ecological footprint indicator (Ewing et al., 2010; Borucke et al., 2013) or the quality of the soil (Milà i Canals et al. 2007b). All these methods, however, do not sufficiently account for the suitability of used land to produce food crops.

To efficiently feed an increasing and wealthier population, we need a novel method that overcomes above mentioned limitations in LUE assessment methods. The aim of this study, therefore, was to develop a novel method to assess efficiency of land use by livestock to produce human food. We illustrated our novel approach for the case of Dutch egg and milk production systems .

2. Methods

2.1. Life cycle assessment

We first used a regular LCA approach to assess land occupation for the production of eggs and milk. In this study, we used an attributional LCA to quantify the current status of LUE to produce egg and milk.

Land use assessment in an attributional LCA focusses on two main issues, i.e., the claim on land by production (e.g., the indicator land occupation) and the impact of used land on biodiversity and soil quality/life support function (Garrigues et al. 2012; Milà i Canals et al. 2007a). Indicators to quantify the impact on biodiversity and soil quality/life support function are still in development and it is not evident yet which indicators should be considered in LUE assessment of livestock systems (Helin et al. 2014; Koellner et al. 2013; Núñez et al. 2013), although some recommend to use soil organic matter (Milà i Canals et al. 2007b) as indicator for soil qualtiy (Food SCP RT 2013). Therefore, and because our focus was on the suitability of used land to produce food crops, we quantified only the claim on land by livestock production.

Land occupation in livestock production mainly results from cultivation of feed ingredients. Therefore, we took into account agricultural land use for feed production only.

2.2. Novel approach for land use efficiency assessment of livestock

Our approach for LUE assessment builds on current LCA calculations. A regular LCA sums occupied land for all feed ingredients per country of origin used for the production of, for example, a kg human-digestible (HD) egg or milk protein. Our approach sums the suitability of this occupied land per country of origin to directly produce HD protein from food crops. We chose HD protein production as parameter for LUE as livestock products contribute especially to the protein demand of humans (De Vries and De Boer 2010; FAO 2009). Protein digestibility was taken into account to correct for the quality difference of plant and animal protein. The concept behind our approach, therefore, is that to maximize LUE, HD protein production should be maximized per agricultural land unit. Our LUE ratio, therefore, was defined as:

$$\text{LUE ratio} = \frac{\text{HD prot livestock}}{\text{HD prot crop}} \qquad \text{Eq. 1}$$

where HD prot livestock is HD protein production from livestock (g HD protein/FU) and HD prot crop is HD protein production from most suitable food crop (g HD protein/FU).

For our case studies we chose kg HD egg or milk protein as FU. Current LCA studies, however, do not yet account for protein digestibility. Therefore, to compare our current land occupation results to values in literature, we expressed these results also in kg egg or milk protein. As the FU was expressed in kg HD livestock protein, the numerator of the LUE ratio was equal to 1000 g HD livestock protein.

The denominator of the LUE ratio was calculated according to Eq. 3.

$$HD\ prot\ crop = \sum_{i=1}^{n} \left(LO_{ij} \times \max_k \left(AY_{jk} \times Prot_k \times Dig_k \right) \right) \qquad \text{Eq. 2}$$

Where, LO_{ij} is current land occupation (m^2.yr/FU) for feed ingredient i and country j, AY_{jk} is average yield (g/m^2.yr) for country j and suitable food crop k, $Prot_k$ is protein content (%) for suitable food crop k, Dig_k is protein digestibility (%) for suitable food crop k and the max function is selecting food crop k with maximum HD protein yield for country j.

To calculate HD prot crop (Eq. 2), first, we identified the country of origin for all feed ingredients. Second, we assessed the suitability of these countries to grow food crops. Five major food crops were considered: wheat, rice (wetland and indica dryland), maize, potatoes (white and sweet) and soybeans. To identify country specific suitability for these food crops we used the GAEZ database on agro-ecological suitability and productivity (FAO and IIASA 2014). This database expresses country-specific suitability of land to grow food crops in a suitability index ranging from not suitable to very highly suitable. This suitability index is based on data of climate (e.g., wet day frequency, sunshine and temperature), crop requirements, prevailing soil conditions (e.g., pH, soil water holding capacity and total exchangeable nutrients), applied soil management, elevation and terrain slope, land cover and protected and administrative areas (FAO and IIASA 2014). If, according to the GAEZ legend, the suitability on country level was good, high or very high (i.e., suitability index >55), the land was considered suitable to produce the crop. Third, for every suitable food crop, the country-average yield in kg/ha was obtained from the FAOSTAT database (FAO 2014). Fourth, these yields were corrected for protein content and digestibility.

The LUE ratio corrects for both limitations in current LUE assessment methods. First, it corrects for differences in amount of HD plant products in livestock diets as these products, of course, are produced on land that has high alternative protein production from food crops, which makes the denominator larger. Second, we correct for suitability of used land to cultivate food crops. For example, when grass is grown on land that could have been used to grow food crops, the denominator becomes larger as well.

2.3. Case studies

We illustrated our approach for the cases of Dutch egg and milk production systems, because these systems yield similar LCA results for land occupation per kg of protein, whereas diets of dairy cows and laying hens differ in amount of HD plant products. As the diet of laying hens is relatively similar for different production systems, we took the most common egg production system in the Netherlands, i.e., a multi-tiered barn (Egg) (Dekker et al. 2011). Furthermore, we included two milk production systems in the Netherlands, i.e., milk production on peat soils (Milk Peat) and milk production on sandy soils (Milk Sand). We selected these milk production systems because of their differences in the suitability of land used for feed production to cultivate food crops.

Current land occupation for Egg was calculated based on data from Dekker *et al.* (2011), FeedPrint 2013.03 (Vellinga et al. 2013) and KWIN-V 2013-2014 (KWIN-V 2013). Data about the composition of the layer hen diet and the corresponding off-farm land use, feed intake and production values came from FeedPrint 2013.03. The egg price, slaughter price and round duration were obtained from KWIN-V 2013-2014.

When a hectare of land yields multiple products, land occupation needs to be allocated to these multiple products. Economic allocation was used to allocate land occupation between egg and meat production. Economic allocation means that occupied land is allocated proportionally to the economic value of the different products. Economic allocation was used for crops with an oil and a meal product also. Economic allocation values for these crops were based on FeedPrint 2013.03. According to FeedPrint 2013.03, residue co-products, like citrus- and beet pulp, maize glutenfeed and wheat middlings, had an economic allocation value of zero. The co-product straw was assumed to have an economic allocation value of zero.

Current land occupation for Milk Sand and Milk Peat was calculated based on data from the Dutch Farm Accountancy Data Network (FADN) database (FADN 2014) and FeedPrint 2013.03 (Vellinga et al. 2013). Data from the FADN database described average milk production, economic allocation percentages for milk as percentage of total revenues from milk and meat, on-farm land use with corresponding crop yields, total feed intake and the proportion of different feed ingredients in the milking cow diet over three years (2010-2012). To get a high contrast between production systems for dairy cows on peat and sandy soils, we selected FADN farms with >90% peat or sandy soils. Allocation rules were applied similarly to the laying hen case.

The HD protein production from food crops on land used for on-farm feed production was not solely based on the GAEZ and FAOSTAT databases. We assumed HD protein production from food crops on peat soils to be zero. Crop yields for wheat, i.e., 7,300 kg/ha.yr and white potatoes on sandy soils, i.e., 56,000 kg/ha.yr and wheat, i.e., 9,200 kg/ha.yr and white potatoes on clay soils, i.e., 50,000 kg/ha.yr were obtained from KWIN-AGV (KWIN-AGV 2012).

3. Results

Land occupation for egg production was about 26 m^2 per year per kg digestible protein (Table 1). On this land, which is spread all over the world, it is possible to produce about 2 kg of HD protein from food crops, resulting in a ratio of 0.5.

Table 1. Land occupation per kg human-digestible (HD) protein and LUE ratio for egg production (Egg) and milk production on sandy (Milk Sand) and peat soils (Milk Peat).

Product	**Land occupation (m^2.yr/kg HD protein)**	**LUE ratio**
Egg	25.8	0.5
Milk Sand	26.1	0.4
Milk Peat	31.6	1.7

Current land occupation was higher for Milk Peat than for Milk Sand, mainly due to higher grass and lower maize content in the diet on dairy farms on peat soils. On-farm maize yields were higher than on-farm grass yields, which led to lower land occupation for maize than for grass. The LUE ratio, however, strongly depended on the soil type. When a dairy farm was situated on peat soils, where hardly anything else than grass could be grown, the ratio was 1.7. This means that more HD protein from milk than from plants could be produced on the land where the feed ingredients are grown. When situated on sandy soils, however, the ratio was about 0.4, which means that production of milk on sandy soils is an inefficient way to produce HD protein.

4. Discussion

According to De Vries and De Boer (2010) the range in land occupation of egg production systems was 35-48 m^2.yr/kg protein. Our current land occupation value, recalculated to kg protein was below this range (25 m^2.yr/kg protein). This can be explained by the relative low feed conversion ratio (FCR) from FeedPrint. Besides, the range of De Vries and De Boer (2010) was based on two studies from 2006. Additional possible explanations, therefore, can be decreasing FCR and increasing crop yields over years. Furthermore, in the current study, only land occupation by feed production, i.e. agricultural land, was considered.

Current land occupation was 25 m^2.yr/kg protein for Milk Sand and 30 m^2.yr/kg protein for Milk Peat. According to De Vries and De Boer (2010) the range in land occupation of milk production systems was 33-59 m^2/kg protein. This range was based on studies from 2000-2009. Our relatively low current land occupation values, just as for the laying hen case, can possibly be explained by decreasing FCR and increasing crop yields over years. Two Dutch studies were used in the review of De Vries and De Boer (2010). These Dutch studies found a land occupation value for Dutch milk production of about 39 m^2/kg protein), which is on the lower side of the range as well (Thomassen et al. 2009; Thomassen et al. 2008).

Current land occupation was highest for Milk Peat, followed by Milk Sand and Egg, but still close to each other (25-30 m^2.yr/kg protein). This land occupation, however, was relatively similar for these livestock systems. This is in accordance with the findings of De Vries and De Boer (2010) that the amount of land required to produce 1 kg of protein is in the same range for eggs and milk. Opposite to our findings, Williams *et al.* (2006) found lower current land occupation values for milk production systems (33-35 m^2/kg protein) than for egg production systems (41-48 m^2/kg protein). This difference can possibly be explained by our relatively low FCR for egg production. Besides, compared to the ranges of De Vries and De Boer (2010) for land occupation of egg and milk production, Williams *et al.* (2006) found relatively high land occupation for egg production and relatively low land occupation for milk production.

The novel approach to assess LUE of livestock systems led to a change in conclusions of livestock systems on their LUE. Wilkinson (2011) found the same conclusions at animal level about the loss or gain of HD protein during the production of eggs and milk on peat soils. Our results for milk production on sandy soils, however, were different, because Wilkinson (2011) didn’t include the fact that, for example, grass fed to dairy cows can be produced on land suitable to grow food crops.

The land use inefficiency of dairy farms on sandy soils compared to dairy farms on peat soils could be explained mainly by the difference in suitability of both soils to grow food crops. Production capacity of land is not fully used for the case of milk production on sandy soils, as grass is grown on land that has high suitability to grow food crops. This shows that animals that convert non-HD protein, originating from land with low capacity to grow food crops, into HD protein efficiently, could contribute to increase global HD protein production. This finding is in agreement with the conclusion of Dijkstra *et al.* (2013) that we should fully utilize the ability of ruminants to convert non-HD products into HD products.

5. Conclusion

Our novel approach to assess efficiency of land use by livestock to produce human food led to a change in conclusions on the LUE of livestock systems. We found highest LUE for livestock production on land that has low suitability for HD protein production from food crops. These results show that animals that convert non-HD protein, originating from land with low capacity to grow food crops, into HD protein efficiently, could contribute to increase global HD protein production. This means that not only the actual type of land use (meadow, arable land, etc.) has to be taken into account in the assessment of efficiency of land use, but also its natural status (e.g. soil type), determining its suitability to produce food crops.

ABSTRACT
Sustainability & Ethics is one of the five macrotrends identified by a group of experts at CETEA/ITAL - Packaging Technology Center of the Food Technology Institute that could drive the processes of innovation and development in the packaging area in the coming years in Brazil. LCA, in its simplest form, *Life Cycle Thinking,* is a powerful tool to be applied to continuous improvement of the existing processes as well as to lead to new products and process development. Many examples of the application of *Life Cycle Thinking* have been achieved with significant measurable reductions in energy, water, raw materials, emissions to water, and air and solid waste residues. The application of this tool for packaging and also for the food sector puts forward four guidelines to be pursued over the next decade: Optimization of the product/package system; Reuse & Recycling; Waste Management & Reverse Logistics and Credibility & Ethics.

Keywords: Sustainability, packaging, life cycle thinking, trends

1. Brazil Pack Trends 2020 report

In order to establish guidelines that could drive the processes of innovation and development in the packaging area in the coming years in Brazil , a group of experts at CETEA/ITAL - Packaging Technology Center of the Food Technology Institute - with over twenty years experience in research and consultancy, identified five macro trends that constitute challenges and opportunities that could encourage enterprises to think about the future possibilities for packaging: Convenience & Simplicity, Aesthetics & Identity, Quality & New Technologies, Sustainability & Ethics and Safety & Regulatory Issues (Sarantopoulos et al., 2012). The purpose of this article is to show the main topics concerning one of the macrotrends - Sustainability & Ethics, which was developed in Chapter 7 of the report Brazil Pack Trends 2020 (Mourad and Jaime, 2012). More than 70 documents including those on global trends were extensively studied which, using the authors´experience, gave rise to the main drivers of this chapter. So, the following sections of this article show the main points discussed in this chapter, but here applied to the food packaging sector.

2. Environment: a global issue

The first aspect addressed in this chapter is the global character that environmental issues have taken on. Globalization, which has intensified from the second half of the '80s, has transformed the environmental discussions from national to global. The social-related aspects refer to global society and not only the regionalized effects. Through globalization, humanity becomes aware of the risk of environmental degradation due to the potential destructive capacity of nuclear plants and contamination of air, water, soil and the food chain by chemical industries.

A new global conscience has gradually arisen as the transformations that the planet has been passing through, accentuated by climate changes that can be clearly seen in every continent, have been understood as consequences of the actions of mankind on nature (IPCC, 2007). The landslides that happened in 2011 in Teresópolis, in the State of Rio de Janeiro, due to a long rainy period, as well as the floods in Pakistan in 2010, the heat waves in France in 2003, the drought in Russia in 2010, the heat in the Alpine resorts in 2006 and the drought in USA in 2012, among other events, are reflexes of climate change. Since these events have been increasingly frequent, the need is urgent for all sectors of the economy, including the packaging sector, to contribute to the reduction in the emission of greenhouse gases and implement actions to reduce the anthropogenic impact on our system.

3. Life Cycle Thinking

As Life Cycle Assessment (LCA) studies measure various forms of environmental impact such as global warming, natural resource depletion, acidification, eutrophication and human toxicity, among others, it has been considered as one of the best instruments for the quantification of human action on the planet. The LCA tool itself is very complex and requires considerable time for completion. For this reason, partial LCA results for identification of opportunities for improvement, including all or almost all of the life cycle phases, have grown in recent years and are based on "life cycle thinking". These studies, although they cannot be classified as a "life cycle assessment", have been very useful for understanding the environmental interfaces of products and have lead to the development of products with lower environmental impacts.

Thus, with the greater maturity of environmental issues, this new more holistic view, "Life Cycle Thinking", has been used in the packaging context. This approach can be translated as "a continuous movement of rethinking packaging", considering the time when natural resources are extracted from nature for their production up to the final destinations of residues and emissions originated from these processes. Figure 1 illustrates how *Life Cycle Thinking* can be used for system optimization.

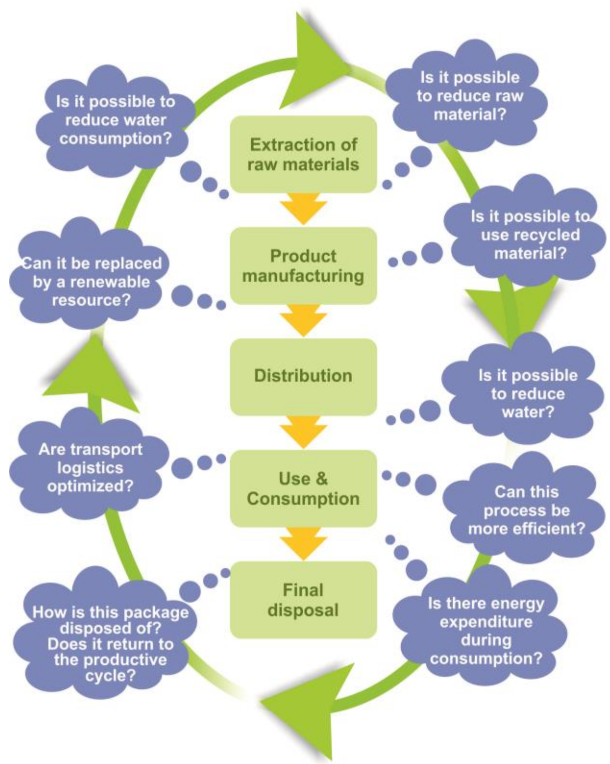

Figure 1. Schematic representation of Life Cycle Thinking.

Through these questions, asked at every phase of the product life cycle, *Life Cycle Thinking* is carried out. The registering, however, of the obtained reductions, must follow the LCA methodology strictly, so the calculated reductions are effectively proved on an internationally recognized scientific basis. It is also important to include analysis of possible trade-offs, ie, possible environmentally unfavorable points arising from the implementation of new processes, such as the increase of emissions to water when increasing the recycling rate or loss of packaged products when reducing the mass of some packages which become more fragile, and so on.

Packages have always been linked to environmental issues and their use is often questioned. It is important to remember that through the package it is possible to distribute food from its places of origin to multiple, often remote, points of consumption. Another aspect to remember is the importance of its correct specification. The use of inappropriate / undersized packages leads to food loss and consequently all natural resources extracted from the environment throughout their supply chain. Thus, the loss of food by failure or lack of packaging has negative consequences for the environment, many times greater than the impacts associated with the manufacture or disposal of packaging.

4. Guidelines for sustainable product/packaging design

4.1. Optimization of the product/package system

Life Cycle Thinking can currently be considered as one of the most important tools for the development of packaging and products that aim to become more sustainable. For packages, this concept means to "rethink the packaging associated with its lifecycle, challenging the limits of weight, shape, materials and accessories, without, however, compromising the integrity and product shelf life." When the wish to become less costly to the environment becomes a goal clearly defined, it reduces the weight of what is not essential; it goes to the limits of technical requirements, values the efficiency more than appearance and generates more responsible packaging options.

When the relation between product or service and the quantity of used package is optimized, the consumption of natural resources is indirectly reduced, such as oil, water, sand, coal and minerals, among others, and, consequently, the resulting emissions to the air, water and soil. This way, the optimization of materials should be one of the priorities in the search for systems with less environmental impact.

Many examples of the application of *Life Cycle Thinking* developed between 2009 and 2013 in a partnership consisting of a retailer (Walmart), manufacturers (Walmart suppliers) and a research institute (CETEA/ITAL) are described with significant measurable reductions in energy, water, raw materials, emissions to water, air and solid waste residues (Walmart Brasil, 2010 and 2011).

Coca-Cola Brazil invested in their organic product, Matte-Leão, which was produced in their new unit. Considered a "green factory", it has received the Leadership Energy and Environmental Design (LEED) certification, issued by the Green Building Council, which assures good planning with the construction and use of energy. Another important innovation was the printing of the life cycle of tea from mate herb on the package, playing an important role on educational and environmental consciousness. The package has been modernized by its clean design: 90% of the printing ink quantity has been reduced (Figure 2).

Figure 2. Organic Matte Leão, by Coca-Cola: 90% reduction of the printing ink. Source: Walmart, 2011.

The company Cargill has shown that it is possible to innovate on traditional products such as the Liza oils line (Figure 3), which, even maintaining the shape, thanks to a re-engineering work on the bottle and cap, a 10% reduction in the package weight was possible, which changed from 22 to 20 grams without significantly affecting its mechanical performance.

Figure 3. Example of optimization with packaging weight reduction. Source: Walmart, 2010.

Derived from technological investment, Danone has applied FOAM technology, which expands the plastic sheet used in the packaging, making it aerated, reducing its mass and, therefore, the consumption of natural resources. This change brought about a 9.4% reduction in weight of a Danoninho pot, without compromising its mechanical resistance (Figure 4).

Figure 4. Example of application of new technology for weight reduction. Source: Walmart, 2011.

4.2. Reuse & Recycling

On the scale of priorities for solid waste management, the minimization of waste generated by optimizing and reducing packaging systems should be encouraged first. Reuse is the second priority, followed by recycling, in third place.

Coca-Cola Brazil launched, in 2011, the 2.5 liter bottle containing 20% of post-consumer recycled PET resin food grade (PCR PET). There is, currently, a bottle-to-bottle recycling plant that was approved by the Brazilian Health Surveillance Agency (Anvisa). The recycled bottle (Figure 5) has the same characteristics as produced from virgin PET resin. In this process, the used bottles used are selected, crushed and washed by an efficient process of decontamination and recovery of the molecular weight of PET, removing contaminants at levels required by food contact packaging legislation. The clean material is then used in the manufacturing process of new bottles. The technology used for the purification of post-consumer PET was created by the company United Resource Recovery Corporation (URRC), from the United States. The use of post-consumer PET encourages the entire chain of collection of these packages, generating income for the street collectors.

Figure 5. Recycled PET bottle. Source: Walmart, 2011.

Example of New Can metallic packaging design, developed by Jiwoon Park and Kwenyoung Choi, has a format that allows for the reduction of volume by one-third of the original after consumption of the product by means of twisting and compression movements.

Figure 6. Example of a package that allows for volume reduction after product consumption. Source: YANKO DESIGN, 2009.

The Taiwanese company Panorama SOY Ink Co. Ltd. has developed inks based on recycled vegetable oils. The inks contain 45% of post-consumer oil, 21% of pigments and 34% of tar, do not contain organic volatile compounds, have good resistance to abrasion, as well as high gloss and good color stability. They dry faster, have better defined impression than traditional paints and can be applied on surfaces of paper or plastic.

4.3. Management of residues & reverse logistics

The establishment of the reverse logistics chain is not a simple task and involves many aspects. In fact, in cases where the use of packaging in a second production process already provides a financial return for the agents involved, as in the case of old corrugated paperboard boxes and aluminum cans, the return of post-consumer packaging already exists. However, in most cases, that chain needs to be created and established. It is very important, however, to realize that the creation of this chain does not occur spontaneously. If there does not exist a clear determination of the generating sector in returning these materials to the production cycle, or an appropriate destination, this chain cannot be established. In order to ensure that the reverse chain is real and can be maintained, it must be economically viable, which means that it must pay all the involved agents in an adequate way.

The Brazil Pack Trends report also presents a successful Tetra Pak case which established a reverse logistic chain for aseptic milk packaging in the country. This perception of the need to go beyond one´s own gates was perceived long ago by Tetra Pak, which is a great example of a company that was able to foster, encourage, and establish the reverse logistics chain of the aseptic packages after use. These containers of liquids are formed by the combination of three materials: cardboard, which gives rigidity and packing structure, alternating layers of polyethylene (PE), which protect the cardboard from external moisture and also constitute the primary contact material with the liquid beverage, and an aluminum foil (Al), which preserves the aroma and extends the shelf life of the product which reaches, in the case of milk for example, up to six months.

This multilayer material is currently separated from the common waste (the current recycling rate is 28%) and the cellulosic fiber content recovered in “hidrapulpers” present in paper recycling companies. The remaining residue consisting primarily of polyethylene and aluminum, is currently intended for the manufacture of PE/Al tiles and to the EET-Brasil Aluminum and Paraffin Ltd. company at Piracicaba. At the EET company, through a plasma process (~15,000ºC), high purity aluminum is obtained and the polyethylene is transformed into paraffin. LCA studies carried out by CETEA attest that recycling has environmental benefits, even considering the impacts of all these stages of the reverse chain.

The creation of this chain, exemplified in Figure 7, was strongly encouraged by Tetra Pak, which took nearly two decades to find the technology and partners that could make the reuse of aseptic packaging environmentally and economically viable.

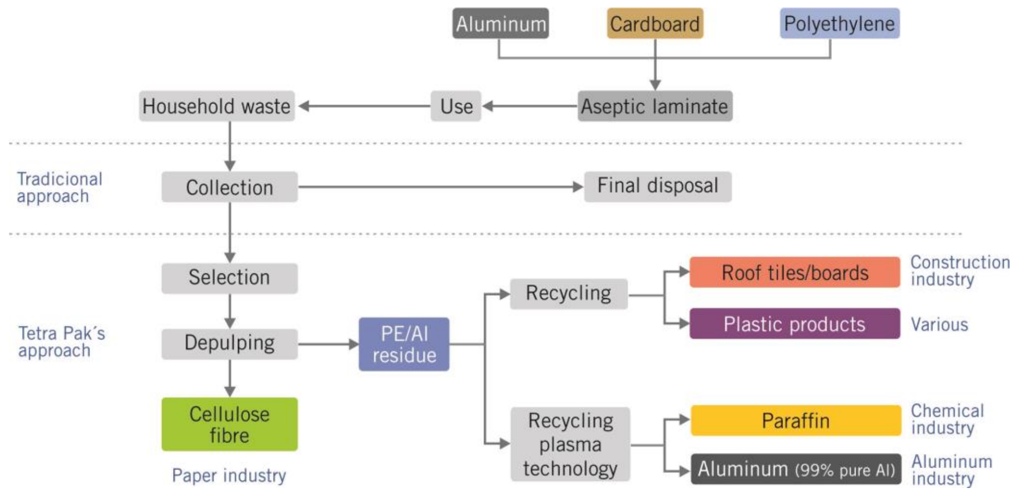

Figure 7. Productive and post-consumer aseptic package recycling flowchart organized by Tetra Pak. Source: Adapted from Osato et al, 2007).

The creation of these products increased the price paid for the collected post-consumer packaging by 79% between 2004 and 2007, which reached EUR 120 per ton and started to be segregated from the household waste.

5. Credibility & Ethics

With the globalization of environmental issues, the strengthening of social networks, the importance of the end consumer´s awareness and the involvement of the whole society in areas before treated only by experts, it is very important that environmental communication will be carried out according to internationally accepted metrics.

Many manufacturers have already noticed the need of having a better attitude to society, extending the responsibility concerning their products to beyond their gates. Such a movement has been called Extender Producer Responsibility (EPR). The publication of sustainability reports, according to the GRI Initiative, is a practice incorporated by several companies and the public sector that have a commitment to sustainable development and have already put into practice the EPR principles. The initiatives involve actions all along the production chain. GRI has been conceived so it is possible to communicate in a transparent way the entrepreneurial action of economic, environmental and social range, according to a method by which a company can be compared both internally and externally. GRI involves principles of balance, comparability, exactness, periodicity, reliability and clearness.

The credibility of the products has been attested using standardized environmental labels and self declarations; both volunteer and offer information about the environmental benefits of a service or product in general terms or one or more specific environmental aspects. The environmental performance certification of a product or service is a world-wide practice, with Germany being, in 1977, the first country to implement a National Program of Environmental Labeling for products, the Blue Angel. This kind of program has been used as a model for many other countries, becoming a strong worldwide trend, examples being: Canada (Environmental Choice), Japan (Eco Mark), United States (Green Seal), Nordic Countries – Denmark, Norway, Sweden, Finland and Iceland (The Swan), and Europe (Eco-Label), among others.

These programs belong to the Type I Environmental Labeling, established in the ISO 14024 and are also known as “green labels” or “ecolabels”. It is a voluntary methodology of certification and labeling for environmental performance of products and services, with a great importance for the implementation of environmental policies aimed at consumers, helping them to choose products less harmful to the environment. The “green label” is generally given by a national certification organ (third party) and is based on multiple criteria from studies of Life Cycle Assessment of a given sector, with focus on reducing the environmental impacts associated with the selected product category. The certification of cellulosic materials by internationally recognized agencies has become a more intense reality in Brazil and around the world, highlighting the label Forest Stewardchip Council (FSC), applied to the cellulosic packages sector. The Brazilian Program of Forest Certification (Cerflor), applicable nationwide, prescribed to the standards elaborated by ABNT and integrated into the Brazilian System of Conformity Assessment. Inmetro is another forest certification program used in Brazil, internationally recognized by the Program for the Endorsement of Forest Certification (PEFC), an international organization that unites systems of forest certifications all over the world. Both programs attest to the sustainable forest handling and the traceability of the custody chain, offering to the consumer the guarantee that the product follows criteria based on practices that promote biodiversity preservation, responsible use of forest resources and the maintenance of soil, air and water quality. They still analyze the practices of companies in the economic and social development of the region where they work. Another strong trend in the package sector is the adoption of the environmental self-declaration for companies, aiming at making public the environmental improvements obtained along a product or service life cycle. Although the self-declaration may offer flexibility and autonomy, as it does not demand the certification by a third party, the companies should make responsible declarations that can be verified and based on scientific rigor. This kind of declaration is called Type II Environmental Labeling and can be found standardized by the ISO 14021, which presents the policies for the use of texts, symbols, and graphs associated with the publicizing of product or service environmental improvements. Texts with vague or non-specific declarations, for example, “environmentally safe”, “environmentally friendly”, “Earth friendly”, “do not pollute” and “ozone layer friendly” should not be used. The consumer search for products with less environmental impact has helped the high investment by companies in selling with environmental appeal. This “green” market trend has stimulated companies to use the moment to associate their products with dubious and opportunist ecofriendly attributions, with no clear criteria that back them up in their environmental pretensions, or even to symbols and visual appeals that can induce the consumer to wrong conclusions about a product or service. Appeals that are presented as fake or induce the consumer to wrong conclusions about a product or service have been called *Greenwashing*. Aiming at describing, understanding and quantifying the growth of *Greenwashing* in the market, the Canadian environmental marketing consultancy TerraChoice has developed a research methodology by printing on the packages orientations about environmental self-declarations established by the ISO 14021 standard. In that report, such fake or dubious appeals were classified in seven categories, called The Seven Sins of *Greenwashing*. Recently, many manufacturers have launched products implying that they are obtained from natural sources. This does not certify that the product was manufactured using the lower environmental impact technologies available, often hiding trade-offs (sin 1) concerning processes with high loads of pollutants. It is possible to see many statements that attest carbon footprint reduction without, however, supporting information by a third party that can validate these statements is the committing of “no proof” (sin 2). To state that a product is compostable in places where an infrastructure for residue collection and composting plants do not exist, is to commit the “sin of vagueness” (sin 3). Statements such as "heavy metal free" or “CFC free” according to the TerraChoice description, can be classified “a sin of irrelevance” (sin 4), since the maximum limits of these components are determined by legislation.

Avoiding *Greenwashing* does not mean the expectation of a perfect product, but that the honesty, transparency and scientific base are founded on the environmental declaration. To combat *Greenwashing*, the Environmental Packaging International (EPI) in the United States released in October 2009 a database of sustainable packaging materials, in which the package suppliers submit data from which information about sustainability of their materials are reviewed and confirmed by a third party. Similarly, the ISO 14021, environmental self-declaration, does not accept “vague” and inaccurate texts either such as “eco-friendly”, “environmentally safe”, “eco responsible”, and so on.

ABSTRACT

Benchmarking the environmental impacts of dairy production systems across the world can provide insights into their potential for improvement. However, collection of high-quality data for an environmental impact assessment can be difficult and time consuming. Based on a dataset of 55 dairy farms from different countries, this study aims to identify an effective set of indicators, that can explain most variation between farms and is relatively easy to quantify. Results show that global warming potential (GWP) per kg milk was highly correlated with nitrogen balance (NB) (r= 0.73, P<0.01) per kg milk, land use per kg milk (r= 0.58, p<0.01) and energy use per kg milk (r= 0.74, P<0.01). Correlations between phosphorus balance (PB) per kg of milk and other indicators, however, were low. Consequently, results of principal component analysis yielded two factors. The first factor consisted of GWP, NB, land use and energy use, all expressed per kg of milk, whereas the second factor contained PB per kg milk. We concluded, therefore, that GWP and PB can be used as proxies to benchmark specialized milk production systems across the world.

Keywords: life cycle assessment, nutrient balance, milk production, correlation analysis

1. Introduction

Milk is an important protein source in human diets. Around 57% of the protein content of an average European diet consists of livestock products, of which about one third is milk-derived (FAOSTAT 2013). The global demand for milk is expected to increase further due to population growth, rising incomes and on-going urbanization. Dairy production, however, has a major impact on the environment. The global dairy sector, producing both milk and meat, is responsible for about 30% of the anthropogenic greenhouse gas (GHG) emissions from livestock (Gerber et al. 2013). Moreover, the dairy sector contributes to resource scarcity (e.g. land and fossil energy) (De Vries and De Boer 2010).

Various environmental assessment methods have been adopted to evaluate the environmental performance of dairy production systems. Two methods are commonly used in the field of agriculture. The first method is based on a nutrient balance, and yields indicators such as nutrient use efficiency and the nutrient balance per unit product. The second method is based on life cycle assessment (LCA), and yields indicators such as global warming potential per unit product or land occupation per unit product (Halberg et al. 2005). Both methods, however, have their own drawbacks. On the one hand, a nutrient balance neglects certain environmental impact categories (e.g., land use, energy use); on the other hand, although LCA incorporates environmental impact categories which are overlooked by a nutrient balance, it is difficult and time consuming to collect all the data required to perform an LCA (Thomassen and De Boer, 2005). For cross-border benchmarking, the simplicity of the indicator sets can be very essential. The aim of this study, therefore, is to select an effective set of indicators from above mentioned methods, that can be used to benchmark the environmental performance of specialized dairy production systems.

Exploring correlations between various indicators can help stakeholders to identify an effective set of indicators to evaluate the environmental performance of dairy farms, i.e. a set of indicators which is relevant, needs a minimal amount of data and is understandable (Lebacq et al. 2013). Previous studies have focused mainly on correlations between indicators within LCA. Their findings suggested that the number of indicators may be reduced because of strong correlation between some indicators (Berger and Finkbeiner 2011; Huijbregts et al. 2010; Laurent et al. 2012; Röös et al. 2013). So far, however, correlations between various indicators derived from a nutrient balance approach and LCA have not been explored within dairy production systems.

The objective of this study is to identify an effective set of indicators to benchmark the environmental performance of dairy production systems. We, therefore, explored correlations between indicators derived from a nutrient balance and from an LCA and see whether we can have a set of simplified indicators that can be used as proxies to benchmark environmental performances of dairy farms.

2. Material and methods

2.1. Data

Data was collected from 55 specialized dairy farms from Dairyman which is a project in the INTERREG IVB program co-funded by the European Regional Development Fund (Dairyman 2010). Environmental performance of these farms has been determined based on different indicators using data of the year 2010. We defined specialized farms as farms that have less than 5% non-dairy purpose animals, and less than 10% of their agricultural area in use for non-dairy purpose activities. The amount of energy, land and fertilizers used for non-dairy purposes was based on farmers' estimates and excluded from the data set. These 55 dairy farms are from different countries and regions (i.e. Netherlands, Ireland, Belgium (Flanders, Wallonia), France (Brittany), Germany (Baden, Württemberg) and Luxembourg).

2.2. System boundaries

As illustrated in Figure 1, we defined different system boundaries for different methods (i.e. nutrient balance and LCA). For the nutrient balance, we examined the farms' performances both at farm and partial chain level. At the farm level, we considered inputs (e.g. concentrates, roughage, animal) and outputs (e.g. milk, meat, crops) per farm, while the farm itself was considered as a black box. At the partial chain level, the system boundary was from cradle-to-farm gate. In addition to nutrient losses at the farm, nutrient losses during the production of purchased feed products were considered. Production of other farm inputs were excluded because their contribution to nutrient losses was assumed to be negligible. For both farm and partial chain levels, manure outputs of the farm were deducted from the input of the system. Stock changes (defined as final stock – initial stock) of the concentrates, roughages and fertilizers were taken into consideration during the computation processes.

For LCA, the system boundary was from cradle-to-farm gate. System boundaries, therefore, included the primary production of farm inputs, and all processes on the farm, such as manure management, milk and feed production. Pesticides and water usage were not considered due to lack of data. Capital goods (buildings and machinery) were not considered because their contributions to the environmental impact of dairy farming were assumed to be negligible (Cederberg 1998).

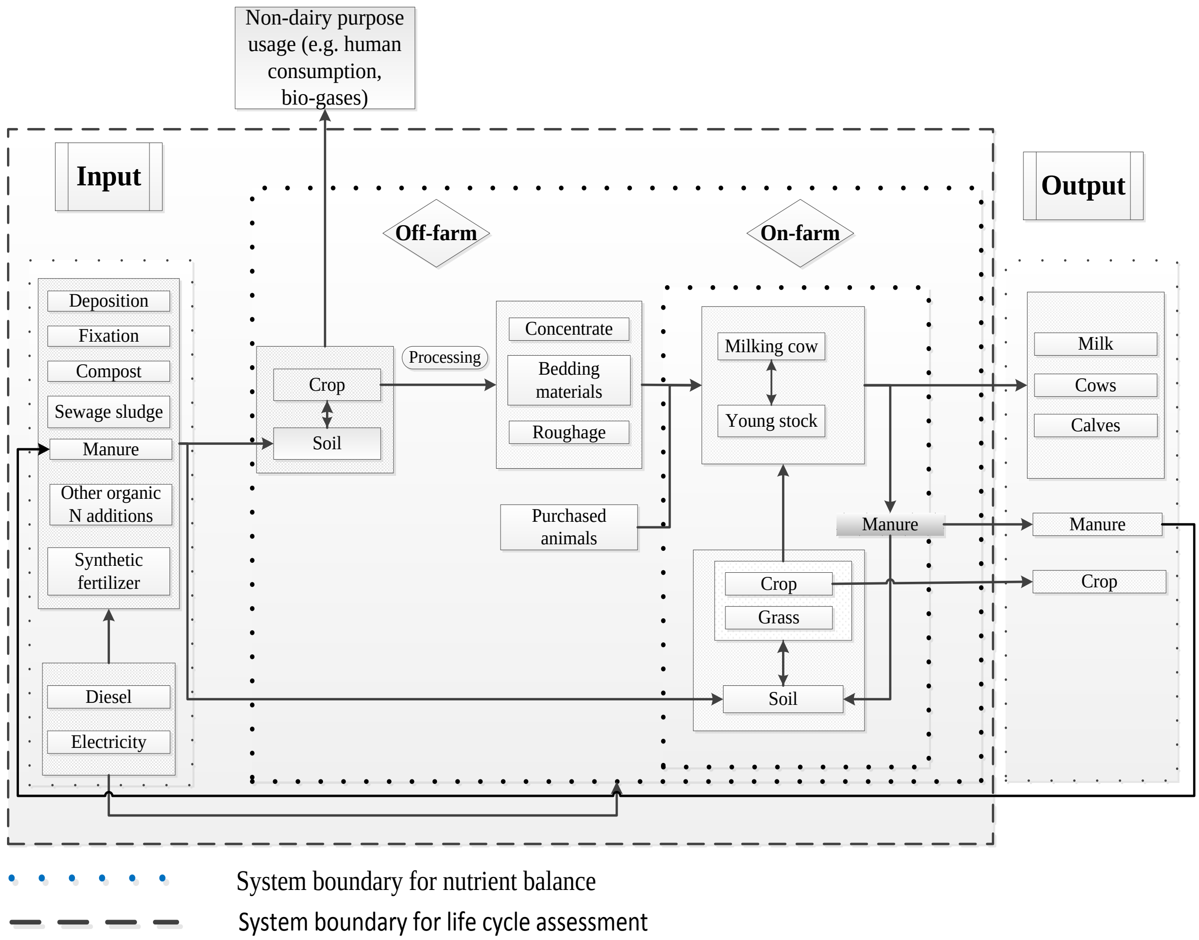

Figure 1. System boundaries

2.3 Nutrient balance

Nitrogen (N) and phosphorous (P) are essential nutrients for plant and animal production. The increased use of N and P for food production, however, also increased emissions of N and P compounds to the environment (Amon et al. 2011). In this study, based on N and P content in all inputs, outputs and stock changes of the systems, we computed N balance (NB) and P balance (PB) for each of the 55 dairy farms both at the farm level and partial chain level. The partial chain level nutrient balance was calculated by summing up the nutrient balance at farm level and the nutrient balance related to production of purchased feed products. Nutrient balance was defined as input-output and was expressed as nutrient balance / kg FPCM (fat-and-protein-corrected milk, i.e. milk is corrected to a fat percentage of 4.0% and a protein content of 3.3% using the formula: FPCM (kg) = Milk (kg) x [0.337 + 0.116 x Fat (%) + 0.06 x Protein (%)] (Product Board Animal Feed 2008)). Table 1 shows relevant inputs, outputs and calculation processes.

Table 1. Nutrient use efficiency for nitrogen and phosphorus

Elements	Calculation[4]	References
Input:		
Purchased animals	Q x nutrient content of animals	Raison et al. 2006
Purchased roughage[1]	Q x nutrient content of roughage	Dairyman 2010
Purchased concentrate	Q x nutrient content of concentrates[5]	Dairyman 2010
Purchased mineral fertilizer	Q x nutrient content of mineral fertilizer	Dairyman 2010
Purchased organic fertilizer	Q x nutrient content of organic fertilizer	Dairyman 2010
Atmosphere deposition	Average value of relevant region	EMEP 2007
Plant fixation[2]	Average value of relevant region	Raison et al. 2006
N&P input for producing feed[3]	N&P input for producing feed	Vellinga et al. 2013
Output:		
Milk output	Q x nutrient content of milk	Dairyman 2010
Animal output	Q x nutrient content of animals	Raison et al. 2006
Organic fertilizer output	Q x nutrient content of organic fertilizer	Dairyman 2010
Plant outputs	Q x nutrient content of plant	Raison et al. 2006

[1] We selected five most commonly used roughages in the dataset of Dairyman, i.e. grass silage, maize silage, hay, wheat straw and alfalfa.
[2] Plant fixation is only applicable for nitrogen
[3] Applicable for nutrient balance calculation at the partial chain level
[4] Q= actual quantity of product purchased or sold, obtained from Dairyman (in kg or numbers)
[5] Composition of the concentrate is based on the information provided by Dairyman

2.4. Life cycle assessment

The impact categories we examined are climate change, land use, and fossil energy use. The functional unit is FPCM. The computation for climate change is described in details in the following subsection.

Climate change. We used global warming potential (GWP) per kg FPCM as an indicator to assess the impact of milk production on climate change. GWP included emissions of the greenhouse gases (GHGs): CO_2, CH_4 and N_2O and was expressed in kg CO_2 eq per kg FPCM. Emissions of GHGs were summed according to the following equivalence factors (100-year time horizon): 1 for CO_2, 25 for CH_4, and 298 for N_2O (Forster et al. 2007).

We computed on-farm emissions of GHGs according to IPCC guidelines (IPCC 2006), generally at Tier-2 level. On-farm emissions included CO_2 emissions from lime and urea application, and combustion of energy resources, such as diesel; CH_4 emissions from enteric fermentation and manure management, and N_2O emissions from manure management and managed soils.

To compute CO_2 emissions from lime and urea application, we used the default emission factor of 0.12 for limestone, 0.13 for dolomite and 0.2 for urea as provided by IPCC (2006) Tier 1. To compute CO_2 emissions from on-farm energy use (i.e. fuel), we used emission factors from Eco-invent (2010).

Enteric CH_4 emission was determined as a function of the average gross energy (GE) intake of the dairy herd and a methane conversion factor of 6.5% (IPCC, 2006). Average GE intake of the dairy herd was calculated based on the total net energy requirement of the herd (i.e. energy required for growth, maintenance, activity, and milk production) and energy availability characteristics of feeds. CH_4 emissions from manure management were calculated based on the amount of volatile solids in manure and manure management system (IPCC, 2006).

During storage, treatment and application of manure, N_2O is emitted via direct and indirect pathways. Direct N_2O emissions from manure storage and treatment were calculated by multiplying the total amount of N excretion within a certain manure management system with an emission factor for that type of system (IPCC, 2006). Direct N_2O emissions from manure application were calculated by multiplying the amount of N in manure applied to the field with the default emission factor of 0.01 (IPCC, 2006). Indirect N_2O emissions were based on the amount of N volatilized in the form of NH_3 and NO_x, and the amount of N leached in the form of NO_3 (IPCC, 2006). In addition, direct and indirect N_2O emissions from application of synthetic fertilizer, crop residues, and from urine and dung deposited on pasture during grazing were included and based on IPCC (2006) calculation rules.

Off-farm GWP was calculated based on GHG emissions from production and transportation of purchased feed (e.g. concentrates, roughages, by-products and from production of synthetic fertilizer. Concentrates were categorized into four categories: cereals (i.e. wheat, barley, triticale, oat, and corn), rapeseed meal, soya meal, and other. GHG emissions related to production of purchased feed products were based on Vellinga et al. (2013). GHG emissions related to production of fertilizers were based on Ecoinvent (2010).

Land use. This impact category examines the area of land (m^2) used to produce one kg FPCM. For on-farm land use, we considered agricultural area used for dairy purpose. For off-farm land use, we considered land used for cultivation of concentrate ingredients, roughage and by-products (Vellinga et al. 2013), and for the production of fertilizers (Ecoinvent, 2010).

Energy use. On-farm energy use relates to milking of the dairy cows and on-farm feed production, and is based on Dairyman (2010). Off-farm energy use related to the production of purchased feed products was based on Vellinga et al. (2013); energy use related to the production of fertilizers was based on Ecoinvent (2010). We assumed that energy used in this study are electricity and diesel.

2.5 Statistical analysis

Principle component analysis (PCA) was applied to characterize the indicators to get an efficient set of indicators that can explain most of the variation. We applied PCA on seven indicators at the chain level i.e. NB, PB, GWP, land use and energy use. Spearman Rho's correlation analysis was conducted due to the fact that most variables are not normally distributed. After that, we did Kaiser-Meyer-Olkin test (KMO>0.5) and Bartlett's Test of Sphericity ($p<0.05$) in order to assure the adequacy of data sampling and suitability to conduct the PCA. We selected factors based on the rule of eigenvalue > 1. All statistical analyses in this study were performed using the software SPSS (SPSS 2011).

In order to interpret correlations identified from correlation analysis, we used the criterion in Cohen (1998, as cited in Röös et al. 2013), where defines r=0.1-0.29 (weak correlation), r=0.30-0.49 (medium correlation) and r=0.5-1 (strong correlation).

3. Results

3.1. Nutrient balance

As shown in Table 2, for nitrogen, the average farm balance/kg FPCM is 16g N, whereas the average chain balance/kg FPCM is 19g N; for phosphorous, the average farm balance/kg FPCM is 1g P, whereasthe average chain balance/kg FPCM is 2g P.

Table 2. Results of nutrient balance

Indicator	Unit	Mean	SD	Maximum	Minimum
Nitrogen					
Farm balance	g N / kg FPCM	16	8	34	4
Chain balance	g N / kg FPCM	19	7	37	6
Phosphorous					
Farm balance	g P / kg FPCM	1	1	3	0
Chain balance	g P / kg FPCM	2	1	8	1

3.2. Life cycle assessment

According to Table 3, producing one kg FPCM contributes to climate change (1.31 kg CO_2 eq), meanwhile, it uses 1.29 m^2 land and 2.92 MJ energy. On-farm processes have a larger impact on climate change and land use than off-farm processes. However, off-farm processes use more energy than the on-farm processes. Finally, variation between farms is greater for on-farm processes than for off-farm processes.

Table 3. Results of LCA

Impact category	Unit	Mean	SD	Maximum	Minimum
Climate change	kg CO_2 eq / kg FPCM				
On-farm		1.08	0.25	1.76	0.75
Off-farm		0.23	0.81	0.54	0.04
Total		1.31	0.29	2.08	0.94
Land use	m^2 / kg FPCM				
On-farm		0.82	0.38	2.23	0.32
Off-farm		0.47	0.21	1.48	0.11
Total		1.29	0.45	2.80	0.76
Energy use	MJ / kg FPCM				
On-farm		0.53	0.15	1.11	0.21
Off-farm		2.39	0.69	4.74	1.28
Total		2.92	0.74	5.26	1.49

3.3. Statistical analysis results

Results of correlation analysis are reported in Table 4. NB shows low correlation with PB (r= 0.04). GWP shows strong correlations with NB (r= 0.73, P<0.01), land use (r= 0.58, p<0.01), and energy use (r= 0.74, P<0.01). Energy use shows strong correlation with NB (r= 0.57).

A positive nutrient balance can cause emissions like N_2O which is a major contribution to the GWP, therefore GWP shows a strong positive correlation with NB. Land use and GWP are both expressed per kg FPCM. A possible explanation for the correlation between land use and GWP is that farms that are less efficient will have a lower milk production per ha (i.e. a higher land use), but also higher losses and, therefore, higher GHG emissions per kg FPCM. In addition, during production and use of energy, there are emissions like CO_2 and N_2O. All these emissions can increase GWP, therefore a high positive correlation is found between GWP and energy use.

The results of Kaiser-Meyer-Olkin (KMO) test and Bartlett's Test confirmed the suitability of conducting a PCA (principal component analysis). Sampling size is adequate (KMO= 0.655) and Bartlett's test of sphericity is significant (p= 0.000). Two factors were extracted from PCA, where NB, GWP, land use and energy use are grouped into one factor and PB is grouped into the second factor. The first factor can explain 58% variation existing in the data, and by also considering the second factor, total 79% variation existing in the data can be explain.

Table 4. Results of correlation analysis

	N balance	P balance	GWP	Land use	Energy use
N balance[1]	1	0.037	0.728^{**}	0.359^{**}	0.567^{**}
P balance[1]	0.037	1	-0.220	0.082	-0.211
GWP	0.728^{**}	-0.220	1	0.584^{**}	0.739^{**}
Land use	0.359^{**}	0.082	0.584^{**}	1	0.498^{**}
Energy use	0.567^{**}	-0.211	0.739^{**}	0.498^{**}	1

** Correlation is significant at the 0.01 level (2-tailed)
* Correlation is significant at the 0.05 level (2-tailed)
[1] N balance and P balance here are both at the chain level.

4. Conclusion

Results of the correlation analysis show that global warming potential (GWP) per kg milk was highly correlated with nitrogen balance (NB), land use, and energy use. Correlations between phosphorous balance (PB) and other indicators, however, appeared to be low. Consequently, results of PCA yielded two factors. The first factor consisted of the indicators GWP, NB, land use and energy use, whereas the second factor contained PB. Therefore, we concluded that GWP and PB can be used as proxies to benchmark specialized milk production systems across the world. Future studies might include other environmental indicators, such as eutrophication potential and acidification potential, to further explore possibilities for identifying an effective set of indicators to benchmark environmental performance of dairy production systems.

Lessons Learned teaching a Massive Open Online Course on the Sustainability of Global Food Systems

ABSTRACT
In the summer of 2013, we delivered a Massive Open Online Course (MOOC) exploring the *Sustainability of Food Systems: A Global Life Cycle Perspective*, which saw thousands of people from 138 countries enrolled in the course. We focused on increasing awareness of the complexity and global reach of modern agriculture and food production systems while enabling students (i.e., consumers) to understand the implications and impacts of their personal/household dietary decisions. The course included full cradle-to-grave consideration of food production; from the seeds that may have been genetically modified, through the choice of organic or synthetic fertilizer application, to the nutrient and calorie waste from poor handling or food spoilage. Through the interactive, discussion-based nature of the course, the students learned at least as much from stories and experiences shared by each other as from the video lectures and readings. As we hoped, many students left the course with an understanding of the substantial environmental impacts from activities throughout the life cycle of food production, and the importance of informed decision-making at the consumer level.

Keywords: teaching, Massive Open Online Course (MOOC), global food systems, sustainable food systems.

1. Introduction

Food systems represent a strong opportunity for those interested in life-cycle assessment (LCA) to affect positive change in reducing the environmental burden of human activities. Agricultural activities cover 38% of global land area (The World Bank), and are responsible for 10 to 12% of global anthropogenic greenhouse gas emissions (Smith et al. 2007) (2011 and 2005 figures, respectively). The supply chains that depend on agriculture are complex, but this complexity means there are many possible intervention points. In the spirit of the adage “an ounce of prevention is worth a pound of cure”, changing the behavior of the final consumer of food and agricultural products has a magnified impact on the agricultural practices at the start of the supply chain. The most effective way to achieve this change may be through education.

From June through August 2013, we helped thousands of students become better educated about global food systems through a Massive Open Online Course (MOOC) on the Coursera platform entitled *Sustainability of Food Systems: A Global Life Cycle Perspective*. A MOOC is free for everyone, anywhere so long as they have an Internet connection; there are no prerequisite courses or degrees, and the students are essentially free to interact with the course materials and each other as much or as little as they wish. Our course saw enrollment from 138 countries, and participation by more than 15,000 students.

Like many extension and outreach-focused efforts from the life-cycle assessment community, this course aimed to increase awareness of the complexity and global reach of modern agriculture and food production systems while enabling students (i.e., consumers) to understand the implications and impacts of their personal/household dietary decisions. Course content was organized around exploring the answers to 15 overarching questions. These included: How and where do we grow our food?; How do we choose what we eat?; and, How does what we eat affect our environment? As illustrated in Figure 1, we began at a personal level in discussing the nature of food and our individual relationships with it, then expanded our scope of investigation in order to illustrate the global nature of modern agricultural supply chains, then looked at the health and environmental impacts associated with this global supply chain, and finally returned focus to the individual in exploring how our personal or household choices could contribute to a more sustainable food system.

In this paper, we will discuss course organization, highlight some of the course topics most relevant to the food LCA community, and reflect on the key outcomes from this experience.

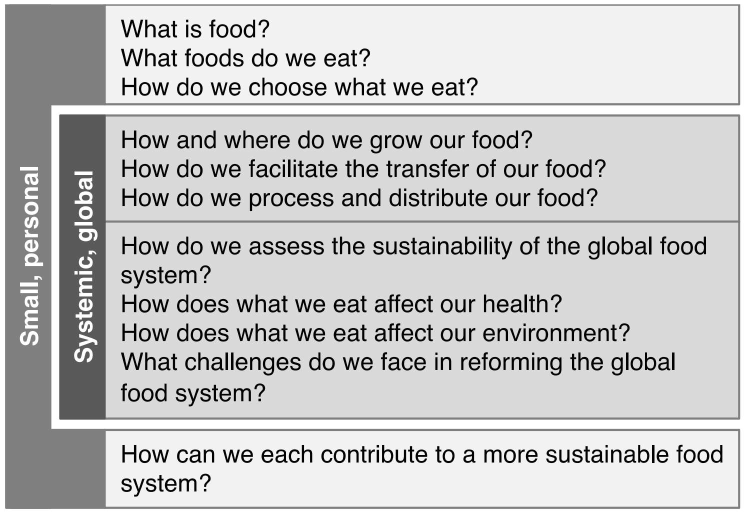

Figure 1. The complex global nature of agricultural supply chains and environmental impacts was the focus of our course, but we bookended the content with smaller scale, personal considerations so that students realized they could still affect change despite being a single actor in the system.

2. Materials and Methods

Course content was delivered in two ways: through readings, and through recorded conversations between Prof. Jason Hill and topic experts from the University of Minnesota. To keep the course ‘open’, readings were required to be accessible to anyone, anywhere, with zero cost. This ruled out using certain published journal articles, or requiring that students purchase any textbooks. It did not, however, rule out small extracts from books or articles as per fair use rules under copyright law. A complete list of readings is included in Table 1.

One of the key challenges of teaching in a MOOC environment is how to assess students' comprehension of the materials and concepts presented. Due to the sheer number of participants, it is not possible for student responses to an essay prompt to be assessed by a professor or teaching assistants. Multiple choice or filling the blank type questions are implementable, but only go so far in assessing student understanding of content. This latter assessment is problematic in a course such as this that requires students to incorporate new knowledge into what they already know about food systems. Our approach, then, was to get the students to engage with each other and discuss topics through the discussion forum on the course website (see Figure 2 for a screenshot). Through these interactions, the students learned at least as much from shared stories and experiences as they did from the video lectures and readings. As instructors, we also learned from these exchanges; stories from students in developing countries about ingenious local production practices, or from students directly involved in food aid assessment add color and context to more academic publications on which we base our understanding of the topics we teach.

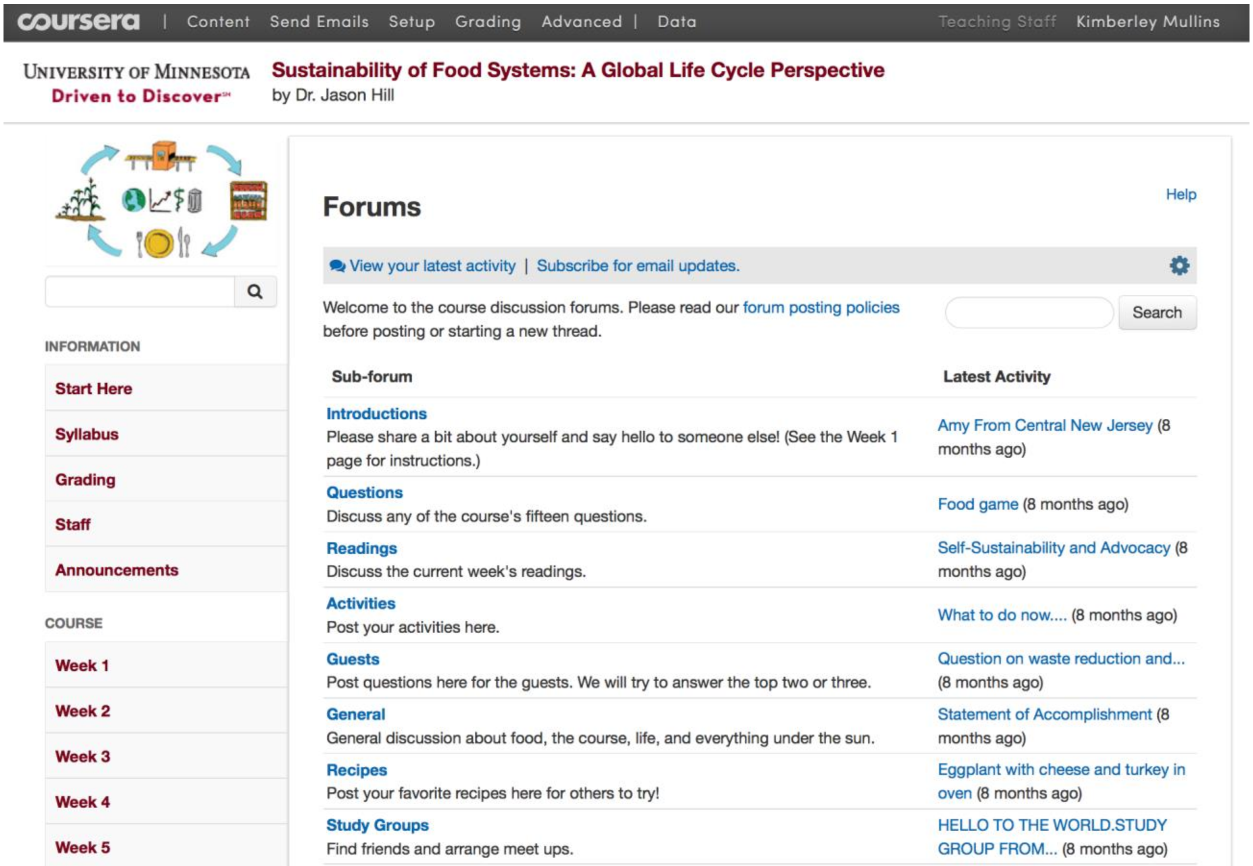

Figure 2. A screenshot of the Forums section of the course on the Coursera platform. Sub-forum headings directed the students towards the appropriate places to post questions, respond to assignment prompts, etc.

To introduce students to the beginning of the food supply chain, we discussed where our food originated historically. This issue is important in considering the sustainability of the global food system, as the plants and animals we consume now depend on the domestication decisions that were made many years ago. One assigned reading highlighted the fact that the domestication process is, in fact, ongoing in Africa (Pye-Smith 2009). We asked the students to pick a recent meal they had eaten, and determine to which regions in the world the basic ingredients of their meal were native. For example, if one had eaten spaghetti and meat sauce (wheat, cow, tomato and basil), the list would include the Eastern Mediterranean, the Andes, and India. The course materials and the exercise encouraged the students to reflect on how the availability of food has changed over time, and to consider the idea of “eating locally”, popular among those wishing to reduce the environmental impacts of their diets, in a new context.

The question of where our food originated was followed by a discussion of how our food is grown today. Prof. Paul Porter of the Department of Agronomy and Plant Genetics at the University of Minnesota discussed the myriad of agricultural practices currently undertaken around the world, highlighting that many practices in the world do not resemble the large-scale agriculture practiced in the midwestern United States. Of course, different practices characterized by labor and chemical input are associated with different yields. We had the students explore which countries produced which crops, and with what yields, using an online database from the UN’s Food and Agricultural Organization called FAOSTAT. This database is free and easy to query, important characteristics for a diverse student population.

A key step in the food supply chain is the conversion of these raw, basic ingredients into what is termed ‘processed food’. This can include anything from pasta to a ready-made frozen meal. This step has become an increasingly important one in developed countries, though the term ‘processed food’ is often used with negative connotations. Students read an article discussing the social and dietary impacts of major multinational food companies moving into Brazil (Monteiro and Cannon 2012). The students then heard Prof. Gary Reineccius of the Department of Food Science and Nutrition at the University of Minnesota describe food scientists' innovative work in food processing to improve the sustainability of the global food system. For example, food scientists can make whole grains more palatable to the general public through the calculated use of polyphenols, a natural plant extract that stops a chemical reaction during baking that produces an undesirable bitter flavor. The unsophisticated response is simply to add sugar to mask the bitter taste. The result of this food science development is that more whole grain low-calorie foods are consumed.

Environmental impacts lie at the heart of assessing the sustainability of the global food system. Prof. Stephen Polasky of the Departments of Applied Economics and Ecology, Evolution, and Behavior presented the concept of ecosystem services to the students. We felt it important to acknowledge that sustainability depends on more than reducing greenhouse gas emissions, but rather the natural systems upon which our food supply depend also influence biodiversity, water quality, air quality, and nutrient flows. A key point made by Prof. Polasky is that the food services we want from our natural systems, namely the profitable yield of food, can be at odds with the services we agree are beneficial but are not easily bought or sold, such as water remediation.

Some students were aware of these types of impacts or benefits because of the various food-labeling standards in place around the world. A discussion of supply chain impacts from Prof. Tim Smith, Director of the Northstar Initiative for Sustainable Enterprise, and a reading on "greenwashing" (Dahl 2010) forced the students to more carefully consider the claims made by labeling organizations and their eco-labels. His central point was that there is an important tradeoff between how rigorous and scientific the labeling requirements are and how many companies will actually engage in the process to receive the label. To reinforce this discussion, we asked the students to investigate two products that bore some claim to sustainability, with the expectation that students would find the requirements to earn the label, or the research and testing done to support an in-house claim of sustainability, vary widely among companies and labeling organizations. A handful of students were able to deliver what amounted to impressive investigative reporting to the rest of the class.

We wanted to make sure the students left the course feeling empowered to affect positive change and hopeful that change is possible, which can seem challenging in the face of a complex global system full of problems. To do so, we discussed broadly how we can provide food more sustainably, and how the individual consumer can contribute to a more sustainable global food system. The students read and heard the strategy of Prof. Jon Foley, Director of the Institute on the Environment, to feed a growing population more sustainably by increasing yields in low-yielding areas of the globe, increasing the use of modest technology options to improve the ratio of calories output to units of water or fertilizer input to an agricultural system, to reduce global meat consumption, and the reduce food lost to waste (Foley 2011).

3. Learning Outcomes

At the end of the course, we asked the students to reflect on what they had learned, and how they could apply their new knowledge in their own lives to improve the sustainability of the global food system. Some key themes emerged in reviewing student responses to the prompt. One of the most common responses given by students was their plan to reduce meat consumption, or at least reduce beef consumption, in light of the negative impacts of a global food system that relies heavily on the production and processing of animal protein.

Many students also left the course feeling better able to find further information on the topic we studied, or new topics we were not able to cover given the introductory nature of our curriculum. This result came from the introduction of tools, such as the FAOSTAT database, resources, of reputable organizations or scholars in the field of food systems and life-cycle assessment, and, simply, from a newfound vocabulary the students could leverage to find reliable information online more quickly.

From a pedagogical standpoint, we learned that emphasizing student interaction in the forums had many advantages, but it was not without drawbacks. Like tends to attract like, and in many cases this lead to a small community within the class that could share resources on specific interests such as vermiculture, managing dietary restrictions related to illness, or the challenges of food aid policy. Unfortunately, on some occasions these communities simply propagated misinformation. Perhaps the strongest such case was a completely erroneous discussion that arose about how using microwaves to heat food causes cancer because radiation affects DNA. We interjected with a post carefully crafted to explain the important differences between ionizing and non-ionizing radiation, and how microwaves employ only the latter, but it went completely unheeded by the discussion participants. Unfortunately, some deeply held convictions and prejudices were not shaken, and the nature of MOOCs made this task all the more difficult.

4. Conclusions

Agriculture, a global system expanding by necessity to feed an increasing population, is associated with many substantial environmental and health issues and changes in human behaviour are needed. This MOOC presented us with an opportunity to increase the awareness of the individual decision maker with regards to the complex and global nature of the modern agricultural system, and the challenges present, along with the resulting opportunities to improve sustainability. Based on participation and the ensuing robust discussions, we believe our efforts were successful.

In addition to being more aware, many students left the course believing that their individual efforts could have an impact on upstream activities in the supply chain. Some declared that they would change their behaviors; others argued that they could not, citing lifestyle pressures and other challenges. Some gained a confirmation of their current choices. The fact that such attitudes were expressed indicated successful engagement.

It was beyond the scope of this (or any) MOOC to assess the true impact on behavior; that is, will students actually behave differently? That said, we feel confident that our efforts have captured their attention and given them cause to consider the course of action they might take.

ABSTRACT

The purpose of this work was to evaluate from cradle to gate the environmental performance of five vegetable oils: palm oil, soybean oil, rapeseed oil, sunflower oil and peanut oil, using a consequential approach and including indirect land use change. The impact assessment focused on greenhouse-gas (GHG) emissions, land use and water consumption. For GHG emissions, rapeseed oil and sunflower oil were the best performing ones, followed by soybean oil and palm oil and with peanut oil as the oil with the highest impact. Focusing on water consumption, sunflower oil was the oil with the smallest impact, followed by rapeseed oil, palm oil and soybean oil, and with peanut oil as the oil with the largest contribution. Regarding land use, palm oil and soybean oil were the oils associated with the smallest contribution, followed by rapeseed oil, and with sunflower oil and peanut oil as the oils with the largest net occupation of land.

Keywords: Palm oil, Soybean oil, Rapeseed oil, Sunflower oil, Peanut oil.

1. Introduction

The aim of this study was to evaluate the environmental impacts of a number of the major vegetable oils: palm oil, soybean oil, rapeseed oil, sunflower oil and peanut oil. Different vegetable oils systems are associated with different quantities of co-products, mainly oil meals, which are used as animal feed. When studying market responses related to changes in demand for the different oils and when substituting different oils, it is a challenge to address the interactions among oils and with the feed markets. The studied product systems were identified using a systems perspective approach where likely market responses and substitution effects are considered.

Previous research on comparative life cycle information on vegetable oils is relatively limited. Examples are Arvidssona et al. (2013) and Schmidt (2010). A larger number of studies exist within the field of biodiesel (e.g. Menichetti et al. 2009), which are most often limited to focus only on GHG emissions compared to mineral diesel (Mentena et al. 2013).

2. Methods

2.1. Goal, scope and functional units

The purpose of the study was to obtain environmental information on different major vegetable oils, to provide decision support for situations where different vegetable oils can be used, i.e. where the oils are substitutable. A functional unit of one ton refined (neutralized, bleached and deodorized; NBD) vegetable oil at refinery gate was used.

2.2. Consequential life cycle inventory modelling

The consequential modeling principles are comprehensively described in Ekvall and Weidema (2004) and Weidema et al. (2009). This approach was consistently applied throughout the study. The attributional approach would fail to comply with the purpose of the study, which focuses on predicting the environmental consequences of choosing different oils.

Production of refined vegetable oils is characterized by being associated with several by-products where the major ones are the oil meals from the oil mills and free fatty acids (FFA), which are a by-product from the refining process. Both the oil meals and FFA are used as animal feed. Schmidt at Weidema (2008) identified two major segments of the global generic animal feed market; namely feed protein and feed energy. Therefore a change in supply of oil meals and FFA will substitute these two products in proportion with their protein and energy content. Since the attributional approach only estimates/approximates the effects from downstream processing of by-products and product substitutions by applying an allocation factor on the upstream effects, this approach does not reflect actual cause-effect mechanisms in the market. The technique for performing the substitution calculations for vegetable oil systems is demonstrated in several studies, e.g. Dalgaard et al (2008) and it is also implemented in ecoinvent v3 (ecoinvent Centre 2013).

2.3. System boundaries

The inventories were established to represent 2011. The production functions for oil mill and refinery operations were regarded as being relatively constant over time, so data for 2005-2010 were used to represent 2011.

The study followed the same cut-off criteria as the ecoinvent v2.2 database (ecoinvent 2010). This implied that inputs of services (such as cleaning, accounting, lawyers, marketing, business travelling), research and developing (laboratories, equipment, offices etc.), and overhead (overhead energy, office equipment etc.) were not included. Further, the use of pesticides was not included in the study. Indirect land use changes (iLUC) were included (see section 2.3).

The oils were inventoried from cradle to gate (at refinery). Each of the five oil product systems included three product stages: 1) oil crop cultivation, 2) oil mill, and 3) refinery. Generally, the oil mills supply crude oil and oil meal (feed energy and feed protein) and the refineries supply refined oil and free fatty acids (feed energy). However, the palm oil system includes an additional step, since the kernels from the fresh fruit bunches are sent to another oil extraction step. As an example, Figure 1 shows the process diagram and mass balance for the palm oil and rapeseed oil systems. When solving the inventory problems related to multiple product output systems using substitution, it was necessary to identify which one of the co-products was the determining one. The latter is defined as the one for which a change in demand leads to a change in supply. In short, for all oils, except the soybean oil system, the oil was the determining co-product. For soybean oil though, it is the demand for the protein meal that determines the supply, not the demand for the oil. Therefore, the modeling of soybean oil did not directly involve the cultivation and processing of soybeans. Instead, a change in demand for soybean oil would affect other users of soybean oil, which would then have to compensate with another oil. The most likely compensation oil was palm oil since this was identified as the marginal one (Schmidt and Weidema 2008). This meant that the environmental impact from demanding soybean oil was similar to that of palm oil. The identification of determining products and byproducts is summarized in Table 1.

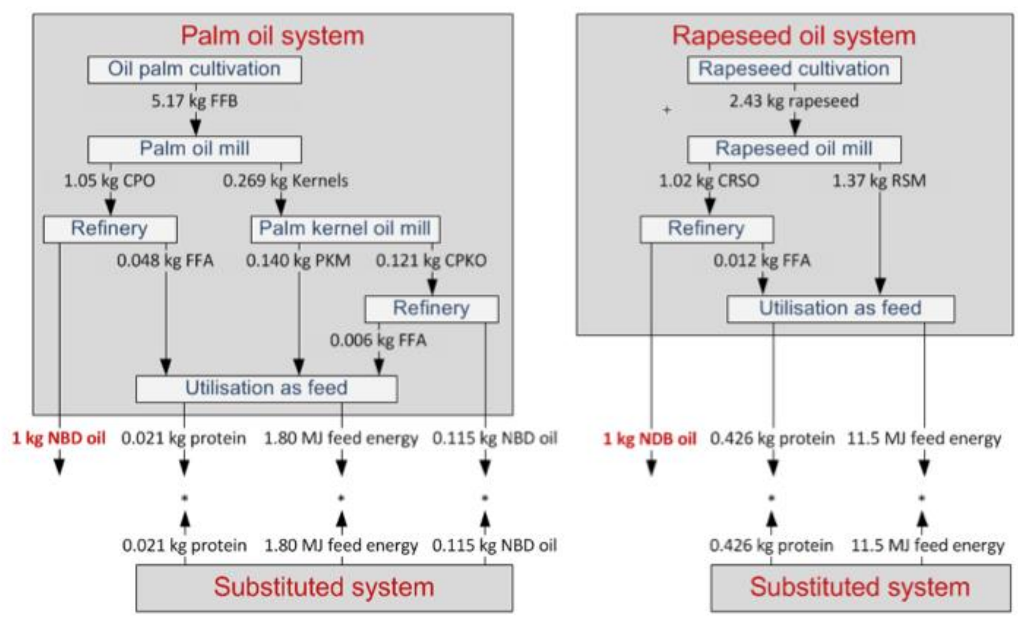

Figure 1. Process diagrams for palm oil (left) and for rapeseed oil as an example of all other oils (right). NBD: neutralized, bleached, deodorized, FFB: fresh fruit bunches, CPO: crude palm oil, CPKO crude palm kernel oil, FFA: free fatty acids, PO: palm oil, PKO: palm kernel oil, PKM: palm kernel meal, RSM: rapeseed meal, CRSO: crude rapeseed oil.

Table 1. Determining products and by-products in the five oil production systems.

	Palm oil system	Soybean oil system	Rapeseed oil system	Sunflower oil system	Peanut oil system
NBD oil	Determining	Byproduct	Determining	Determining	Determining
NBD palm kernel oil	Byproduct	n.a.	n.a.	n.a.	n.a.
Protein meal	Byproduct	Determining	Byproduct	Byproduct	Byproduct
FFA	Byproduct	Byproduct	Byproduct	Byproduct	Byproduct

n.a.: not applicable.

For the substituted systems caused by the by-products, the marginal supply of feed energy and feed protein were identified as barley and soybean meal in Schmidt and Dalgaard (2012, 63-64, 85). Furthermore, Schmidt and Dalgaard (2012), identified the marginal suppliers of barley and soybean meal as Ukraine and Brazil.

The inventoried regions of the five oils were identified as the country/region with the highest increasing trend in production volume of the oil crops from 2001 to 2011 (FAOSTAT 2013a), as this trend indicates which region could be a good candidate for the marginal one, i.e. the country/region that is likely to supply a change in demand for a specific oil. It was assumed that the oil mills and refineries are located in the same region/country as the cultivation of the oil crops. The chosen regions were:

- Fresh fruit bunches: Indonesia/Malaysia
- Soybean: Brazil
- Rapeseed: Europe (EU27)
- Sunflower: Ukraine
- Peanut: India

2.4. Indirect land use change (iLUC)

In the current study an advanced cause-effect based iLUC model described in Schmidt et al. (2012) is applied. This model was developed by 2.-0 LCA consultants through a larger project (2.-0 LCA consultants, 2014) supported by a large range of industries (e.g. Unilever, DuPont, TetraPak, Arla Foods, DONG Energy, United Plantations), universities (e.g. Swedish University of Agriculture Sciences, Aalborg University and Copenhagen University) and other research related organisations (e.g. The Sustainability Consortium, the ecoinvent LCA database, the Roundtable on Sustainable Palm Oil (RSPO) and the Japanese National Agricultural Research Center) plus several others.

This model considers land as capacity for biomass production. There exists a market for land, which is called the land tenure market. Since crops can be grown in different parts of the world and since crops are traded on global markets, it is argued that this market for land is global. The ‘product’ traded on this global market is capacity for biomass production. It should be noted that this capacity can be created in different ways:

1. Expansion of the area of arable land (deforestation)
2. Intensification of land already in use (through e.g. increased use of fertilizers)
3. Crop displacement, i.e. someone reduces consumption, e.g. induced by increases in prices, in order to allow others for using the biomass production capacity (social impacts)

The third point above is assumed to be zero because LCA considers long-term effects of changes in demand. In the long term, suppliers will adjust their production to match demand, and unless the production costs are higher, the prices will remain unchanged.

The capacity for biomass production needs to be measured in an appropriate unit. An obvious option for a reference flow of a land-tenure activity would be occupation of land (ha yr). However, this approach does not take into account that the potential production on 1 ha yr land in e.g. a dry temperate climate is very different from the potential in wet tropical climate. Another option would be the potential Net Primary Production (NPP_0), measured in kg carbon, which was the solution adopted.

As it can be seen in Figure 2, the model accounts for emissions related to both expansion (deforestation) and intensification of land. The proportion between expansion and from intensification is calculated based on the total NPP_0 on new arable land and total NPP_0 (carbon in crops) from an increase in fertilizer use in one year. All inflows to the land-market tenure activity are measured in kg NPP_0 (as kg carbon). The NPP_0 from expansion is determined based on general NPP_0 per ha yr figures (Haberl et al. 2007) and figures on annual increase of arable land. The NPP_0 from intensification is calculated as the carbon in crop produced via intensification during one year. The intensification is determined based on crop yield dose-response figures for fertilizer input (Schmidt 2008) combined with information on which crops and where intensification takes place (data from FAOSTAT) and current fertilizer levels for these crops (IFA 2013).

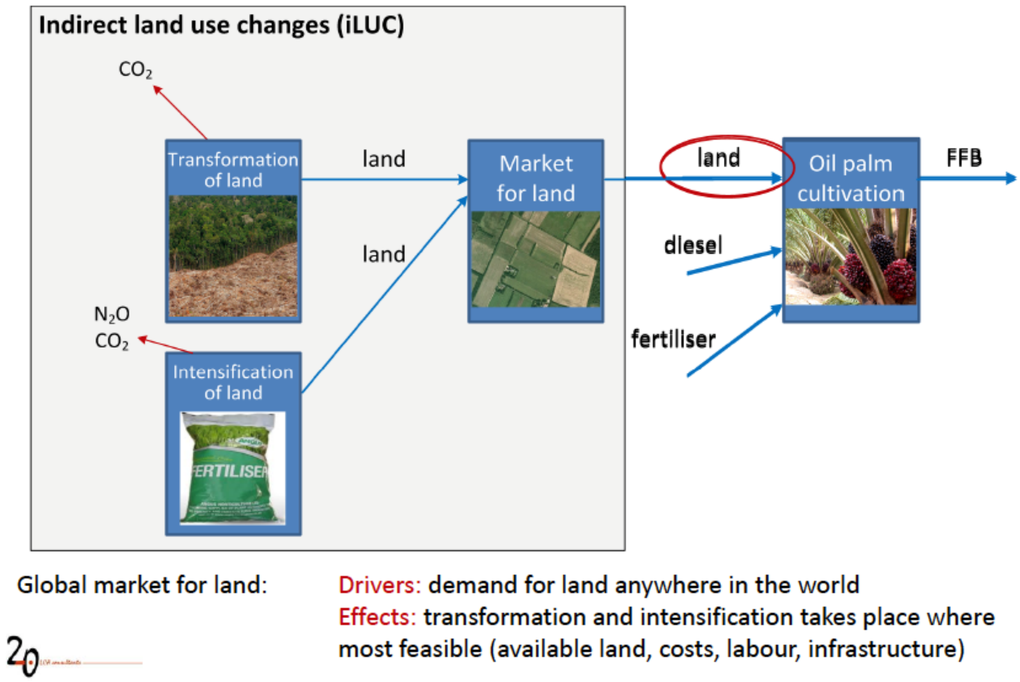

Figure 2. Conceptual representation of the iLUC model used in the study.

When the occupation of land causes deforestation, a critical point is often to decide the period of time over which the deforestation emissions should be allocated or 'amortized'. The current model does not operate with amortization. If only expansion is considered, occupation of 1 ha in 1 year will cause 1 ha deforestation. After the duration of 1 yr, the land is released to the market for land, i.e. to other crops, which can then be grown without deforestation. Hence, the occupation of 1 ha yr is modeled as 1 ha deforestation in year 0 and -1 ha deforestation in year 1. In order to model the GHG effects of this intermediate acceleration of deforestation, the method described in Kløverpris and Mueller (2013) is used.

Overall this iLUC model has several key characteristics that make it superior to many of the other existing models: is applicable to all crops (also forest, range, build etc.) in all regions in the world, it overcomes the allocation/amortization of transformation impacts, and it is based on modeling assumptions that follow cause-effect relationships and standard modeling consistent with any other LCA-processes. It is acknowledged though that this is one among many other models, and that there is currently no consensus in the LCA community on how to model iLUC. Therefore, the contributions to results from iLUC are reported separately.

2.5. Life cycle inventory data sources

The oil crop (and barley) yields were estimated for 2011 by linear regression over the period 2001-2011 with use of data from FAOSTAT. For oil palm a weighted average of Malaysia and Indonesia was applied, based on area cultivated: 40% MY and 60% ID. Fertilizer inputs are identified in the following data sources: Oil palm (Schmidt 2007), Soybean (Dalgaard et al. 2008), rapeseed oil (Plantedirektoratet 2004), Sunflower (FAO 2005), Peanut (Diwakar 2004; Talawar 2004), and Barley (FAO 2005). The fertilizer mixes of different sources of N, P and K are identified at the country level in IFA (2013). Diesel consumption was obtained from Dalgaard et al. (2008), Cederberg et al. (2009) and Schmidt (2007). Water use for irrigation was modeled using data from AQUASTAT (FAOSTAT 2013b) and FAOSTAT (2013a). Oil palms are not irrigated and <1% of the area with barley and sunflower in Ukraine is irrigated. Irrigation data for rapeseed in EU27 were approximated by non-crop specific data for Germany and France. For the iLUC model, the potential productivity of the occupied land was estimated based on Haberl et al. (2007). N-related emissions for all crops (NH_3, NOx, N_2O, NO_3, N_2) were estimated based on a N balance, using the methodology from IPCC (2006).

In average 18% of the cultivated oil palms were assumed to be grown on peat, based on Agus et al. (2013). It should be noticed that this proportion may not reflect the marginal producers of palm oil, but the current average. CO_2 emissions from peat were estimated as 43 t CO_2 per ha yr (for average drainage depth) based on a review of several studies (Agus et al. 2013b; Melling and Henson 2011; Hooijer et al. 2010; Hooijer et al. 2012). N_2O emissions from peat oxidation were calculated by using IPCC (2006).

The inventories for oil extraction in the mills were based on Schmidt (2007), Dalgaard et al. (2008) and Dalgaard and Schmidt (2012) for soybean oil, palm oil, palm kernel oil and rapeseed oil. For sunflower and peanut oils the meal/oil ratios were obtained using statistics on global oil and meal production from the period 00/01 to 05/06 (Oil World annual 2005). The milling operation includes thermal energy inputs, electricity inputs (as well as outputs exported to the grid), transports, water inputs, and capital equipment (mill). The by-products from the milling process e.g. empty fruit bunches, meal, are utilized as fertilizers or feed and thereby substitute mineral fertilizer or feed energy (barley) and feed protein (soybean meal) on the market.

The inventories for the refining process are based on Schmidt (2007) and Schmidt and Dalgaard (2012). These refineries supply refined oils and FFA (free fatty acids). The latter is used for livestock feeding and thereby substitute feed energy on the market.

The ecoinvent database v.2.2 (ecoinvent 2010) was used to model the background system (production of fertilizers, and other materials, energy, and capital goods. This database version is not linked using consequential modeling. However electricity profiles used in the foreground system (Europe, India, Brazil, Indonesia, Malaysia, World) were defined using a consequential approach, as explained in Schmidt et al. (2011).

Inventory data for marginal sources of feed protein (soybean meal from Brazil) and feed energy (barley from Ukraine) were obtained from Dalgaard and Schmidt (2012) and Schmidt and Dalgaard (2012).

2.6. Life cycle impact assessment

Life cycle impact assessment focused on three indicators, namely global warming, land occupation and water consumption. Global warming is calculated using IPCC's GWP100 (Forster et al. 2007). Biogenic CO_2 was included as CO_2 stored in oils. Biogenic CO_2 emissions originating from iLUC were also included. Land occupation is used in this study as an early midpoint indicator for impacts on biodiversity, and it includes only occupation of arable land. With regard to water consumption we used the terminology from the Water Footprint network (Hoekstra et al. 2011), however only 'blue' water (irrigation) is included in the impact assessment, whereas 'green' water (rain water) as well as 'grey' water (pollution) were excluded. Water consumption was assessed with two complementary approaches, namely consumption in volume (m^3), and consumption after characterization using the Water Stress Index (WSI) from Pfister et al. (2009), measured in m^3-eq.

3. Results and discussion

3.1. Results per ton of oil

Figure 3 shows the results of the impact assessment. The results for soybean oil and palm oil are equal. This is explained by the fact that soybean oil is a dependent co-product, thus an extra demand for soybean oil does not affect the soybean oil production, but instead the production of palm oil. The GHG emissions include in all oils a credit due to the embedded carbon in the oils, of 2.8 tons CO_2 per ton oil. It is common in many studies to omit this short-term storage of carbon in products, given that it is expected to be compensated by an equal emission at the end of life. In order to compare our results with studies using this approach, the GWP results in Figure 1 would need to be changed by means of adding 2.8 tons CO_2 per ton oil, for all oils.

When iLUC emissions are considered, the overall GHG emissions are considerably higher for peanut oil compared to the others. This is mainly because the land occupation per ton refined oil is high (as shown in the land occupation graph in Figure 1). High land occupation results in high iLUC-related GHG emissions. When iLUC emissions are excluded, the overall GHG emissions are reduced for all oils, and the ranking changes slightly, with sunflower oil as the best performer, whereas when iLUC is included rapeseed oil is the best performer. For the other oils, iLUC does not affect the ranking.

The results for blue water use show that palm oil, soybean oil and peanut oil have a net consumption of water while rapeseed oil and sunflower oil are associated with a net water saving. This may seem surprising because both rapeseed and sunflower are irrigated. However, the by-products of rapeseed oil and sunflower oil, i.e. the oil meals, displace soybean meal, barley, and palm oil. Since soybeans and barley are irrigated more than rapeseed and sunflower, the net use of water becomes negative. Palm oil is associated with a low water use because it is not irrigated, however it is not zero due to contributions from the oil mill, refineries, production of chemicals, fertilizers, machinery, etc. When the WSI is applied, it does not change the ranking of oils as compared to blue water by volume.

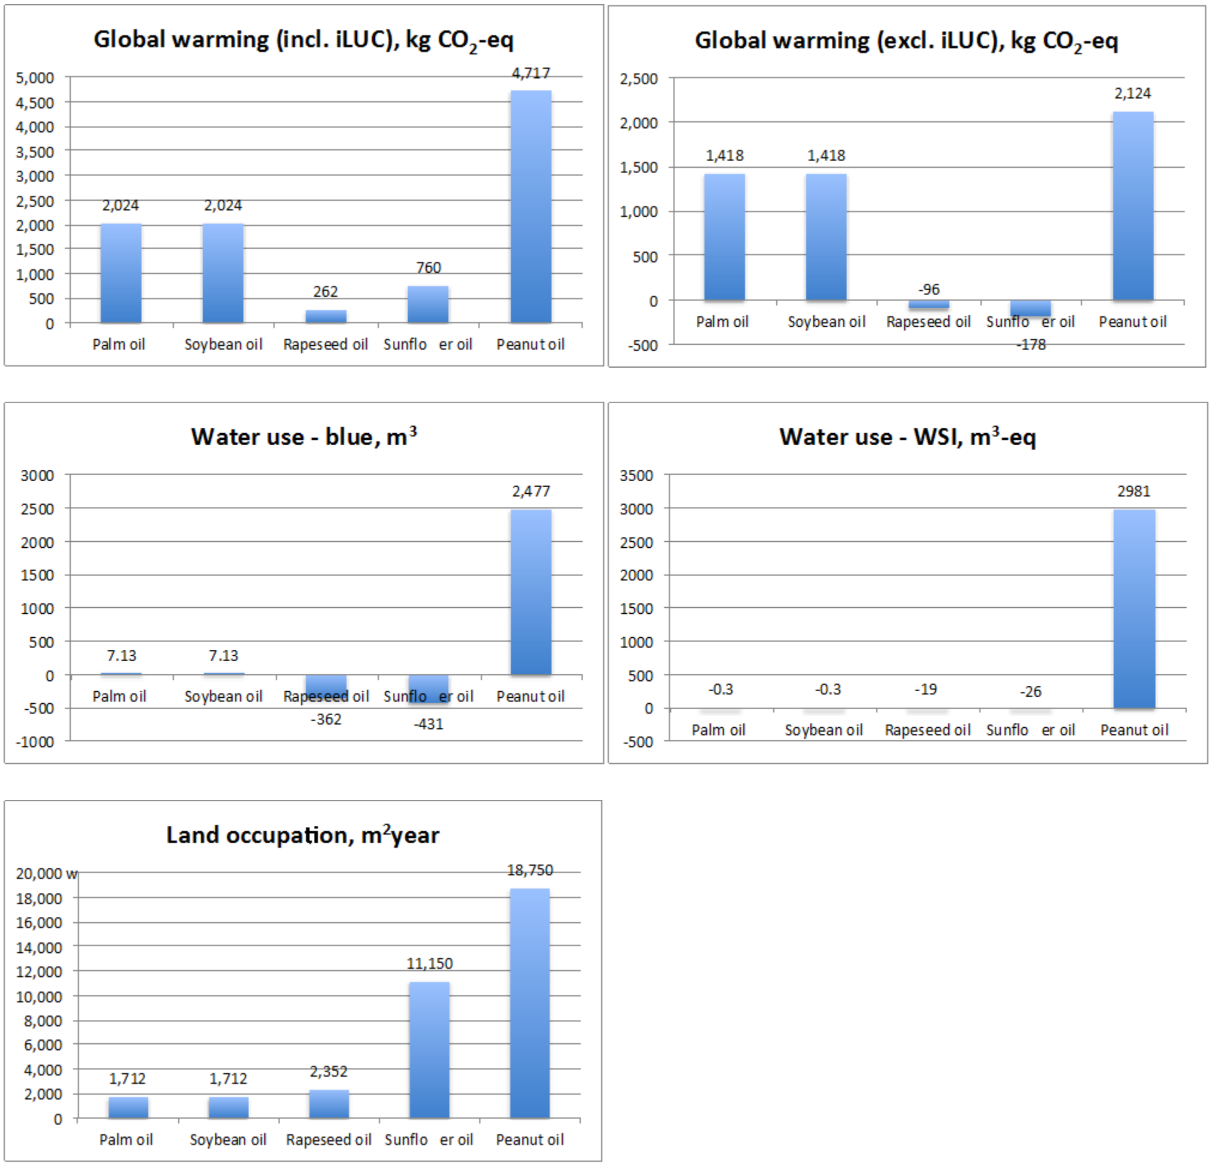

Figure 3. Results for five different refined vegetable oils, per ton refined oil. Global Warming includes biogenic carbon sequestration in the oil.

With regard to land occupation, the highest contribution for all oils is caused by the crop from which each of the oils is extracted. Other contributions are related to substitutions caused by by-products. Even accounting for substitutions, it is the land occupied by the oil crop itself the one that determines the main impact. The best-performing oils are palm oil and soybean oil, followed by rapeseed oil. Sunflower oil and peanut oil, in this order, are the ones with the highest land occupation.

3.2. Sensitivity analyses focused on GHG emissions

A number of sensitivity analyses were carried out, with a focus on GHG emissions. They are summarized in Table 2.

Table 2. Sensitivity analysis summary.

Parameter	Description	Sensitivity analysis outcome
Palm oil: FFB yields	Oil palm is cultivated with Malaysian and Indonesian yields respectively, rather than weighted average.	Low sensitivity, ranking unchanged
Palm oil: Share of oil palm area on peat soils	Default share of peat (18%) compared to cultivation on mineral soil (0% peat), 11% peat (Malaysian average) and 22% (Indonesian average).	Low peat share leads to palm oil with similar GHG emissions to rapeseed oil
Palm oil: CO_2 emission factor for peat soils	Default emission factor of 43 ton CO_2/ha yr compared to 27.5 and 85.5 ton CO_2/ha yr	Sensitive but ranking unchanged
All oils: Fertilizer manufacturing (nitrous oxide emissions from nitric acid)	Default emission factor is 8.39 g N_2O/kg HNO_3 compared with 4.5 g N_2O/kg HNO_3 (IPCC default value) and 1 g N_2O/kg HNO_3 (representing best available technique).	Low sensitivity, ranking unchanged
All oils: Source of marginal barley (feed energy)	Marginal supplier of barley (Ukraine) changed to Argentina.	Low sensitivity, ranking unchanged
All oils: iLUC model	Default iLUC proportion between transformation and intensification is 37% and 63%, respectively. This is changed to transformation and intensification being 90% and 10%, respectively.	Low sensitivity, ranking unchanged

The most significant individual sources of uncertainty related to GHG emissions were identified as the share of oil palm grown on peat, and the CO_2 emission factors for peat soils. If the share of peat is very small, the GHG emissions for palm oil become close to rapeseed oil. In the future, when the palm oil expansion may take place in other regions than Indonesia and Malaysia, the issue of peat may change if this will take place in e.g. Africa or Latin America.

3.3. Uncertainties in water use

The data used for water consumption are often not crop-specific. Hence, these data are associated with significant uncertainties. Substantial uncertainty is also associated with the determination of WSI values, given that the exact location where crops are grown is not known in detail, and average values for regions, countries or groups of countries need to be used.

4. Conclusion

A consequential cradle-to-gate LCA has been carried out on five major vegetable oils. The environmental impacts assessed were GHG emissions, water consumption and land occupation. When we look at the environmental impacts of demanding an additional ton of oils, we see clear tradeoffs. Rapeseed oil and sunflower oil perform best in GHG emissions, sunflower oil in water consumption and palm oil and soybean oil in land use. The poor performance of peanut oil stands out in all impact indicators.

It was found that iLUC emissions have a substantial contribution to GHG emissions, especially in those oils with relatively low yields. As for water consumption, the use of WSI factors didn't change the ranking of oils, but mainly increased the differences between them.

ABSTRACT

Social impacts regarding the production of meat are on the agenda, especially due to reoccurring problems, like food hygiene, the use of antibiotics and disregard of animal's welfare. Thus, the assessment of social impacts for meat production seems essential, but has not been determined within social life cycle assessment (SLCA), yet. As pork has the biggest proportion of the global meat production per mass; the focus of this study is on pork production. The SLCA method is used to address the related impacts. Currently it addresses only human beings, while completely neglecting the impacts on animal's life. Therefore, this study aims to integrate animals into SLCA alongside the common stakeholder groups' workers, local communities, and consumers. Indicator sets are developed to assess the value chain of pork. All indicators are allocated to relevant midpoint impacts to indicate impact pathways. Further research is needed regarding the characterization of occurring impacts.

Keywords: social life cycle assessment, animal well-being, indicator development, meat production

1. Introduction

Social impacts regarding the production and consumption of meat are on the agenda. Meat consumption is increasing worldwide. This increase in consumption originated in western civilization, but is also arising in newly industrialized countries like the BRICS[1] states. This causes several problems for societies on a global scale. Most of the occurring problems are connected to industrial animal farming. Feedstuff production is mostly outsourced resulting in monocultures. Animal farming, which is detached from feedstuff production, creates great quantities of manure. Relevant topics in connection with the meat supply chain are popping up not only in the media but also in politics and public discussions. It starts with working conditions of farmers for both animal feedstuff and animal husbandry. Further topics of interest are working conditions of abattoir workers, food hygiene, the usage of antibiotics and hormones within animal farming, and last but not least the animal treatment primarily within industrial farms (Safran Foer 2010; Chemnitz et al. 2014). Especially the latter is gaining increasing awareness within different movements of society. Although, the status of animal rights has not been fully clarified, interest in animal's well-being in connection is increasing, as current practice contradicts with common ethical values of society (Sunstein and Nussbaum 2004; Singer 2006; Daigle 2014). However, current assessment practice of food products in general including meat products is limited to life cycle assessment (Dalgaard 2007; Roy et al. 2009), but no social life cycle assessment (SLCA) has been performed addressing meat production chains. No set of indicators exists considering affected stakeholders due to animal husbandry, feedstuff and meat production or meat consumption processes. Hardly any impacts along the supply chain are covered by current methods. In addition, common SLCA practice (Benoit and Mazijn 2009) is completely neglecting the impacts on animal's life. Facing these shortcomings within this study a set of indicators is developed addressing workers, local communities, consumers and animals. It is focused on pork meat and the related production chain, as it has the highest market share per mass and records increasing rates for emerging countries (Chemnitz et al. 2014).

2. Methods

The pork production chain is examined focusing on the inclusion of indicators by considering feedstuff production, animal farming and slaughter and the consumption of the final product pork (see Figure 1). The focus is on intensive livestock farming, as it contributes with the highest amount to the pork supply. In this connection global supply chains are relevant, as e.g. feedstuff production is up to a great extend outsourced (BLE 2011).

[1] BRICS states are Brazil, Russia, India, China and South Africa.

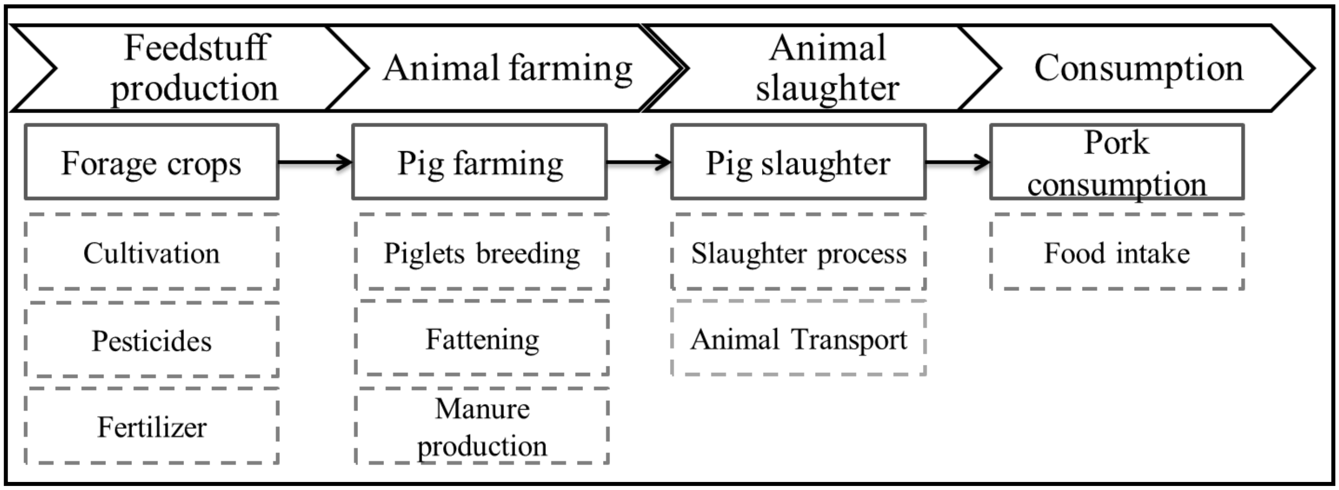

Figure 1: Pork production chain including feedstuff production, animal farming, animal slaughter and the pork consumption; all relevant steps from a SLCA point of view are included

The SLCA method is used, targeting the development of a set of indicators that integrates human as well as animal well-being, which so far is not included into SLCA. It is orientated on the Guidelines of SLCA (Benoit and Mazijn 2009) and the related Methodological sheets (Benoît et al. 2013). It is focused on indicators in connection with midpoint impact categories, addressing aggregated repercussions on human and animal well-being. In addition, existing indicators are analyzed, which are not yet included into SLCA practice. Subsequently, additional indicators are developed to better match the broad range of appearing impacts. Indicators used in SLCA studies are qualitative, semi-quantitative or quantitative (Dreyer et al. 2006) and are provided by different organizations. The Methodological sheets provide guidance for case studies based on indicator approaches, exemplary data sources and relevant international conventions (e.g. conventions of the International Labour Organization) (Benoît et al. 2013). In order to enable a preferably broad indicator review the Global Reporting Initiative (Global Reporting Initiative 2013) and the Product Sustainability Assessment Guidance published by the Institute of Applied Ecology (Grießhammer et al. 2007) are taken into account, too.

According to the guidelines of SLCA (Benoit and Mazijn 2009) five stakeholder groups are defined: workers, local communities, societies, consumers and value chain actors. The stakeholder groups affected can be different dependent on the respective case study. Commonly addressed is the stakeholder group workers, which is in close relation to production processes (Norris 2006b; Klöpffer 2008; Jørgensen 2012). Local communities and consumers are also often considered, e.g. in connection with health aspects. Health issues even if originally located in LCA are shifted to SLCA to avoid double counting and to ensure a consistent separation of social, environmental and economic issues. Value chain actors and societies are more relevant at the organizational perspective, reflecting social responsibility activities (Benoît et al. 2013). Animals are thus far not addressed within SLCA.

Within SLCA two topics are always addressed: workers or working conditions and health aspects (Hunkeler 2006; Norris 2006a; Weidema 2006; Parent et al. 2010; Jørgensen 2012). Besides that another important topic, which is listed quite frequently as well is education. According to the Methodological sheets six midpoint impact categories are defined: human rights, working condition, health and safety, cultural heritage, governance and socio-economic repercussions. However, Benoît et al. (2013) states that these categories can be complemented by further ones. Therefore fair wage and level of education are suggested as additional midpoint categories by (Neugebauer et al. 2014).

3. Considering animals in SLCA

So far animals are not considered within SLCA. However, the consideration of animals or animals´ well-being in connection with animal husbandry and farming already has a great history in philosophy. Several philosophers have already discussed the topic of animal rights and the moral responsibility of mankind´s behavior with respect to animals. Generally it is focused on the differences and similarities between species and the resulting rights for each species. Highlighted topics in this context are the ability of most animals to feel not only pain and pleasure but also the existence of the inherent will to survive and the presence of future plans (Regan 2004;

Sunstein and Nussbaum 2004; Singer 2006). Especially in connection with industrial animal farming[2] these topics become highly relevant. Already in the early sixties Harrison (1964) stated the situation of poultry in industrial farms, which resulted in the first public awareness actions against industrial farming. It served as a kick-off for the Brambell Report in 1965 (Brambell 1965) including the five freedoms for farm animals[3]:

1. Freedom from hunger and thirst - by ready access to fresh water and a diet to maintain full health and vigor
2. Freedom from discomfort - by providing an appropriate environment including shelter and a comfortable resting area
3. Freedom from pain, injury or disease - by prevention or rapid diagnosis and treatment.
4. Freedom to express normal behavior - by providing sufficient space, proper facilities and company of the animal's own kind.
5. Freedom from fear and distress - by ensuring conditions and treatment which avoid mental suffering.

The five freedoms serve as the basis of the European Convention for the protection of animals kept for farming purposes (Council of Europe 1976) and have also been included in the endeavors of the Welfare quality network[4]. However, even if several actions exist the reality shows different, when taking a closer look at the everyday practice in industrial farms. Almost constantly the points 3)-5) are harmed (Safran Foer 2010; FAWC 2011; Chemnitz et al. 2014). Therefore, there is a need to include animal’s welfare or well-being into SLCA to address the impacts on animal’s life.

4. Results

According to the above mentioned, indicators are selected, developed and allocated to the respective stakeholder group and the affected midpoint category. For each step of the defined life cycle (see Figure 1) relevant stakeholder groups are identified and the related effects are analyzed. Thereafter relevant indicators are taken from existing SLCA studies complemented by own indicators developed to tackle all analyzed effects.

Within the defined life cycle the two stakeholder groups’ workers and local communities are directly affected. Workers might be impacted in all production processes from feedstuff production to the animal slaughter, as none of the related processes can get along without manual work. Local communities are always influenced, when boundaries between agriculture and living areas overlap and confounders result from the agricultural activities. The stakeholder group consumers are affected at the end of the supply chain, due to the consumption of pork. The remaining stakeholder groups, value chain actors and societies, are not included in this study, as they are mainly related to companies’ behavior reflecting organizations understanding of promoting social responsibility (Benoît et al. 2013). The named stakeholder groups reflect the interest of human well-being, but neglect the impacts on animal´s life resulting from animal farming. Addressing these shortcomings, indicators are included representing the impacts on animals life. Following the defined midpoint impact categories for humans (see section 2) three midpoint impacts are considered: animal rights, animal health and species specific repercussions. As the status of animal rights is not finally clarified, it is seen as a subordinated midpoint category. The remaining categories (e.g. fair wage) are assumed as irrelevant for the well-being of animals. The discussion of how to include the proposed indicators into the existing SLCA framework cannot be solved easily, but proposals are given in section 4.4.

4.1. Stakeholder group workers

Along the supply chain for pork production different groups of workers are affected. According to Figure 1 workers in feedstuff production, animal farming and slaughterhouses are considered. Within the feedstuff production the focus is on cereals and soy production processes. Whereas cereals are often produced locally soy production happens mainly in South America (Burley 2008). Workers are impacted due to land grabbing (Burley

---

[2] Of course also in connection with animal testing and animal husbandry, but within this study the focus is clearly on animal farming.
[3] Provided by the Farm Animal Welfare Council (http://www.fawc.org.uk/freedoms.htm)
[4] Can be accessed under http://www.welfarequalitynetwork.net/network

2008; Fritz 2011), forced labor (Sakamoto 2010), disrespect of indigenous rights (Greenpeace 2006; Fritz 2011) and health impacts caused by pesticides (PAN 2010; Fritz 2011).

For workers within the industrial pig farms different impacts are anticipated. The standard of living in connection with indebtedness and fair wages seems to be important, as the historical development of pig farming in Germany shows trends towards mass based industrial farming achieving a minimum of economic efficiency (Korbun et al. 2004). In addition health impacts are relevant due to the existence of MRSA[5] germs on pig farms (Neeling et al. 2007; Khanna et al. 2008; Frick 2010) and frequent cases of chronic bronchitis and asthma of farmers (Iversen et al. 1988; Vogelzang et al. 1999; Iversen et al. 2000; Radon et al. 2001). Besides, as most of the reviewed farms within this study[6] are family businesses, child labor might have a small impact. The respective regulations and laws therefore have to be considered.

Workers within modern slaughterhouses are forced to perform a high number of slaughters per hour to be cost-efficient. Thus, the workers are exposed to high psychological pressure, which may result in abnormal behavior (Bundestierärztekammer 2010; Safran Foer 2010; Albert Schweitzer Stiftung 2011).

According to these findings in Table 1 a list of indicators is presented. Indicators are taken from the Methodological sheets, the GRI criteria and the PROSA report complemented by the authors of this study´s own indicators. Relevant midpoint impacts are allocated to the indicators based on the definitions in section 2.

4.2. Stakeholder group local community

Local communities are affected in connection with the feedstuff production but also by pig farming and slaughter. The already mentioned soy production in South America is heavily impacting local communities through land use, relocations, land grabbing and health effects caused by pesticides (UNFPA 2001; Casson 2003; PAN 2010; Fritz 2011). In addition, feedstuff production is affecting local communities through the pollution of groundwater (Anderson and Sobsey 2006). Complaints partly are noted regarding odor caused by manure used for fertilizing.

The pig farming itself impacts local communities by noise and odor (e.g. through ammonia emissions) and the potential loss of work places, which causes at least in Germany, waves of protest against industrial farm projects (BUND 2013). Additional factors are health effects, caused by emissions (e.g. ammonia, antibiotics, sulfurous substances and bacteria) from accruing manure (Wing and Wolf 2000; Nimmermark 2004; Walker et al. 2007; European Commission 2011).

Problems occurring in the neighborhood of slaughterhouses[7] are high traffic volumes and related noise impacts, but also groundwater pollution with pathogenic agents, fats and excrements (Johns 1996; BMLF 1999).

Indicators addressing these impacts can be taken from Table 2. They are connected to relevant midpoint impacts. Indicators are taken from the Methodological sheets complemented by the authors´ own developments.

[5] Methicillin-resistant Staphylococcus aureus
[6] As part of the study different pig farmers in Germany have been interviewed.
[7] Nowadays slaughterhouses are mostly highly efficient and highly industrialized operating units with a high number of animals killed per hour.

Table 1: Indicator selection for the stakeholder group workers divided in general, feedstuff production, pig farming and pig slaughter indicators, complemented by new indicators and allocated to relevant midpoint impacts

Worker		
	Indicators	**Impacts[1]**
General indicators	Existence of labor laws per organization, sector and country [a]	WC, H&S, FW
	Potential of country/organization not passing labor laws [b]	WC, H&S, FW
	Violations of obligations to workers under labor or social security laws and employment regulations [b]	HR, WC, H&S, FW
	Freedom to join unions and to perform collective bargaining [b]	HR, WC
	Existence of transparent wage systems [c]	WC, FW
	Highest/lowest wage paid per organization, sector and country [b]	WC, FW
	Minimum and non-poverty wages per organization, sector and country [b]	WC, FW
	Duration and way of continued pay in case of sickness [c]	WC, FW
	Existence of contracts for work and labor [a]	WC
	Existence of regulations of working hours and overtime arrangements [b]	WC
	Compliance of legal recovery times [a]	WC
	Cases of discrimination and actions taken per organization, sector and country [d]	HR, WC, SER
	Ratio of basic salary of men to women by employee category [d]	HR, WC, FW, SER
	Accidents per organization, sector and country [b]	H&S
	Injuries, occupational diseases and lost days per organization, sector and country [d]	H&S
	Social benefits provided to the workers (e.g. health insurance, pension fund, child care, education, etc.) [b]	WC
	Existence and cases of child labor per organization, sector and country [b,c]	HR, WC, SER, E
	Existence and cases of forced labor per organization, sector and country [b,c]	HR, WC, SER, E
Feedstuff production	Health effects due to pesticide use per organization, sector and country [a]	H&S
	Prevalence of racial discrimination per organization, sector and country [b]	HR, SER
	Indigenous land rights conflicts/land claims [a,b]	HR, SER
Pig farming	Indebtedness per organization, sector and country [a]	WC, SER
	Excessive working hours per organization, sector and country [b]	WC, H&S
	Occurrence of chronicle diseases per organization, sector and country [a]	H&S
	Health effects due to (resistant) germs per organization, sector and country [a]	H&S
Pig slaughter	Number of slaughtered animals per hour and worker per organization, sector and country [a]	WC
	Psychological health effects per organization, sector and country [a]	H&S

[1] Midpoint impact categories allocated to the defined indicators according to Benoît et al. (2013) and Neugebauer et al. (2014); see section 2 – found to be relevant for workers are human rights (HR), working condition (WD), health & safety (H&S), social-economic repercussions (SER), level of education (E) and fair wage (FW)
[a] Developed indicators by the authors of this study
[b] Indicators taken from the Methodological sheets of SLCA (Benoît et al. 2013)
[c] Indicators taken from the Product sustainability assessment guidance (Grießhammer et al. 2007)
[d] Indicators taken from the Global Reporting Initiative (Global Reporting Initiative 2013)

Table 2: Indicator selection for the stakeholder group local community divided in general, feedstuff production, pig farming and pig slaughter indicators, complemented by new indicators and allocated to relevant midpoint impacts

Local community		
Indicators		Impacts[1]
General indicators	Changes in land ownership [b]	HR, SER
	Use of abiotic and biotic resources and water per sector, area and country [a,b]	SER
	Prevalence of conflicts based on resource use per sector, area and country [b]	SER, H&S
	Freedom of expression and protest per sector, area and country [b]	HR, SER
	Relocations of persons per sector, area and country [b]	HR, SER
	Protection of cultural heritage per sector, area and country [b]	SER
	Health effects and diseases per sector, area and country [b]	H&S
Feedstuff production	Health effects due to pesticide use per sector, area and country [a]	H&S
	Pollution of water and groundwater due to pesticides per sector, area and country [a]	H&S, SER
	Prevalence of racial discrimination per sector, area and country [b]	HR, SER
	Indigenous land rights conflicts/land claims per sector, area and country [a,b]	HR, SER
Pig farming	Pollution of water and groundwater due to (resistant) germs per sector, area and country [a]	H&S, SER
	Occurrence of chronicle health effects per sector, area and country [a]	H&S, SER
	Increase in noise and odor per sector, area and country [a]	SER, H&S
	Health effects due to (resistant) germs per sector, area and country [a]	H&S, SER
Pig slaughter	Pollution of water and ground water per sector, area and country [a]	HR, SER, H&S
	Increase in traffic, noise and odor per sector, area and country [a]	SER, H&S

[1] Midpoint impact categories allocated to the defined indicators according to Benoît et al. (2013) and Neugebauer et al. (2014); see section 2 – found to be relevant are human rights (HR), health & safety (H&S) and social-economic repercussions (SER)
[a] Developed indicators by the authors of this study
[b] Indicators taken from the Methodological sheets of SLCA (Benoît et al. 2013)

4.3. Stakeholder group consumers

Consumers are affected by the final product pork, which per se does not cause negative effects. However, health effects are becoming more relevant, when considering the societal background and the overconsumption of meat in western societies. This overconsumption correlates with common civilization diseases like cardiovascular diseases, diabetes mellitus and some cancers (Walker et al. 2007; McMichael et al. 2007). Further, risks have been determined in connection with the use of antibiotics in animal farming and resulting resistances of bacteria and health effects on the consumer side (Böckel 2008; European Commission 2011; BfR 2014). Open questions remain in connection with genetically modified feedstuff (e.g. soy beans) and possible health effects. With this regard, information provided about the product by the producer to the consumer is clearly lacking. More research is needed, as no valid data are available, yet.

Relevant indicators can be taken from Table 3. Indicator sources are the Methodological sheets and the PRO-SA report complemented by own developments. The indicators are allocated to relevant midpoint impacts.

Table 3: Indicator selection for the stakeholder group consumer divided in general and pork consumption indicators, according to the analyzed effects, complemented by new indicators and allocated to relevant midpoint impacts defined

Consumer		
Indicators		**Impacts[1]**
General indicators	Complaints of consumers per organization, sector and country [b]	SER
	Amount of information on/about the product [b]	SER, H&S
	Presence of law/norm regarding product´s transparency per organization, sector and country [b]	SER, H&S
	Results from hygiene and quality checks per product, organization, sector and country [a]	H&S
	Health effects and diseases resulting from the products use [a,c]	H&S
Pork consumption	Labelling and transparency regarding genetically modified products within the supply chain [a]	(HR), H&S, SER
	Information about a balanced diet per sector and country [a]	H&S, E
	Occurrence of civilization diseases resulting from products use [a]	H&S
	Health effects due to (resistant) germs resulting from products use [a]	H&S

[1] Midpoint impact categories allocated to the defined indicators according to Benoît et al. (2013) and Neugebauer et al. (2014); see section 2 – found to be relevant are human rights (HR), health & safety (H&S), social-economic repercussions (SER) and level of education (E)
[a] Developed indicators by the authors of this study
[b] Indicators taken from the Methodological sheets of SLCA (Benoît et al. 2013)
[c] Indicators taken from the Product sustainability assessment guidance (Grießhammer et al. 2007)

4.4. Animals and assignment within SLCA

Animals are impacted during the processes of pig farming and the slaughter at the end of the value chain. During the farming process the pigs are constantly restricted in their natural behavior[8], due to limited space (e.g. limitations in lying down, in sexual behavior or piglets nursing) and abilities in connection with livestock density (e.g. limitations for cooling, like mud bathing). Further various psychological and physical health impacts are often observed, e.g. digestive diseases, skin and claw injuries and behavioral disorders, expressed in aggressions against other animals (LAVES 2010; Rutherford et al. 2011; Albert Schweitzer Stiftung 2013). Therefore the curly tails and canine teeth are cut, which mostly happens without any anesthesia. Existing laws for animal protection do not see any contradiction with common animal welfare principles, as long as it happens before a certain age of the piglets (BMJV 2013). The same accounts for the castration of male piglets. In addition, due to the high number of animals in a limited space the risk of epidemics is increased (BMJV 2013).

Further, animals are heavily affected by the transportation to the slaughterhouses and the pre-slaughter stopover. The fact that the animals will not survive this step in the product life cycle is neglected within this study, as the argumentation in favor of ending the animals life cannot be solved within SLCA and neither is there any consensus about a justification or right to kill animals for food reasons. However, the transportation of the animals involves a high level of stress often resulting in circulatory collapse or death. During the slaughter process failures in anesthesia occur on a regular basis. Further the broadly used CO2 anesthesia causes additional stress through defensive reaction of suffocation (Provieh 2003; Wendt 2006; Puttrich 2012).

Indicators reflecting these impacts are included in Table 4. Included midpoint impacts are animal rights, which are seen as subordinated (see section 4), animal health and species specific repercussions.

[8] Pigs have a distinctive social behavior, which is described in detail in (Hörning et al. 1999).

Table 4: Indicator selection for the stakeholder group animals divided in general, pig farming and pig slaughter indicators, according to the analyzed effects, allocated to relevant midpoint impacts defined

Animals		
	Indicators [a]	**Impacts[1]**
General indicators	Restrictions in species specific behavior (e.g. reproductive behavior, offspring nursing, social behavior etc.) per organization, sector and country	AR, AH, SSR
	Injuries and occupational diseases per organization, sector and country	AH
	Behavioral disorders per organization, sector and country	AH
	Health effects due to (resistant) germs per organization, sector and country	AH
	Mutilations performed per organization, sector and country	AR, AH
	Fattening period compared to natural live expectation	AR
	Genetic descent per organization, sector and country	SSR
	Freedom of hunger, thirst and pain	AR, AH
	Quality, dimension and hygiene of stables per organization, sector and country	AH
	Livestock density per organization, sector and country	AR, AH
Pig farming	Occurrence of death, injuries and behavioral disorders due to farming practice per organization, sector and country	AR, AH
	Distance and means of transport of piglets to the fattening farm per organization, sector and country	AH
Pig slaughter	Distance and means of transport to the slaughterhouse per organization, sector and country	AH
	Occurrence of injuries, fear and failure in anesthesia during the slaughter process	AH
	Guarantee of a painless and quick death	AR

[1] Midpoint impact categories allocated to the defined indicators; inspired by the already defined midpoint impacts according to Benoît et al. (2013) the following midpoint impacts for animals are defined: animal rights (AR), animal health (AH) and species specific repercussions (SSR)
[a] All indicators are developed by the authors of this study.

The assignment of animals within SLCA is not straightforward, as no stakeholder group exists to represent animals´ well-being. The Guidelines of SLCA define stakeholder groups as “a cluster of stakeholders that are expected to have shared interests due to their similar relationship to the investigated product systems” (Benoit and Mazijn 2009). According to Freeman (2010) a stakeholder is any group or individual who can affect or is affected by a certain action. Even if both sources originally focused on human beings, animals could be defined as a group of individuals affected by livestock farming processes, which shared interests due to their similar relationship to the product. However, the inclusion of animals within an own stakeholder group may cause inconsistencies with existing stakeholder groups, as e.g. children are also not defined as an own group, but as a subcategory. Further, animals cannot advocate for their own concerns and thus would need representatives (e.g. NGOs) to fight for their rights. The inclusion in existing stakeholder groups causes some shortcomings and difficulties as well. However, two groups seem reasonable at first sight: consumers and workers. By including animals into the group consumers, the animals´ interest is only represented through the consumers´ judgment or value choice, contrary to e.g. child labor which is also represented in the stakeholder group workers. Thus, the risk of not representing animals´ interest adequately is quite high. When including animals as a subcategory into the stakeholder group workers, problems occur, as animals are not workers per definition. Since the stakeholder group society only covers societal impacts of organizations, animals cannot be represented within this group, even though industrial farming could indirectly harm the ethical values of society. As a consequence, further research is needed to define a proper place for the inclusion of animals’ well-being within the stakeholder concept of SLCA. Until this issue is resolved, the proposed indicators should be used as an additional set of indicators independent from a particular stakeholder group.

5. Discussion

The presented indicator sets for animals and the three stakeholder groups reflect the life cycle of pork production. However, the indicators listed do not raise a claim of completeness, but rather address common hotspots within the supply chain. The same accounts for the considered midpoint impacts. In addition, impact pathways including characterization factors are not part of this study.

For the first time animals are included into SLCA, but animal rights and the treatment of animals is still under discussion. Thus, one might say that animals cannot be equated with the defined stakeholder groups. The proposal within this study is rather targeting the general inclusion of animals into SLCA, than to start discussions about the equality between different stakeholder groups or subcategories. However, more research is needed to solve the assignment problem of animals in connection with the existing SLCA framework.

Further, some stakeholder groups are not considered in SLCA in general or within this study, e.g. future generations. According to Klöpffer (2008) the inclusion of future generations is of importance for sustainability assessment. Agricultural activities in relation with animal farming are not unlikely to affect future generations by overusing abiotic resources like soil and water. Therefore it is recommended to address future generations within SLCA in foreseeable time.

6. Conclusion

The proposed set of indicators can serve as a starting point for SLCA studies of meat production and the inclusion of animal well-being in current assessment practice. Based on the indicator selection in connection with the affected midpoint impacts the logical next step would be the practical implementation into SLCA case studies. Adaptations are probably necessary and further indicators are possibly needed. However, the provided set of indicators serves as a first step towards the implementation of social aspects for meat production chains especially for the production of pork into SLCA. In addition for the first time impacts on animal's life are considered within SLCA.

ABSTRACT

Life Cycle Assessment (LCA) is a methodological framework that estimates environmental impacts of products, systems or services in a life cycle perspective at local to global scales. Some environmental impacts, however, can vary depending on the characteristics of their surroundings and therefore on the location of the activity. This variability can be taken into account in impact assessment using spatialized LCA. Spatial differentiation is especially relevant when studying territories (ca. 100-10,000 km^2), which often have high heterogeneity in environmental characteristics. In this study, we focus on defining a method to apply spatialized LCA to study land-use planning in an agricultural territory. In light of agricultural impact assessment, we suggest a future method for spatialized territorial LCA, which is currently being tested on an agricultural territory, the *Lieue de Grève* watershed in Brittany, France.

Keywords: life cycle assessment, spatialization, territory, land-planning, agriculture

1. Introduction

Currently, most agricultural and urban land-planning decisions are made at the territorial level. Since rural and urban development is increasingly addressed at the territorial level, developing a method to estimate environmental impacts of a territory seems important. The concept of "territory" is still debated and varies among and within scientific communities and countries. We focus on agricultural territories, defined as geographically delimited areas in which the majority of land use is based on agriculture. Agriculture contributes to a range of impacts on the environment, and some of these impacts vary depending on the biophysical context in which potential pollutants are emitted (climate, soil type, slope, hedgerow presence …).

In Life Cycle Assessment (LCA), potential environmental impacts are calculated through all stages of a product's or system's life (from cradle to grave). Many LCA studies of agricultural production focus on the field or farm level (Brentrup et al. 2004a,b; Nguyen et al. 2013; Prudêncio da Silva et al. 2014; van der Werf et al. 2009). Focusing on the territorial level, however, allows interactions between farms to be assessed.

Loiseau et al. (2012) highlighted the use of LCA to estimate potential environmental impacts of a territory for land-use planning purposes, such as where to locate different activities in a territory to reduce their environmental impacts. Due to the large size of territories (100-10,000 km^2), the use of spatialized data seems necessary to estimate environmental impacts accurately. This is especially relevant for an agricultural territory, where many emissions and impacts depend on their surroundings. It thus seems relevant to develop a method to estimate environmental impacts of activities within an agricultural territory ("territorial LCA") by considering their locations in a spatially explicit manner. The method developed can be called "spatialized territorial LCA".

We propose to apply the principles of spatialized territorial LCA to determine how and why it can support territorial approaches for assessing environmental impacts of an agricultural territory. The method developed will be illustrated with a case study: the *Lieue de Grève* territory, in Brittany, France. The objective of this case study is to help local stakeholders making decisions by determining which kinds of agricultural activities should be implemented in the studied territory, and where to locate them, to decrease their overall environmental impacts.

2. Spatialized LCA: a brief review

Environmental impacts caused by a pollutant emission depend on the quantity emitted, its properties, characteristics of the emitting source, and sometimes characteristics of receiving environment (Finnveden et al. 2009). In most LCA studies, the receiving environment is considered a standardized "unit world" with generic characteristics (Potting and Hauschild 2006). For some impact categories, such as climate change, this assumption holds true. However, some environmental impacts – such as acidification or eutrophication – vary depending on characteristics of the receiving environment and therefore on the location of the emissions. Spatialized LCA can take this variability into account in impact assessment.

In the literature, spatially explicit LCA has been addressed mainly at two levels: spatialized Life Cycle Inventory (LCI) and spatialized Life Cycle Impact Assessment (LCIA). While spatialized LCI is mainly based on the use of spatially differentiated databases and Geographic Information Systems (GIS) (Dufossé et al. 2013; Dresen and Jandewerth 2012; Engelbrecht et al. 2013; Geyer et al. 2010a,b; Núñez et al. 2010; Tabata et al. 2011; Tessum et al. 2012), spatialized LCIA focuses on spatial differentiation of characterization factors (CFs) for mid-point impacts such as acidification or eutrophication (Huijbregts et al. 2000; Krewitt et al. 2001; Potting et al. 1998; Shah and Ries 2009) or impacts of resource scarcity, such as that of water or soil (Boulay et al. 2011; Frechette-Marleau et al. 2008; Pfister et al. 2009; Saad et al. 2013; Verones et al. 2012). Spatialized LCIA has addressed mainly country, watershed or ecozone spatial scales (Pfister et al. 2009; Potting et al. 1998; Saad et al. 2011). Mutel et al. (2011) developed a computer program to combine spatialized LCI with spatialized LCIA. This technical solution still needs improvement, however, to be used by LCA practitioners. Spatialized LCA is increasingly common due to the use of GIS and the development of spatially differentiated CFs.

The debate about whether spatialized LCA reduces uncertainties in LCA studies remains open (Finnveden and Nilsson 2005). The amount of local data needed to spatialized LCA studies can indeed increase uncertainties in the LCI phase. Studies have shown, however, that using generic CFs can induce errors in LCIA, such as differences between site-specific CFs and site-generic CFs ranging from 2-4 orders of magnitude (Hellweg 2001; Hettelingh et al. 2005; Huijbregts et al. 2000). Therefore, taking the spatial variability of impacts into account seems necessary, especially when assessing the environmental burden of a territory.

3. Applying spatialized LCA to an agricultural territory

Few studies have used LCA to estimate a range of environmental impacts for an entire territory (e.g., Yi et al. 2007). Loiseau et al. (2013) developed a territorial LCA method but did not include spatial differentiation within the territory. We intend to develop a territorial LCA method that includes spatial differentiation within a territory for pollutant emissions and their associated impacts. For illustration purposes, we will apply this method to an agricultural territory.

To produce food or bioenergy for humans, agricultural territories induce environmental impacts that may vary depending on their surroundings where potential pollutants are emitted. Spatial analysis of agricultural territories has been performed outside the LCA domain for years. For example, models have been developed to predict spatially explicit dynamics of cropping systems (Leenhardt et al. 2010; Salmon-Monviola et al. 2012), spatial organization of land-use and rural territory dynamics (Benoit et al. 2012; Hinojosa and Hennermann 2012; Le Ber and Benoit 1998), or pesticide contamination risks in an agricultural watershed (Macary et al. 2014). The inclusion of a spatial differentiation in an LCA approach would provide a broader assessment of overall impacts.

3.1. Territorial LCA applied to an agricultural territory: the need for spatial differentiation

When estimating environmental impacts of a territory, one can consider it as a “black box” that interacts with other black-box territories via a variety of inputs and outputs. In this case, impacts of human activities are independent of location within the territory. We believe, however, that the territory should be considered as a system in which emissions occur at different places and impacts are influenced by the sensitivity of the receiving environment (Fig. 1). The need for spatial differentiation is especially relevant for land-use planning, where the location of certain activities may increase their environmental impacts. The method we develop thus aims to estimate spatialized impacts of an agricultural territory for land-use planning by coupling territorial LCA with spatialized LCA.

Although spatialized territorial LCA may require more data or time, it seems important to develop, especially for agricultural landscapes. It may help decrease impacts of a territory by estimating (1) what kinds of crop or livestock farming should be developed and where to locate them or (2) effects of land-use planning and how to minimize impacts of exchanges of resources or products with other territories, which may aid policy-making.

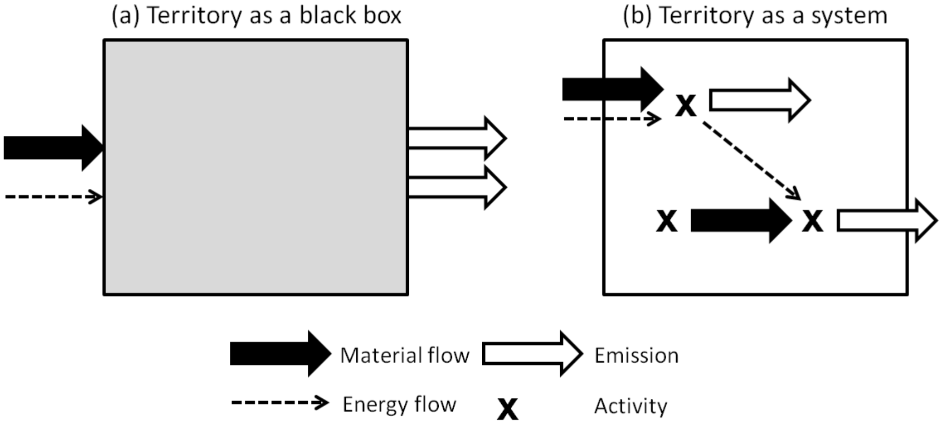

Figure 1. Two ways to estimate environmental impacts of a territory: (a) as a black box or (b) as a system whose activities, and inputs and outputs of those activities, are spatially explicit.

3.1.1. Defining the territory

The first step in a spatialized territorial LCA is to define the boundaries, functions, and issues of the territory under study. In agriculture, geographic boundaries of a territory are generally defined by the locations of farms and their fields but can be extended if entire agricultural sectors are studied. Next, defining territory functions and determining which of them is the most important is a crucial step in spatialized territorial LCA, since LCA is function-based. Loiseau et al. (2013) stated that territory functions can be mainly environmental, economic or societal. Functions of an agricultural territory may include producing food for human consumption or maintaining a certain living environment for the human population (Table 1).

Table 1. Examples of functions of agricultural territories.

Category	Functions
Environmental	Support biodiversity (e.g., reproduction and diversity of species)
	Support ecological processes (e.g., streamflow)
Economic	Produce revenue from agricultural activities
	Provide resources for industrial activities
	Support tourist activities
Societal	Produce food for human consumption
	Support livelihoods of the local population
	Maintain a certain living environment for the population (e.g., employment, quality of life)

The last step is to define issues at stake in the territory, such as to produce more food, to feed the local population or to decrease the amount of nitrate (NO_3) emitted to surface waters. Territory boundaries, functions, and issues, will influence which emissions and impacts will be studied (Fig. 2). They can be chosen iteratively (Goal and scope, Fig. 4) with the help of local stakeholders and experts, or with systemic analyses (pers. comm. Lynda Aissani, IRSTEA, Rennes, France).

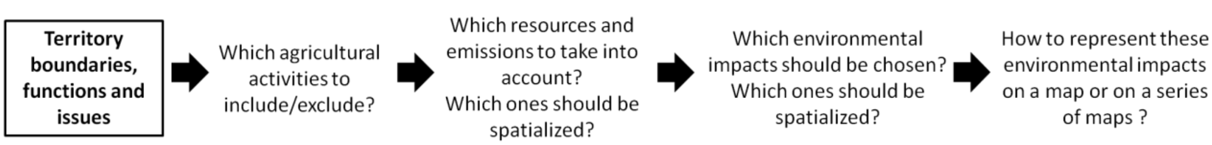

Figure 2. Effects of defining boundaries, functions, and issues of an agricultural territory on the LCA method.

3.1.2. Spatialized LCI

The next step is to spatialize the LCI, which requires distinguishing processes occurring within the territory from those occurring outside of it.

3.1.2.1. Processes occurring within the territory

Spatializing the LCI of the territory under study can be divided into three steps. The first step is to identify all agricultural and non-agricultural economic activities in the territory (e.g., with databases) and to geolocate them using GIS. It is important to include the non-agricultural activities, even though they will be examined in less detail. Since assessing the environmental burden of each human activity within a territory is too time-consuming, we propose developing a typology of agricultural activities, and use the typology proposed by Loiseau et al. (2013) for non-agricultural activities. The second step is to divide the territory under study into "zones of homogeneous environmental sensitivity" to each type of emission (e.g., nitrogen, phosphorous, and carbon compounds) using GIS. These zones (classified into an "environment" typology) should take into account environmental characteristics, such as the soil type, slope, and the distance to waterbodies. The third step is to calculate a spatialized LCI of activities within the territory. We propose to combine data from the activity and environment typologies to estimate spatialized emissions using appropriate models (Fig. 3). For example, nitrogen emissions from fields could be predicted using the TNT2 model (Beaujouan et al. 2002). Emission models should take into account pollutant fate as well as pollutant transport. Predicting transport is indeed crucial, since it will determine whether an emission (and thus its impact) will remain in the territory under study or travel to other territories. We propose performing LCA from the cradle to the territory gate, as suggested by Loiseau et al. (2013). A cradle-to-grave spatialized territorial LCA can be explored later.

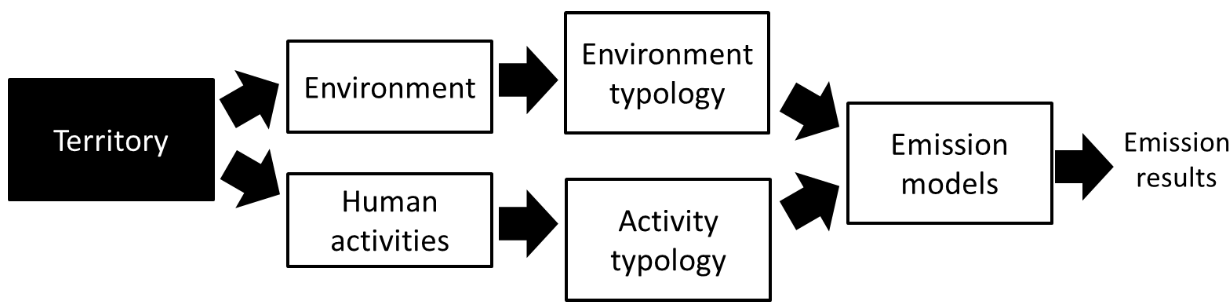

Figure 3. Spatialized life cycle inventory of activities within a territory

3.1.2.2. Processes occurring outside the territory

Indirect emissions from processes that occur outside the studied territory should also be included in the spatialized territorial study. The location of these emissions should be identified at least to the regional level, such as state or national level, when the origins of their contributing background processes are known

3.1.3. Spatialized impact assessment

Once emission locations, transport, and fate are determined, environmental impacts can be estimated. Spatialized environmental impacts will be estimated from spatialized emissions using spatially explicit characterization models. For each impact category, we propose assigning a CF to each zone of homogeneous environmental sensitivity. Environmental impacts in a given zone will be estimated from the emissions that end up there.

The appropriate spatial scale of each impact will depend on its impact category (Table 2). As a global impact, climate change does not need spatialization, unlike local impacts (e.g., eutrophication), which can be estimated more precisely with spatialization. For agriculture within a territory, we propose using a spatial scale at which a given impact is equivalent, such as a field for land-use impacts, homogeneous area of soil for terrestrial eutrophication and acidification, or homogeneous density of population for human toxicity (Nansai et al. 2005). A CF should be derived for each area of equivalent impact, which could be determined with GIS.

Table 2. Impacts categories and their spatial scales considered in spatialized impact assessment of an agricultural territory.

Impact category	Suggestion for spatial scale
Global warming	World
Eutrophication	
- Terrestrial	Homogeneous area of soil (e.g., type of soil, pH)
- Aquatic	Groundwater or surface water bodies
Acidification	
- Terrestrial	Homogeneous area of soil
- Aquatic	Groundwater or surface water bodies
Resource depletion	Location of resource extraction
Water consumption	Field
Land use	Field
Soil quality	Homogeneous area of soil
Energy consumption	Farm or homogeneous farm type
Human toxicity	Homogeneous density of population
Ecotoxicity	Ecozones

Larger spatial scales (e.g., watershed, region, or country) can be used for regions in which background processes occur. Importantly, the spatial scale of impact categories will depend on the impact category considered, the spatial scale of the environmental compartment (e.g., air, water, soil), and the type and quality of the environmental compartment (e.g., surface/ground water). If the agricultural territory under study is larger than the spatial scale of the impact categories, spatial differentiation within the territory seems necessary. In this case, site-dependent impact assessment can be used.

3.1.4. Interpretation

The final step, interpretation, can be a challenge, beginning with how to best map spatialized impacts to support decisions. We propose creating a detailed map of impacts within the territory along with a map of impact occurring throughout the world. To facilitate understanding, we recommend avoiding additional maps, showing only locations where impacts are the highest and reducing impacts on maps to a small number of scores. One objective of our method is thus to express spatially explicit environmental impacts in an optimal manner.

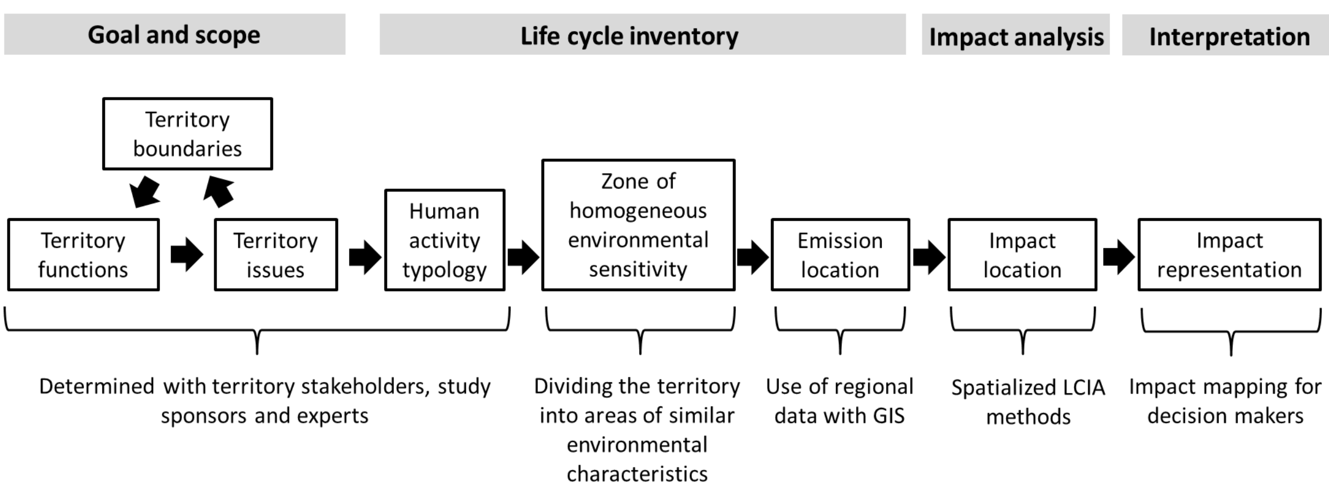

Figure 4. Spatialized territorial LCA steps

3.2. Case study: The *Lieue de Grève* watershed in France

Once methodological issues are addressed, we will apply the approach to the agricultural territory of the *Lieue de Grève* watershed in Brittany, France (Figs. 4 and 5). This territory was chosen because it is primarily agricultural with few urban areas, its main agricultural impacts define its boundaries (i.e., sub-watersheds of the

Saint-Michel-en-Grève Bay), and it has been studied before in research projects. Consequently, many descriptive data and a partnership with local stakeholders exist.

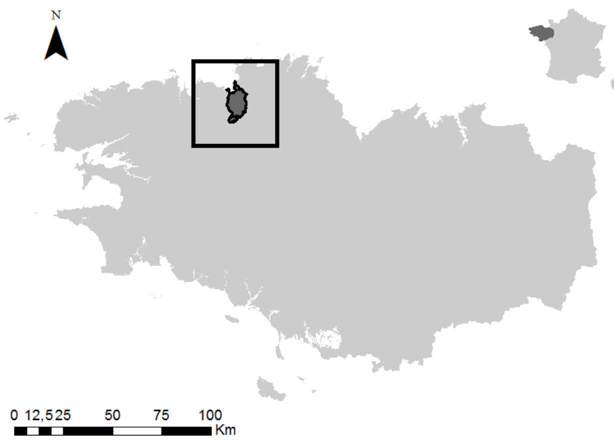

Figure 5. Location of the *Lieue de Grève* watershed (dark gray) in the region of Brittany, France.

Figure 6. Sub-watersheds in the *Lieue de Grève* watershed.

The *Lieue de Grève* watershed is composed of five sub-watersheds covering 120 km² and containing 12 towns and 13,500 inhabitants. Approximately 70% of the territory is covered by agricultural land, divided among 194 farms. Up to 85% of the agricultural land is used as dairy farms, while intensive pig/crop farming occurs on the eastern and western edges of the watershed.

The objective of the study is to analyze land-use planning scenarios to determine which kinds of agricultural activities should be implemented in the *Lieue de Grève*, and where to locate them, to decrease the territory's environmental impacts.

The main function of the *Lieue de Grève* agricultural territory is to produce agricultural products (mainly milk and beef), but this is common to all agricultural territories and does not represent a unique feature. One function with greater importance in the *Lieue de Grève* is the transfer of nutrients to the sea. Due to intensive agricultural practices and biophysical characteristics of land and bay, agricultural N and P that flow into the bay cause proliferation of green algae in the bay. Since this issue is important to the local population, we choose this function for the *Lieue de Grève* and define its geographic boundaries as its 5 sub-watersheds. In future research, the influence of changing the territorial function in LCA will be investigated.

The next step, spatialized LCI, is currently in progress, pinpointing with GIS locations of farms; their fields, emissions, and resource consumption; and environmental characteristics, using local datasets, on-farm surveys, and regional statistics. Transport and fate models will be used to determine the final locations of major emissions inside or outside the territory. The final steps will involve spatialized LCIA and interpretation of the spatialized results where scenarios of land-use planning will be compared.

4. Conclusion

Our method aims to combine spatialized and territorial LCAs to assess environmental impacts of an agricultural territory with a higher level of precision. This method refers to "spatialized territorial LCA". The key steps of spatialized territorial LCA are to: (1) define territory boundaries, functions, and main issues, since these characteristics will influence subsequent steps and results; (2) spatialize the LCI and LCIA using GIS; and (3) determine the best way to represent environmental impacts on a map to help stakeholders make decisions.

The objectives of this method are to: (1) give more accurate results than a territorial LCA without spatial differentiation, (2) help decrease impacts within a territory by determining which agricultural activities should be developed and where to locate them, and (3) help avoid or minimize impacts of exchanges of resources or products with other territories.

This method is still under development, and many methodological questions have yet to be resolved, particularly about the impact categories, and therefore the emissions, considered. The next step is to determine which indicators to use to define the zones of homogeneous environmental sensitivity. Another methodological issue is raised when combining these zones with the activity typology to determine the spatially differentiated LCI, particularly which emission models to choose to include spatial information in LCI calculations. It is also necessary to determine how to link the spatialized LCI to a spatially differentiated characterization method and how to best map impacts to aid decision making. For the latter, impacts occurring outside the territory must be represented.

The method will be applied to the *Lieue de Grève* territory, in Brittany, France, to assess its relevance from scientific and operational viewpoints. Ultimately, comparing spatialized and non-spatialized impacts will help us confirm – or disprove – the utility of the method.

ABSTRACT

Meneghina Express is 44 day and 13,000 km long journey from Shanghai to Milan, covered via electric motorcycles as a representation of electric mobility and sustainable food production and consumption. The purpose of this journey was to promote sustainable mobility and also gather knowledge and best practices regarding food production and consumption along the route. In this context, the University of Bari developed a database that allowed the evaluation of the environmental burden related to various foods in terms of carbon footprint. Starting from the databases of the FAO, the carbon footprint of the consumed foods was estimated, drawing up an inventory of their life cycle. The result is a carbon footprint report, thanks to which it is possible to compare the "sustainability" of different foods encountered along the journey, with those of the Mediterranean diet.

Keywords: carbon footprint, diet, sustainable food consumption

1. Introduction

Various studies carried out during the last two decades have demonstrated that most of the human food chains are not sustainable because of their environmental burdens that occur during the various life cycle phases of the food systems. In fact the contribution of the food and drink sector to the total environmental impact deriving from private consumption, according to the European Science and Technology Observatory (ESTO) project on "Environmental Impact of Products" (EIPRO), ranges from 22 to 34% (Tukker et al. 2006). In the UK, food consumption is responsible for 19% of the overall 2008 national greenhouse gas (GHG) production. Similarly, according to the United Nations Food and Agriculture Organization (FAO), the livestock sector is responsible for 14.5% of the overall global GHG emissions (Gerber et al. 2013). In a search, over the last fifteen years, for some indication on more sustainable means for food production and consumption, various sustainability assessment instruments have been used, among which is the Life Cycle Assessment methodology (LCA). This has been predominantly used for the identification of the environmental impacts of food during its life cycle and also as a means of supporting environmental decision making (Notarnicola et al. 2012a).

In view of the above mentioned context the Meneghina Express project, object of the present paper, was developed. It entails a 44 day and 13,000 km long journey from Shanghai to Milan, covered via electric motorcycles as a representation of electric mobility and sustainable food production and consumption. This journey aimed not only at promoting sustainable mobility, showing that even adventurous journeys such as this one from Shanghai to Milan can be carried out by relying on renewable energy, but it also aimed at gathering knowledge and best practices regarding food production and consumption along the route. Since these themes are also among the main ones of the Expo2015 that will be held in Milan, the organizing committee of this exhibition sponsored the initiative.

For such a project, the University of Bari developed a database that enabled the evaluation of the environmental load related to the various types of food consumed during the journey. Currently, at global level for agro-industrial systems, there seems to be a growing interest in *carbon and water footprints* that represent "mono-indicators" that exclude the effects of other important impact categories such as eutrophication and eco/human toxicity. The current project also used the carbon footprint (CF) as means of evaluating the environmental sustainability of the food consumed during the journey; however a more comprehensive approach, that includes other indicators, is more desirable (Notarnicola et al. 2012b) and might be considered in the future. Specifically, starting from the UN Food and Agriculture Organization (FAO) databases, the CF of the single products was estimated thus creating a life cycle inventory of both primary (agricultural and livestock) and transformed products. This task was carried out for each nation crossed during the journey since the energy mix and other production variables imply different CFs for both primary and transformed products of different countries. The next sections of this paper discuss the methodologies and sources used for the construction of the inventory and the main results of the carbon footprint report of the journey.

2. The database for the food carbon footprint calculation

The starting point for the work regarding the calculation of the food CF database, was the analysis of the existing relevant data found in the scientific LCA literature regarding food products (agricultural and transformed ones). Also existing food databases (e.g Ecoinvent, FoodlcaDk and others) were preliminarily consulted together with data from environmental product declarations. Next, in a more specific manner, the FAO databases were used as data sources since they detail, for each country, the type of product and the relative land use, the use of fertilizers, the CO_2 emissions and other greenhouse gases (GHG) both for the agricultural phase and for livestock production (FAOSTAT 2013).

From the above mentioned data the CF for each single food product considered was calculated thus enabling the construction of the database of both primary and transformed products. The calculated CFs are intended as quantities of $CO_{2eq.}$ associated with the production of the specific food type and include other GHG such as CH_4 and N_2O. The phases included in the inventory analysis are the agricultural phase, the production and use of fertilizers and pesticides, the transport of auxiliary products and of the finished ones and the transformation. For livestock products the animal enteric fermentation and the type of manure management were also accounted for. All the results are referred to 1 kg of finished food product. For the conversion of all the GHG emission data to absolute values of $CO_{2eq.}$ the IPCC characterization factors were used (IPCC 2007).

The FAO database contains information on the following: total agriculture, combustion of agricultural residues, cultivated land, residues from cultivation, rice cultivation. All these inventories are calculated according to the *Tier1* approach indicated in the IPCC guidelines for the calculation of the national GHG inventories (IPCC 2006).

The inventories regarding the impacts of livestock, contained in the FAO database, are the following (also calculated according to the *Tier1* approach indicated in chapter 10 Vol.4 (IPCC 2006):

- <u>manure management</u>: the relative emissions are constituted mainly by methane and nitrous oxide deriving from the aerobic and anaerobic decomposition of the manure;
- <u>enteric fermentation</u>: this includes the emissions of methane produced mainly by ruminant digestive systems and in minor amount by those of non ruminant animals.

The CF of each product was calculated specifically for each country crossed during the journey. This is because the energy mix, the production factors and the efficiencies in terms of useful product vary between countries. The computation of the energy mix and its relative association to amounts of $CO_{2eq.}$ was based on the International Energy Agency databases (IEA 2013). As a result, for the non-transformed agricultural products, a database was generated, subdivided per each country, containing CFs of 136 products (not shown here for sake of brevity).

For the CF calculation for the various types of milk originating from different countries the yearly animal production yield illustrated in Table 1 was used.

Differences between intensive and extensive animal farming were also taken into account in the CF calculations. Specifically freely grazing animals are responsible for lower amounts of $CO_{2eq.}$ with respect to those of intensive systems which not only are accountable for emissions from enteric fermentation and manure decomposition but also for the production of fodder. However, intensive farming results less impacting in terms of CFs due to the higher production yields associated to the animals.

Table 2 illustrates the CF of milk form different countries. In some cases the results are particularly divergent. For example the CF of Mongolian milk is ten times higher than that of European milk which averages 1 $kgCO_{2eq.}$/kg. This is due to the extremely low yields in terms of product. Specifically, the FAO database reports a yearly milk yield per Mongolian bovine animal of 479.5 kg which is much lower than the Chinese (3,003.0 kg) or Russian yearly yield (3,857.2 kg). Such a result is well known and documented in literature as reported by Gerber et al. (2011). These results also are in line with the LCA report on GHG emissions from the dairy sector in which large variations in emissions between the different world regions have been estimated, with regional average emissions ranging from 1.3 to 7.5 kg $CO_{2eq.}$ per kg of fat and protein corrected milk (FPCM) [±26 percent]. Livestock systems in the temperate regions, mainly in industrialized countries, were found to have much lower emissions per kg of milk and meat than systems in the arid and humid zones in the developing countries (FAO 2010).

Table 1. Production yield in terms of milk produced (in kg) per animal over a period of one year for each country

	China	Mongolia	Kazakhstan	Russia	Moldavia	Ukraine	Romania	Serbia	Croatia

camel	5.11	7.00	-	10.30	-	8.66	-	-	-
cow	0.65	9.60	1.22	0.68	0.71	0.51	0.67	0.76	1.02
goat	0.69	7.77	2.90	0.51	1.06	0.25	-	-	0.84
sheep	2.86	10.30	1.37	3.70	4.01	1.43	1.63	2.43	1.78

Global scale analysis has clearly shown that GHG other than CO_2, such as methane and nitrous oxide, are inversely correlated to animal productivity. In other words, compared to animals with low milk yields, animals that produce more milk, will consume more fodder and other foods, will undergo more enteric fermentation and produce more manure that will produce more GHGs. However when scaled to the amount of milk produced the CF is lower for animals with a high productivity. Hence increasing the productivity of livestock represents an effective strategy for the mitigation of the greenhouse effect associated to livestock breeding (Hristov et al. 2013).

Similar results are also obtained for meat production. In fact there appears to be a divergence in results in terms of CF also due to the differences in yields illustrated above.

Overall the database consists of 411 products for which a CF has been calculated. For 188 of these products the indicator was calculated for each country involved in the journey, whilst for the remaining 223 products the data was gathered from literature and existing databases.

3. The carbon footprint report

By using country specific food and energy mix data it was thus possible to evaluate the CF of each type of food eaten during the journey which varied considerably from country to country.

In China the nutrition of the team was based mainly on rice, pasta, eggs, vegetables and fruit with meat and small quantities of dairy products consumed on only two occasions.

In the Mongolian steppe, the nutrition was based mainly on dairy products and meat. In fact Mongols still practice nomadism and have large availabilities of such products. Specifically the nutrition included a type of pasta made from soft wheat, camel and goat milk, butter, sheep meat and a few onions and potatoes (the only vegetables eaten). This is mainly because Mongolia has very little arable land and thus produces few vegetables which are usually imported from China. This makes the Mongolian diet unbalanced, lacking vegetable foods and rich in proteins. This is also dependent on the fact that such a hyper caloric diet is necessary for surviving in a country with very rigid winters. In fact the capital city of Mongolia, Ullanbator, during the winter can reach temperature of -50°C. It thus appears that the climatic factor may be of considerable importance in the comparison between diets.

During the 11 days spent in Kazakhstan the team continued a diet similar to that undertaken in Mongolia, mainly based on meat with a lack of vegetable food. This depended on the route of the journey that involved crossing the northern part of the country through the city of Astana the second coldest capital of the world. In the southern part of the country the climate is milder and locally grown vegetables can be found.

During the 6 days spent crossing Ukraine the nutrition of the team was more continental, similar to that of northern Italy with a few variations based on fish from the Black sea.

A “carbon footprint report” was created in which, for each country, the average CF of the daily diet was calculated based on the food eaten. These values have been compared to those of the Italian Mediterranean diet. Presuming that the energy need during the journey could vary between 2000-2500 kcal per day, the CF of the Mediterranean diet varies from 4.9kg of CO_{2eq} to 6.1kg of CO_{2eq} per day.

Figure 1 reports, for each country, the averaged calculated CF of the daily nutrition. The horizontal line represents the Mediterranean average value.

As already mentioned the worst results are relative to Mongolia due to the high consumption of meat and dairy products. Specifically the team leader during the journey through Mongolia consumed 1.850 kg of vegetable food for a total of 0.54 kg CO_{2eq}., 0.55 kg of milk and other dairy products for a total of 8.64kg CO_{2eq}. and 0.3kg of meat for a total of 2.4 CO_{2eq}. as well as 0.2kg of transformed products for a total of 0.1kg CO_{2eq}.The highest contribution is from the dairy products and there is no major contribution from the electricity mix since most products (apart from butter) are consumed without any transformation. The meat consumption regards sheep and goat meat that typically have lower CF values than beef.

Summarizing, the results are higher than typical Mediterranean values due to the high consumption of milk and dairy products. The higher than average values for such products for Mongolia are due to the extensive nature of cattle breeding in such country. The best results in terms of CF regard China and are due to the high consumption of vegetables. In this particular case the nutrition of the team was biased towards such products due to safety food precautions that partially excluded milk based products from the diet.

The diets from the other countries, shown in figure 1, indicate a sustainability profile, in terms of CF, similar to the Mediterranean one and their largest contribution to the CFs depended on meat consumption.

These results confirm some findings of the extensive literature on diets. Indeed several studies compare different foods or compare various types of diets. A review by Heller et al. (2013) compared 32 LCA studies on diets. The results of all these studies pinpointed some key areas:

- in general, foods of animal origin show a worse environmental performance than those of plant origin;
- consequently vegetarian diets have a better environmental profile than other diets;
- there is a strong regional difference in food habits and production processes.

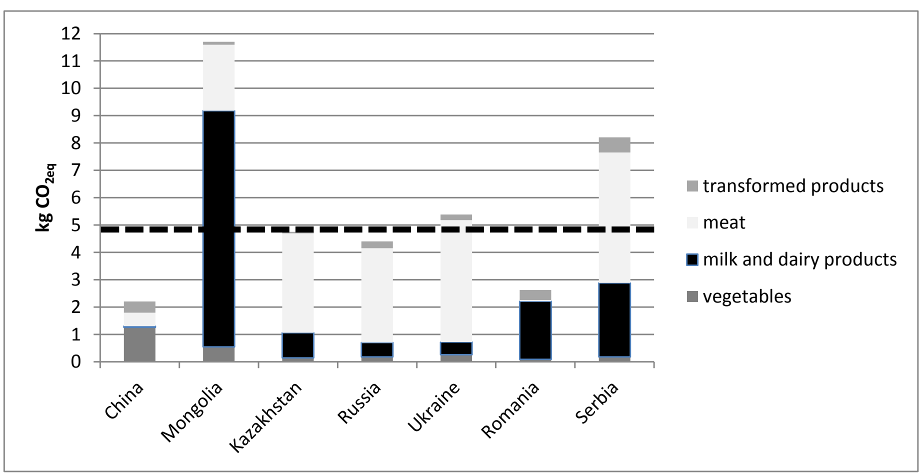

Figure 1. “Carbon footprint report”: CF of the daily diet calculated for the various countries

4. Conclusions

The Meneghina Express project, that obtained the Guinness world record for the longest distance travelled on electric motorbikes, represented a good occasion to focus on the environmental sustainability of food and diets. The desired results were reached thanks to the synergy between the exploration team and the University of Bari.

Regarding the creation of the database for the environmental sustainability assessment of food, it should be pointed out that it is a mere carbon footprint; the inclusion of other environmental aspects and impact categories was initially discussed but then excluded due to the lack of sufficiently reliable sources.

Overall the database is made up of the CF of 411 products. For 188 of these the indicator has been calculated for each country crossed during the journey, whilst for the remaining 223 products the data was gathered from literature and existing databases.

For many of the products the CF value varies considerably among countries due to the different production techniques and the their respective efficiencies.

Based on the data collected regarding the team's nutrition during the journey it was possible to generate a "carbon footprint report" of the various diets of the various countries and these have been compared to the Mediterranean diet. The results are of course representative only of this particular experience and do not represent national average values. Overall what emerges is that in the colder countries the diets are hyper caloric, based on meat and dairy product consumption and are less eco-compatible. In China where the nutrition was based mainly on vegetables the resulting CF is lowest hence counterbalancing the effects of the Chinese kWh which is based 79% on coal.

Concluding, food sustainability will continue to remain at the center of attention with the ever growing awareness of consumers, but it also needs technical instruments and reliable sources to find a scientific solution to the many problems connected to such a topic.

ABSTRACT

In this study, the GHG emissions of the farmed fish willow shiner (called Honmoroko in Japanese) were calculated including the GHG emissions for reforming the rice field to the aquaculture pond and expendable materials consumption on their production as well as the GHG emissions caused by energy on their production. Furthermore, the nitrous oxide (N_2O) volatilization from an aquaculture pond was estimated. As the results, the GHG emissions for the production of willow shiner were calculated as 3.62 t-CO_2e/t, which was correspond to 1,447 g-CO_2e/m^2/year, and the direct volatilization of N_2O was also estimated to be 572 g-CO_2e/ m2/ year. Nutritive salts removal experiment shows that SunPatiens flower has enough potential to remove inorganic nitrogen in the aquaculture pond. In other words, an aquaculture system with hydroponic plants has a capacity to make a clearance of N_2O from the aquaculture pond.

Keywords: GHG emission, aquaculture, cyprinoid fish, willow shiner, hydroponic plant, absorptive removal, nitrous oxide, volatilization

1. Introduction

There are many studies on the calculation of the GHG emissions for food, which are however calculated only for their production processes using the data of energy and expendable materials consumption. In this study, the GHG emission of the farmed fish willow shiner (called Honmoroko in Japanese) is calculated including the GHG emissions for reforming the rice field to the aquaculture pond and expendable materials consumption on their production. However, it is significant to know the direct volatilization potential of N_2O from the aquaculture pond caused by non-consumed feed and waste (ammonia and feces) of fish, moreover, the removal potential of inorganic nitrogen by hydroponic plant cultivated in aquaculture pond is also important to reduce the GHG emissions.

2. GHG emission of willow shiner

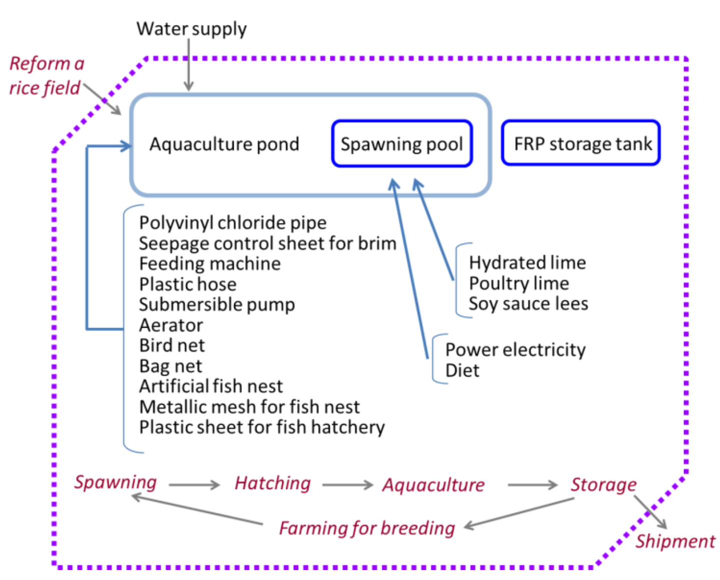

Figure 1. System boundary

In this study the amount of GHG emission for the farming of willow shiner is calculated including initial investment to reform the rice field to the aquaculture pond. The system boundary is illustrated in Figure 1. As water supply system differs according to farming region and area, it is excluded from the system.

The materials used for reforming rice field, aquaculture instruments, consumable goods, commercial fish feed, power consumption, hatching goods and storage materials are included in a system boundary. In order to obtain the amount of consumption of materials and energy, the balance of payment was used which is shown in a Tutorial Manual No.9 － Honmoroko Farming Technology－published by Saitama Prefectural Agriculture and Forestry Research Center Fisheries Research Insti-

Figure 2. Examples of reformed rice fields in western Japan

tute. Additional interviews were performed in the Fisheries Research Institute in Saitama Prefecture and Honmoroko Farming Manual by Kusatsu city in Shiga Prefecture was also used as supplements for the GHG calculation. The rice field reform is performed shown in the figure 2 which are examples in Tottori Prefecture.

The 50-60 cm water depth is needed by digging a bit deeper the rice field and raise on the ridge. Waterproof sheets are laid on the ridge as shown in Figure 2. The amount of the GHG emission into units of CO_2 equivalent (CO_2e) is calculated according to the aquaculture schedule of the Table 1. 400 kg willow shiner per 1,000m^2 (10a) reformed rice field was produced in a year.

To calculate the GHG emission of the willow shiner farming, the official secondary data for Japanese Carbon Footprint Program are used firstly as the CO_2e emission factors and then the 3EID data (2000) derived from I/O analysis for Japan are used secondly. Table 2 shows the amount of consumption for durable /expendable materi-

Willow shiner (Inland water culture)	0	3.62	3.62

als and energy to produce willow shiner per 1,000m^2 pond in a year and their CO_2e emission factors. Furthermore, Table 2 shows also the calculation results of GHG emissions (CO_2e) per 1,000m^2 pond per year. The amount of durable materials per year was obtained by dividing the whole weights by the years using them.

As the result, the CO_2e emission for the production of willow shiner is 1.447t-CO_2e/1,000m^2, which correspond to 3.62t-CO_2e /t-willow shiner. It is almost the same as those for other farmed fishes. However, as the edible part of willow shiner is 100%, while those of other fishes are about 50%, the actual GHG emission of willow shiner is thought to be smaller than the GHG emissions of other farmed fishes shown in table3.

3. Estimation of the GHG emission including Nitrous oxide (N_2O) from the aquaculture pond

670kg of fish feed, shown in Table2, was fed in the 1,000m^2 pond to produce 400kg of willow shiner per year. Non-consumed feed and waste (feces and ammonia) from fish are in the pond. The CO_2 emissions caused by them do not need to be counted, because the fish feed was produced by some plant and wild fish meal of phytoplankton origin, they are thought to be carbon-neutral. Moreover, the emission of CH_4 caused by non-consumed feed and waste from fish is negligible, because oxygen is always supplied by aeration in the pond for fish. However, we have to count the emission of N_2O caused by protein included in fish feed, because the global warming potential of N_2O is higher than CO_2.

As mentioned above, 670 kg fish feed was fed in the pond, which has 45.1kg of nitrogen because the 3 kind of commercial feeds shown in Table 4 were used. On the other hand, 400 kg of willow shiner has 11.2 kg nitrogen because the protein ratio of willow shiner is 17.5% according to the data of Standard Tables of Food Composition in Japan (2010) and nitrogen ratio of protein is 16% by nitrogen-protein conversion factor. It means 33.9kg of nitrogen was discharged into pond a year, which is the difference between 45.1kg contained in feed and 11.2kg of willow shiner.

Table 4. Ingredient labeling of commercial feed

Diet brand	Feeding period	The ratio of weight % to all diet (670kg)	Protein content (%)	Protein weight (kg)	Nitrogen weight (kg)
New carp mash	5/12～6/15	19.4	30	38.99	6.24
Carp juvenile C-2	6/1～7/31	34.3	45	103.41	16.55
Carp juvenile C-3	8/7～11/12	46.3	45	139.59	22.33
Total				281.99	45.12

Almost no research has been conducted to quantify N2O emission on aquatic production.

Ahn et al. quantified the annual N_2O emissions of 12 wastewater treatment plants across the United States and found that the N_2O emission can be as high as 1.80% of influent nitrogen. Using this ratio, the CO_2 equivalent emission (CO_2e) of N_2O for the production of willow shiner is calculated as follows. Global warming potential 298 is compliant with the (AR4).

$33{,}900 \text{ g} \times 0.018 = 610\text{g-N}$
$610 \text{ g} \times 44/14 = 1{,}917 \text{ g-}N_2O$
$1{,}917 \text{ g-}N_2O/ 1000\text{m}^2/ \text{year} = 1.92 \text{ g-}N_2O/ \text{m}^2/ \text{year}$
$1.92 \times 298 = 572 \text{ g-}CO_2\text{e}/ \text{m}^2/ \text{year}$

Adding this to the CO_2 emission, the total GHG emission (CO_2e) for the production of willow shiner is calculated.

$1{,}447+572 = 2{,}019 \text{ g-}CO_2\text{e}/ \text{m}^2/ \text{year}$

Around 2,000 g-CO_2e/ m^2/ year are totally emitted for the production of willow shiner. But it is very rough estimation because the conversion ratio of influent nitrogen to N_2O, i.e. 1.8%, was estimated by the studies of wastewater treatment plants which were probably different from aquaculture conditions.

4. An absorptive removal experiment of the inorganic nitrogen by hydroponic plants in a similar condition to an aquaculture pond

Hydroponic plants can absorb and remove the inorganic nitrogen in water. The potential to reduce the GHG emission from willow shiner aquaculture pond introducing hydroponic culture in the pond was estimated using the data of the following experiments by SunPatiens Salmon (*Impatiens* hybrid) flower, which showed the high absorption potential of nutrients in the water.

Hydroponic pots of SunPatiens and plant-free pot were prepared in small pools without aeration, which was called as “Pool condition”.

- Hydroponic pots of SunPatiens and plant-free pot were prepared with aeration condition, which was called as “Aeration condition”. It was the very similar condition to willow shiner aquaculture pond.
- 10% Hoagland’s solution was used as nutrient (NH_4-N: 10mg/L, NO_3-N: 10mg/L, etc.).
- Every week 10L 10% Hoagland’s nutrient solution was exchanged.
- Experimental period was for 7 weeks from 28th June to 11th August, but 5th week it was 6 days to be exchanged the 10% Hoagland’s solution and 7th week it was 3 days to be exchanged it (44 days), because SunPatiens salmon absorbed nutrient completely before 7th day in these weeks.

Table 5 shows Nitrogen absorption rate by SunPatiens Salmon. Aeration condition is similar to willow shiner pond. Mean absorption rate of total nitrogen (ammonium nitrogen and nitrate nitrogen) is 423mg/m^2/day. Figure 3 shows Nitrogen concentration changes of Hoagland’s nutrient solution, that an ammonium nitrogen concentration decreased more rapidly on the aeration condition plant-free pot than pool condition plant-free pot, and furthermore, the nitrate nitrogen concentration on the aeration condition plant-free pot was higher than pool condition plant-free pot. It is considered that aeration accelerate the nitrification and volatilization of ammonia. The 423mg/m^2/day might be over estimation because the ammonia volatilization is included. However, figure 3 also shows SunPatiens Salmon absorbed the nutrient of 10*l* Hoagland’s solution in a few days. As the period become progressively shorter in accordance with the biomass growth of the SunPatiens, and as expected the rate of absorption becomes larger, it would be used as the reasonable average value 423mg/m^2/day.

In the case of the mean absorption rate of total nitrogen i.e. 423mg/m^2/day, one plant has the absorption potential of 76g /m^2/180days. It means that 33,900g-N can be removed by 446 plants in 180 days.

Table5. Nitrogen absorption rate by the hydroponic plant (SunPatiens)

Pool condition

	Ammonium nitrogen			Nitrate nitrogen		
	Average loading (mg/m^2/day)	Mean absorption rate (mg/m^2/day)	Removal rate (%)	Average loading (mg/m^2/day)	Mean absorption rate (mg/m^2/day)	Removal rate (%)
SunPatiens (Salmon)	360.631	229.628	63.7	344.095	301.585	87.6
Plant-free	360.631	75.663	21.0	344.095	2.782	0.8

Aeration condition

Plant-free	360.631	192.691	53.4	344.095	9.652	2.8

Average loading, mean absorption rate and removal rare made an allowance for plant-free pot values

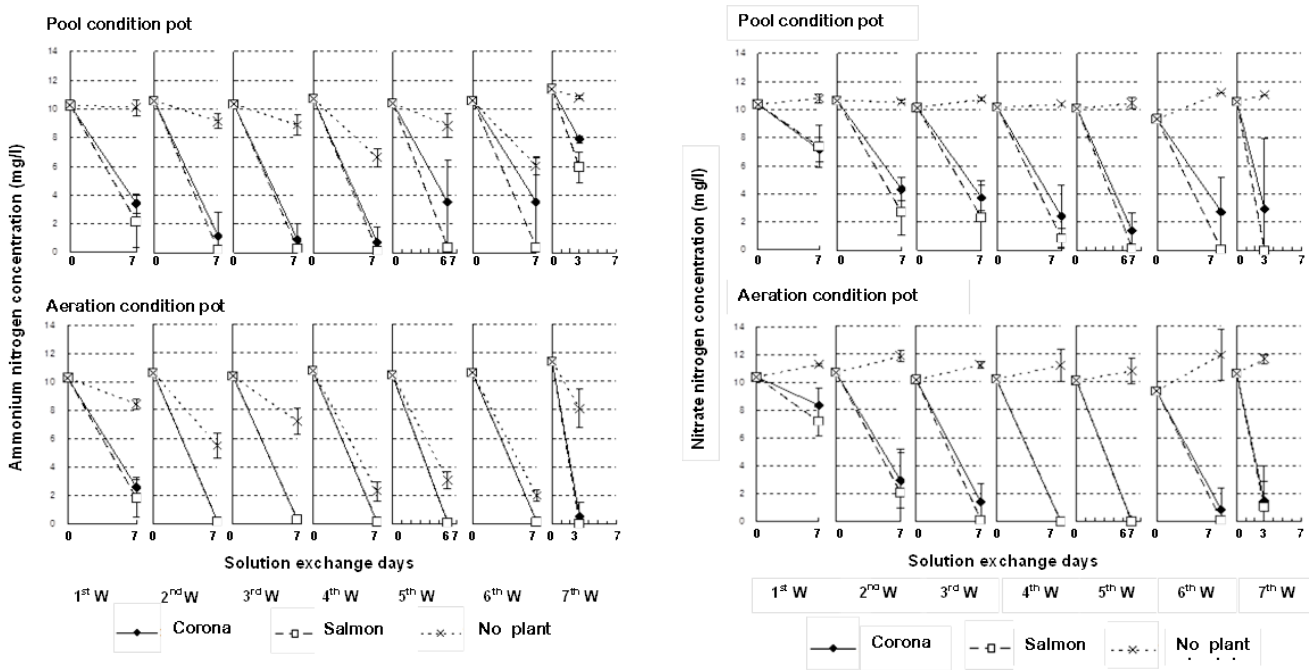

Figure 3 Nitrogen concentration changes of Hoagland's nutrient solution

5. Conclusion

A GHG emission for the production of farmed willow shiner in reformed rice field in Japan is around 2,000 g-CO_2e/ m^2/ year. It will be 3-4 times larger than the GHG emission of rice production of 728g CO_2e/m^2/year in Japan, which is calculated using 1.35kgCO_2e/kg-rice by the carbon footprint secondary data (B-J301001) and 539kg-rice /1000m^2 /year by the averaged rice annual crop (2013) of Japan.

The result shows the GHG emission caused by electricity consumption is the largest in willow shiner farming. The power is consumed for the aeration which is essential to freshwater aquaculture. The development of aeration technology which consumes little power is needed. The second largest emission source is fish feed. The fish feed production process of less GHG emissions should be developed, which might be the process using food waste.

In this paper, the absorptive removal potential of inorganic nitrogen by hydroponic flower, SunPatiens Salmon was estimated. The 33,900g-N, which was discharged in 1,000 m^2 pond for 400kg production of willow shiner in 180days, could be removed by 446 plants. As SunPatiens has the purifying effect of the aquaculture pond, the higher density fish farming can be achieved which could lead the less GHG aquaculture per the production volume.

An evaluation of upstream assumptions in food-waste life cycle assessments

Thomas Oldfield*, Nicholas M. Holden

UCD School of Biosystems Engineering, University College Dublin
* Corresponding author. E-mail: *Thomas.oldfield@ucdconnect.ie*

ABSTRACT

The aim of this paper was to evaluate the tenability of the "zero burden assumption" for a waste stream with an economic value. Thirty comparative life cycle assessments (LCAs) addressing food-waste treatment were analysed and five questions were asked: (i) was the "zero burden assumption" used and what percentage of the waste system environmental impact was contributed by food-waste production? (ii) was there any indication that the waste had economic value? (iii) was it a comparative study? (iv) was the approach different between peer reviewed journals and commercial studies? and (v) if an environmental burden were assigned to the waste in each study, how might it be estimated? It was evident that the upstream 'zero burden assumption' is commonly followed in food waste LCA and no quantitative environmental impact is associated with the food waste resource, be it a comparative study or not. Few studies acknowledged that waste has an economic value. The argument for including the environmental impact of food waste and waste in general was reasoned on two fronts. Firstly, it was shown that the environmental impact of the waste itself may hold a large percentage of the overall system impact and should therefore be included. Secondly, with the valorisation of waste and its subsequent use as a feedstock in other systems that produce a product with an economic value, it is no longer directed to a biosphere sink, and should therefore not be called a waste as it stays in the technosphere as a resource. Future food-waste and waste LCA in general could follow the approach that was explored and quantify the environmental impact of waste by using a 'meta-waste-based accounting' approach.

Keywords: Life cycle assessment, zero burden, economic value, up-stream assumptions, technosphere, meta-waste-based accounting

1. Introduction

By definition, life cycle assessment (LCA) estimates the environmental impact of a product over its entire life from conception to disposal. The application of LCA for waste system analysis has been applied at macro, meso and micro levels in a large number of countries globally (Anderson et al. 2012; Khoo et al. 2010; Saer et al. 2013). A fundamental approach in LCA methodology is the modeling of a system being carried out in such a way that inputs and outputs to the system are followed from the 'cradle' to the 'grave'. This means that input flows should be drawn from the biosphere without human transformation, and outputs should be flows that are discarded to the biosphere without subsequent human transformations (ISO, 2006a). In the case of waste LCA a common approach applied in practice since the late 1990's is known as the "zero burden assumption" (Ekvall et al. 2007). It is applied when the waste coming into two comparative systems is regarded as the same across both systems and thus can be omitted from calculations (or assumed to have zero burden). In a scenario where there are differences in the amount of wastes coming into the systems under comparison the upstream boundary may have to be changed to include the impact of producing the waste (Finnveden, 1999). This is recognised as being difficult to do in practice, as waste is a non-homogeneous product (Ekvall et al. 2007). The aim of this paper was to evaluate the tenability of the "zero burden assumption" if the waste stream has an economic value, for example as a feedstock for nutrient recovery technology. Findings are discussed in relation to identified limitations, new developments and possible future research in the waste sector.

2. Methods

This study is limited to assessing upstream assumptions in food waste (FW) LCA. Other studies have reviewed the four stage procedure for carrying out FW LCA (Bernstad and la Cour Jansen, 2012). To evaluate the upstream assumption thirty LCA studies were considered (Table 1) from four continents, Asia (5 studies), North America (3 studies), Australasia (1 study) and Europe (21 studies). Criteria for accepting a study were established based on the following:

1. Include at least one nutrient recovery technology capable of accepting FW.
2. Adhere to LCA methodology.
3. Include global warming potential (GWP) as an impact category.
4. Have been published between the years 2000 and 2014.

A review matrix was then developed for the systematic review of the thirty papers, and the following five questions were then answered:
(ia) Was the “zero burden assumption” used and (ib) what percentage of the waste system’s environmental impact was contributed by food-waste production?
(ii) Was there any indication that the waste had economic value?
(iii) Was the study a comparison of more than one technology?
(iv) Was the zero waste assumption approached differently between peer reviewed journals and commercial studies?
(v) If an environmental burden were to be assigned to the waste in each study, how might it be estimated?

CBA: Cost Benefit Analysis.

A limited number of commercial LCAs have been carried out for FW. From this limited analysis (question 4) it was seen that there was no difference in the approach taken for commercial FW LCA in comparison to that of the academic papers. The zero burden approach was followed for both types of analysis with four (13%) studies making reference to following the 'zero burden' approach, whilst the other twenty-six followed the approach but made no reference to it. Subsequently, none of the thirty studies (commercial or academic) associated a quantitative environmental burden to FW.

The FW entering each system in the thirty studies was different in each case, which means assessing its environmental impact in a cradle to grave system is impossible (question 5). One method for calculating the environmental impact of FW would be to follow the approach taken by Milà i Canals et al (2011) who assessed the footprint for the Knorr food portfolio. A bottom up approach was impractical in this case due the complexity of the product range, which is a similar challenge for FW LCA. The 'meta-product-based accounting' LCA approach that created sixteen product types, for example, "dry soup–instant" with an average recipe that does not exist in the market, but is a good-enough representation of the hundreds of variants of instant dry soups in the market could also be applicable to FW LCA where waste can be categorised into a number of sub-groups (vegetable, meat, grain, processed food and so on) and an environmental impact could be assigned. To illustrate this approach and the potential impact that FW could have in its simplest form, three food products (beef, tomatoes and pasta) were identified where verified LCAs have been carried out and only the impact GWP was considered (Table 3).

Table 3: GWP of three food types

Product	**kg $C0_2$ eq/kg**	**kg $C0_2$ eq/kg (Average)**	**% of waste**	**kg $C0_2$ eq/kg for % waste**	**Reference**
Beef	11-25.3	18.15	10	1.815	Casey and Holden (2005); William et al (2006)
Tomatoes	0.5-1.7	1.1	80	0.88	Hogberg (2010)
Pasta	0.85-2.5	1.675	10	0.1675	Barilla (2013)

If it was assumed that FW consisted of 80% tomatoes, 10% pasta and 10% beef a GWP of approximately 2.9 Kg CO_2-e per Kg of FW would be estimated (Table 3). This is a similar value to the estimated two tons of CO_2 per tonne of FW (European Commission, 2010).

Table 4: Adapted from Blengini, (2008a), GWP impact for FW composting system

Process	**Kg CO_2 eq/kg**	**Percentage**
Waste bags†	0.017	0.53
Road transport†	0.012	0.38
Waste processing†	0.045	1.41
Biogenic Emissions from composting†	0.156	4.88
Avoided Products and carbon sinks†	-0.10	3.13
Waste generation	2.8655	89.67
Total	3.1955	100

†Number are approximations taken from graphs in the original publication.

Taking Blengini's (2008a) research as a case study (FU is 1 kg of waste and has detailed breakdown of process GWP impacts) and including the embedded GWP impact of waste (Table 4) it can be seen that waste generation has a considerable impact at approximately eighty-nine per cent of the total.

4. Discussion

In relation to FW LCAs and according to the ISO standard (ISO, 2006) an LCA should be carried out in such a way that inputs and outputs to the system are followed from the 'cradle' to the 'grave'. It has been identified in this paper that this is not the case for LCA carried out for FW and waste in general. The 'zero burden' assumption has been followed for well over a decade in waste studies, comparative or not, and was seen in all thirty of the studies reviewed, with the result being that waste was not given a quantitative burden in waste systems when carrying out life cycle analysis.

All of the thirty studies included a nutrient recovery technology that produced a product that has an economic value that could offset some or all of the inherent negative economic value of the waste, however the majority of the studies made limited reference to waste having an 'economic value' as a resource, although twenty-five studies had an avoided burden associated to the replacement of a fossil material. The fact that this resource stream stays in the technosphere and does not enter the biosphere as a waste as per the definition of 'grave' by the ISO standard (ISO, 2006) means that it should be referred to as a resource (Figure 1).

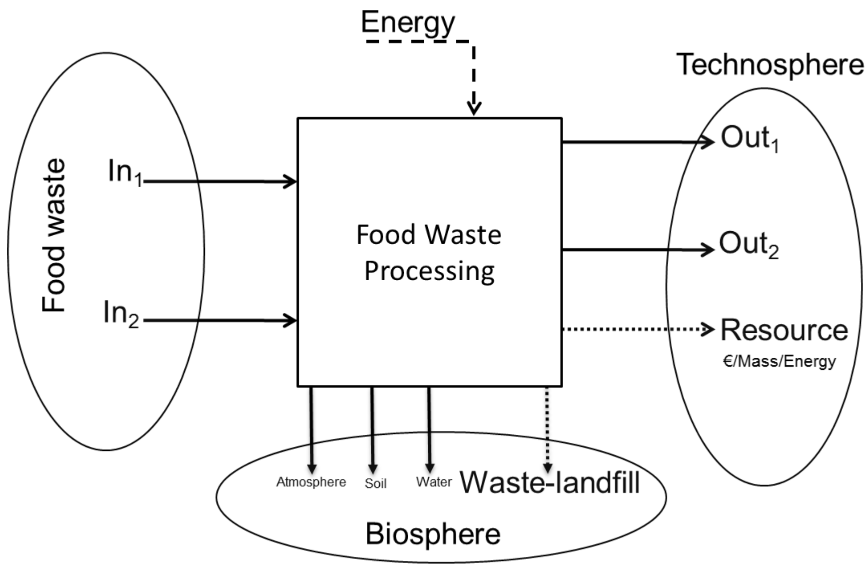

Figure 1: Waste verses resource

The term 'circular economy' is increasingly being used by governments and organisations (Mirabella, 2014) that are trying to find ways to close the loop on waste. This means it is used as a resource in other systems, such as a feedstock or raw-material replacement. In the case of biological nutrients found in FW this could be by composting or another nutrient recycling technology. However, the waste hierarchy defines that waste minimisation be the priority and in the case where reductions cannot happen it proposes that, reuse, recycling and recovery be achieved in that order. These two approaches can be seen as contradictory. In the case of adopting nutrient recovery technologies that would require investment and are privatised in many European countries, a return on investment and subsequent profit would be expected, which would come from the products produced (in addition to gate fee). Therefore it can be assumed that the owner of the facility would have no incentive to reduce the waste collected as this would decrease profit. This may not be the case in all locations across Europe, but with sustainability at the forefront of government policy and recycling rates on the increase waste can no longer be seen as a valueless resource, and must be dealt with in a manner that not only considers its economic value, but also the associated environmental burden.

This valorisation of waste, which has resulted in it becoming a feedstock for a number of technologies means that there is a strong relationship between its economic value and the amount that is available. In a case where 20% of total food produced is wasted (Figure 2) and becomes a feedstock in a recovery technology there will be a much stronger relationship between its economic value and the amount of the waste (20%) than that of the economic value and mass of the consumed food (80%). It can be argued that in this example where 80% of food produced is consumed that the economic value of this food or its disposal would have to increase significantly if this were to be the over-riding relationship between the amount of food wastage and amount food consumed.

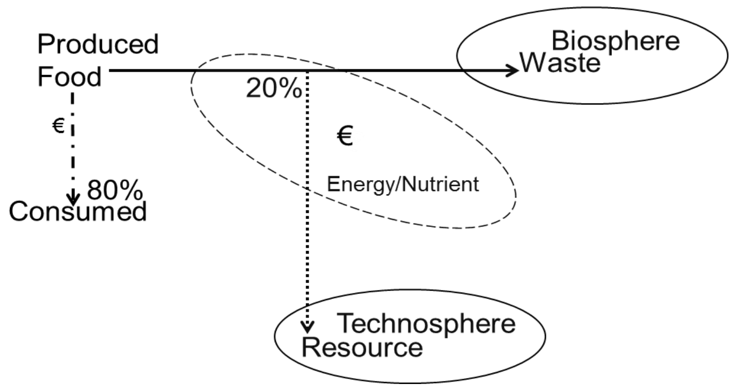

Figure 2: Relationship between the amount of waste and its value

5. Conclusion

In carrying out this review it was found that in response to the five questions asked: (1) the "zero burden assumption" was followed in all the studies thus no impact was assigned to food waste generation in all cases; (2) in five of the studies there was no reference to economic value, one study carried out a cost benefit analysis, whilst in the remaining twenty-four the product of the conversion process, i.e. compost or energy was identified as having a substitute value, but no value was mentioned for the food-waste itself ; (3) twenty-six of the studies compared two or more technologies; (4) the approach followed is the same for both academic journal and commercial studies; (5) the food waste entering each system in the thirty studies was different in each case, which means assessing its environmental impact in a cradle to grave system is very difficult.

It is evident that the upstream "zero burden assumption" is commonly followed in food waste LCA and no quantitative environmental impact is given to the food waste resource. The argument for including the environmental impact of FW and waste in general was presented on two fronts, firstly, it was shown that the environmental impact of the waste itself may hold a large percentage of the overall system impact and should therefore be included to show likely decreases if waste reduction occurs. Secondly, with the valorisation of waste and its subsequent use as a feedstock in other systems that produce a product with an economic value, it is no longer directed to a biosphere sink, and should therefore not be called a waste as it stays in the technosphere as a resource. Future FW and waste LCA in general could follow the approach that is suggested above and quantify its environmental impact by using a'meta-waste-based accounting' approach.

ABSTRACT

The objective of this study was to evaluate whether introducing the OBEO caddy to the home organic food waste disposal system would result in a lower environmental footprint than if the food waste was sent to landfill. A streamlined life cycle assessment (LCA) was carried out and the environmental impacts were quantified in terms of primary energy consumption (PEC), global warming potential (GWP), acidification (EP) and eutrophication (EP) potential. It was found that the OBEO caddy has the potential to greatly reduce the environmental and resource consumption impact of organic food waste and had a positive effect for PEC, GWP and EP. A negative effect for AP was found. Fill rate, and product design to achieve maximum fill rate need further attention and comparisons with plastic caddy's and recycled paper bags need to be undertaken to complete the evaluation of the OBEO caddy.

Keywords: LCA, Food Waste, Composting, disposal caddy

1. Introduction

Food waste is a global issue with an estimated one third of all food produced being wasted (UNRIC, 2014). In Ireland, a limited amount of food waste is captured in brown bins, which are sent for recovery in compost facilities. The Irish product design company OBEO has created an innovative, simple and fully compostable disposal caddy to facilitate food waste disposal in the home by making it clean and easy to undertake. OBEO's market research identified that by 2016 population agglomerations of more than 500 households would have access to a brown bin, which equates to a potential market of 1.2 million households in Ireland. The existing practice of landfilling food waste is no longer accepted as a suitable management option. The aim of this study was to estimate whether introducing the OBEO caddy to the home waste disposal system would result in a lower environmental impact than if the food waste was sent to landfill.

Figure 1. OBEO compostable Caddy

2. Methods

The streamlined environmental footprint and comparative analysis were performed in adherence to LCA methodology, standardised by ISO 14040 and 14044 (ISO, 2006a, b). LCA methodology has been used to evaluate and compare a large number of waste management technologies (Blengini, 2009; Kong et al. 2012; Martinez – Blanco et al. 2009). The LCA methodology consists of four phases: (1) goal and scope definition; (2) inventory analysis; (3) impact assessment; (4) interpretation, which were followed for this study.

2.1. System boundary and functional unit

The study is a comparative LCA, evaluating food waste disposal in landfill and in-vessel composting facility. This study did not consider the environmental impact of waste generation and its subsequent use as a resource. The upstream boundary was set at the waste collection stage. This is the approach followed in the majority of waste management studies, known as the "zero burden assumption" (Ekvall et al., 2007) and is applied when the waste coming into two comparative systems is regarded as being the same for both systems and thus can be omitted from calculations, or assumed to have zero burden (Finnveden, 1999). This method did not allow for the quantification of the food waste impact, but as this was a streamlined LCA it allowed the manufacturer to get a clear understanding of the potential impact their product may have.

The system under study consisted of the OBEO caddy manufacture and transportation to point of use; waste transportation from household to composting facility; treatment of waste in composting facility, the reference system was the collection of food waste and transport to landfill. The functional unit of the study was the disposal of 1000 kg of food waste.

2.2. In-vessel composting system

Once the food waste has been placed into the OBEO caddy it is consigned to the brown (organic waste) bin and sent for further treatment. The treatment process that was modelled in this study was in-vessel composting as it is the most suitable technology and is commonly used in Ireland. Full details of the composting process are outlined in Table 3. The data used in this study were taken from a number of LCAs carried out for Irish and European in-vessel composting processes. The composting plant modelled in had the capacity to process 15,000 t yr^{-1} of organic food waste.

2.3. Life cycle Inventory

The OBEO caddy consists of a paper bag which is housed in a cardboard (Kraftpack) case. Table 1 presents the inventory for the caddy manufacture and transportation.

Table 1: Characteristics of the food bag and kraftpak and distribution distances for the OBEO caddy.

Characteristics	**Food bag**	**Kraftpack**
Food bag mass (for one bag)	0.019 kg	-
Dimensions	200 x 115 x 390 mm = 0.00897 m^3	220 x 736 mm = 0.162 m^2
Volume/Mass	0.00897 m^3 = 8.97 litres Manufacturers assume 8 litres	0.162 m^2 x 0.283 kg/m^2 = 0.0458 kg
Manufacturer	Segezha Packaging	Kapstone paper
Location of manufacture	Southern Sweden	Illinois, USA
Delivery mode to Ireland	Ship & truck	Ship & truck
Distance	1637 km	5909 km

The OBEO caddy is held together with a glue and ink is used to place the logo on the Kraftpack. These items were not included in the analysis. Site specific data for the manufacture were not available, thus industry average data from the eco-invent and ELCD databases were used. It was assumed that these data were representative of the current, European produced paper and cardboard. Market research by OBEO defined typical food waste data (Table 2) used to design the OBEO caddy. Sensitivity analysis of the fill rate for the OBEO caddy was undertaken to evaluate the impact if not being completely full on environmental performance.

Table 2: Food waste data for the design of the OBEO caddy

Characteristic	Value
Food waste density range	343-515 kg/m^3
Food waste density average	429 kg/m^3
Mass of waste per OBEO	Maximum 2.3kg

It was assumed that the food waste for the reference system would be collected in a plastic bag at a rate of 10kg per bag. Table 3 presents the inventory data for the plastic bag.

Table 3: Characteristics of the plastic bag and distribution distances for the reference flow.

Characteristics	Plastic bag
Food bag mass (for one bag)	Assumed 10 kg
Volume/Mass	50 L
Location of manufacture	Assumed Illinois, USA
Delivery mode to Ireland	Ship & truck
Distance	5909 km

The compost facility data used for the study are presented in Table 4, whilst the data for Landfill is presented in Table 5.

Table 4: Compost inventory data used for the streamlined LCA.

Type of flow	Units	Quantity	Reference
Input			
Diesel	kg	4.73	Martínez-Blanco et al. (2009)
Electricity	KWh	50.5	Martínez-Blanco et al. (2009)
Food Waste	Tonne	1	Martínez-Blanco et al. (2009); Blengini (2008); White (2012).
Output			
Compost	Tonne	0.2	Martínez-Blanco et al. (2009); Blengini (2008); White (2012)
CO_2	kg	156	Blengini, 2008
Ammonia	kg	0.6	Blengini, 2008
Methane	kg	0.034	Martínez-Blanco et al. (2009)
VOC	kg	1.210	Martínez-Blanco et al. (2009)
Nitrous Oxide	kg	0.092	Martínez-Blanco et al. (2009)

The landfill was modeled using the process "landfill of biodegradable waste" from the ELCD database. Table 5 presents the typical flows for landfill.

Table 5: Landfill inventory data used for the streamlined LCA (ELCD, 2014).

Type of flow	Units	Quantity
Input		
Electricity	KWh	222
Food Waste	Tonne	1
Plastic Bag	g	300
Output		
CO_2	kg	62.6
Methane	kg	27.8
Nitrous Oxide	kg	0.00291

2.4. Life Cycle Impact Assessment

Four impacts (Table 6) were assessed, three followed the impact methodology CML 2001 (GWP, EP & AP).

Table 6: Impact Category, indicator and unit

Impact Category	Indicator	Unit
Global warming potential (Specifically - CO_2, N_2O, CH_4)	GWP_{100}	Kg CO_2 eq
Eutrophication potential	EP	Kg PO_4 eq
Acidification potential	AP	Kg SO_2 eq
Primary energy consumption	Energy Consumed	MJ

3. Results and Discussion

The results for the OBEO (Table 7) and landfill (Table 8) scenarios indicated that the OBEO caddy could lead to reduced PEC, GWP and EP, but increased AP (Figure 2).

Table 7: Impacts at composting per 1000 kg organic food waste if the OBEO caddy encouraged targeted disposal

	PEC (MJ)	GWP (kg CO_2e)	AP (kg SO_2e)	EP (kg PO_4e)
OBEO production	5.64	77	0.073	0.011
OBEO transport	0.53	3.5	0.0045	0.057
Waste transport	1.83	5.6	0.025	0.006
Composting process	700	150	35	0.22
Total	708	236	35.1	0.29

Table 8: Impact at landfill for 1000 kg of organic food waste

	PEC (MJ)	GWP (kg CO_2e)	AP (kg SO_2e)	EP (kg PO_4e)
Plastic Bag	4.6	5.0	0.013	0.001823
Waste Transport	52	4.0	0.019	0.0046
Landfill process	800	434	0.303	1.77
Total	856.6	443	0.335	1.776

Energy consumption might be reduced by 148 MJ for every tonne of waste composted rather than landfilled. There is approximately 200,000 tonnes of food waste generated in Ireland annually. If employing the OBEO caddy encouraged composting, this could result in a reduction of 29.6 million MJ of electricity consumption per year which is approximately 0.03% of Ireland's annual energy consumption. Reduction in GWP was calculated at 207 kg CO_2e ton^{-1} when using the OBEO caddy. This was mainly due to the amount of methane that is emitted during landfilling and the CO_2e associated with energy supply. Employing the OBEO caddy resulted in a potential increase in AP of 34.8 kg SO_2e ton^{-1} due to the composting process generating more documented acidifying emissions than the landfill process. It is worth noting that if this study was expanded to a full LCA then the result may be different because post-composting processes and more detail of landfill would be included in the full system model. A significant reduction in EP was observed with the introduction of the OBEO caddy and subsequent composting.

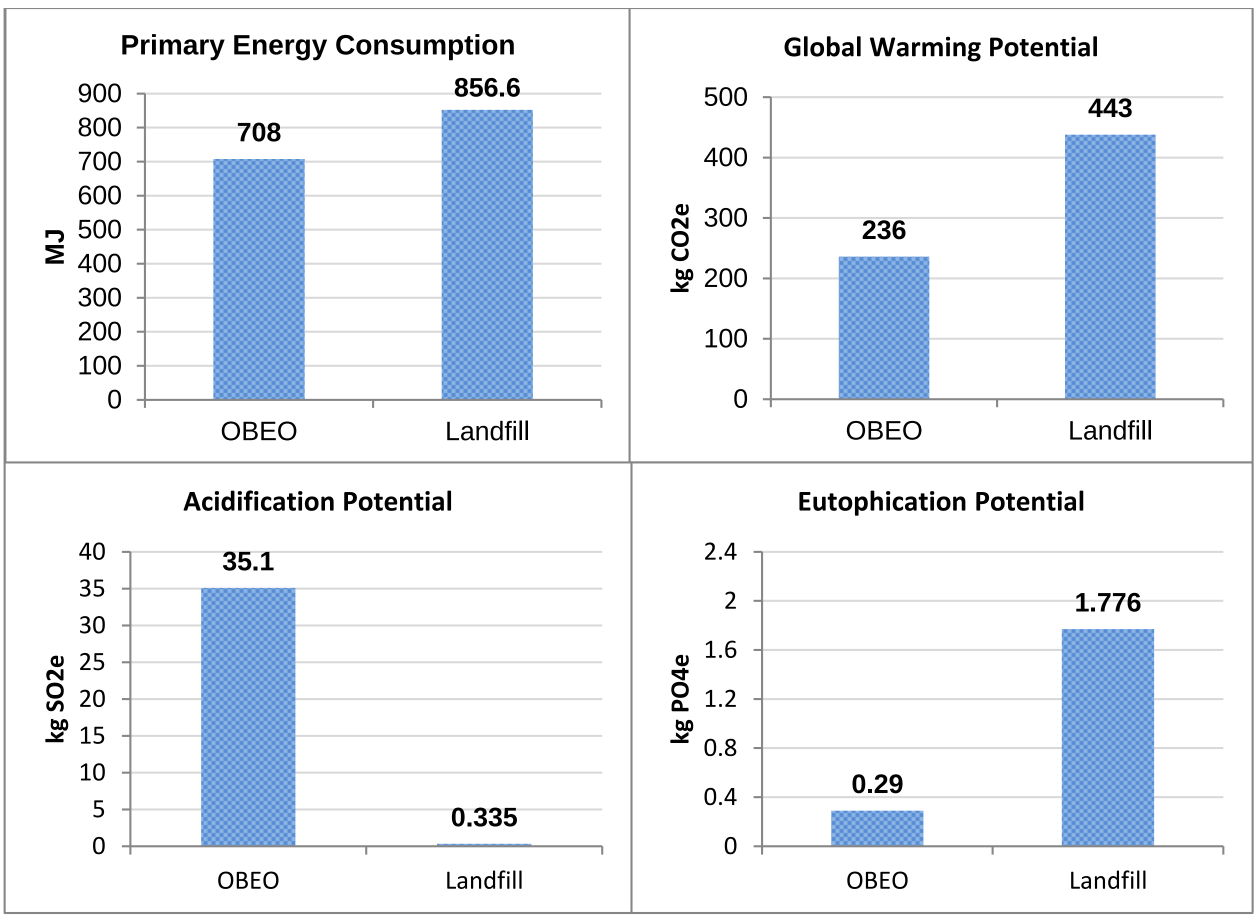

Figure 2. Comparison of the impacts for one tonne of waste composted with the OBEO caddy or landfilled

As this study was limited to a streamlined LCA, the main assumption tested was fill rate. It was assumed that the OBEO caddy would be filled to its maximum with a standard composition food waste (Table 2) when calculating the environmental impacts. The sensitivity analysis examined a 50% and 25% file rate. Reducing fill rate had a very small impact on PEC, AP and EP (data not shown), but there was a large impact on GWP (Figure 3). A 50% reduction infill rate caused a 74% increase in GWP. For 1 kg of waste to be captured approximately 0.4 OBEO caddies have to be produced and used at 100% fill rate. If the fill rate was 50% 0.8 OBEO caddies are needed and at 25%, 1.6 OBEO caddys. At a 25% fill rate the OBEO caddy, while encouraging composting would perhaps result in greater GWP because of the environmental impact of the manufacture and distribution stages in the product life cycle. Therefore to make sure the lowest GWP is realised, the design of the OBEO caddy must facilitate a high rate of food waste capturing, i.e. if an OBEO has a one day life span then its size should reflect the average amount of food waste disposed in one day. The sensitivity analysis suggested that consumers need to maximise use of the caddy to achieve optimum GWP benefit from composting using this system.

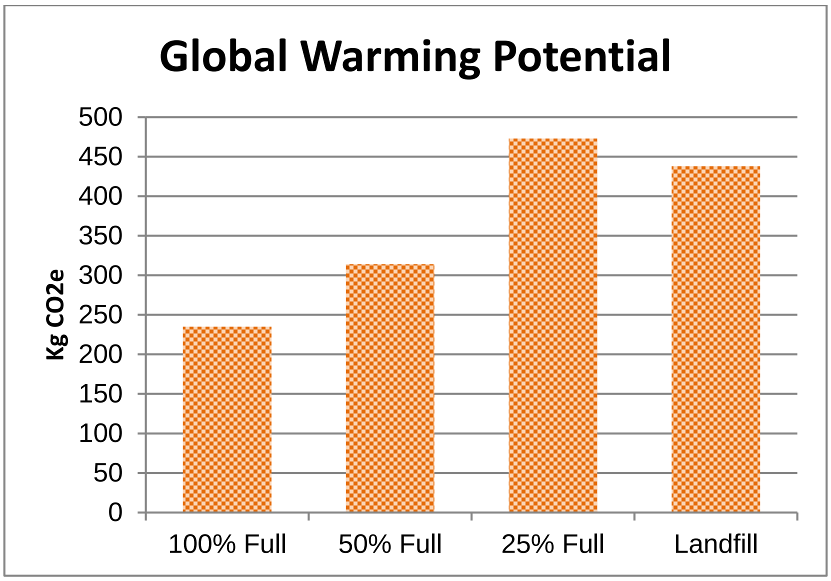

Figure 3. Sensitivity analysis of OBEO caddy to fill rate for GWP impact

As this was a streamlined LCA there was a limited comparison made between using the OBEO caddy to encourage composting and landfill. In reality there are at least two other approaches to food waste capture for composting that might be considered. Firstly the household simply captures food waste in recycled paper bags. As these are the most common bags for carrying shopping in Ireland due to the levy on plastic bags, it is a possible alternative. Secondly, the household captures food waste in a plastic caddy that is reused over and over. This latter alternative could also be lined with recycled plastic bags. It is clear from the design process of the OBEO caddy that simply using paper bags alone will not work well with food waste, which tends to have a high water content and thus paper shopping bags tend not to support wet food waste for transport to the recycling bin. While such an approach is likely to have less impact than the OBEO caddy if a zero burden assumption is used and a high fill rate, it is unlikely to encourage food waste recycling because of the mess and unreliability. This was the very reason for designing OBEO caddy in the first place. The use of plastic caddies is perhaps a serious competitor. In this case the life cycle burden will be diluted over many reuses of the caddy, but a cleaning impact (water use and EP may be important here) will arise. These alternative scenarios, and consumer behavior data on the relative encouragement that each scenario gives to separating food waste for composting need further research.

4. Conclusion

This study identified that the OBEO caddy has the potential to greatly reduce the environmental and resource consumption impact of organic food waste. The OBEO caddy has a positive effect for PEC, GWP and EP impacts but has a negative effect for AP impact, but this may be an artefact of the streamlined LCA. It was identified that fill rate, and product design to achieve maximum fill rate needs to be a focus of attention. To fully assess the value of OBEO from an environmental perspective a more complete LCA study should be undertaken.

It must be noted that the OBEO caddy by itself does not reduce the environmental impact, this only occurs when the food waste is diverted away from landfill and is composted. Thus, if the OBEO caddy was employed to collect food waste which was subsequently landfilled – there would be no environmental benefit, in fact there would be an increase due to its use.

An important outcome of this work is that if by using the OBEO caddy we can encourage more people to separate their food waste which would subsequently be composted in Ireland, then it should of course be used. For this study the important aspect of the lifecycle analysis is the waste treatment process, for Ireland composting or landfill. The OBEO caddy merely facilitates the transportation of the food waste.

ABSTRACT

PES (payment for ecosystem services) schemes generally operate locally, however it is important to consider their benefits from a life cycle perspective. This paper presents insight into the application of LCA to identify net environmental gains from CAMBI – a pilot scheme for sequestering soil carbon on-farm. A life cycle approach is applied by considering above ground GHG emissions from project implementation for a case CAMBI paddock in relation to soil C sequestration. The results suggested that increased soil C sequestration under CAMBI was sufficient to offset GHGs from project implementation and resulted in 0.58-0.7 t CO_2-e ha^{-1} yr^{-1} of avoided emissions under business-as-usual scenario. Further studies are needed to assess indirect impacts to identify environmental trade-offs from 1) land use changes in other areas of the farm or beyond; 2) farming input supply chain; or 3) other environmental impact categories. LCA can assist to identify net environmental gains from PES by addressing these issues.

Keywords: LCA, CAMBI, leakage, GHG emissions, Australia

1. Introduction

Agriculture is a dominant form of land management globally, covering nearly 40% of terrestrial land area (FAO stat 2010). Environmental impacts on ecosystems from agriculture are a function of: agricultural expansion into areas of natural ecosystems, agricultural intensification (higher yields from same or lesser land area), land use zoning schemes (which allocate land to restricted uses to ensure that natural ecosystems are not converted), and farming practices which can have both positive and negative impacts on the environment. Contrary to the belief that agricultural intensification and land use zoning reduces agriculture's impacts on ecosystems by halting agricultural expansion into natural ecosystems, studies suggest otherwise. Agricultural intensification or land use zoning in one geographical area potentially triggers compensating changes in trade flows of agricultural commodities and thus affect land use in other areas or countries (Lambin and Meyfroidt 2011; Pfaff and Walker 2010; Ramankutty et al. 2010). For example increases in import of cereals and wood products have been associated with countries that introduced conservation policies to keep land out of cultivation compared to countries without such policies (Gan and McCarl 2007; Mayer et al. 2005; Rudel et al. 2009). Thus in the era of globalization where there is worldwide interconnectedness of people and markets, and a greater separation between point of supply and demand, there is a greater need to understand and model outcomes of land use policies using a systems thinking approach.

Payment for ecosystem services (PES) is one such conservation tool that could benefit from a systems thinking approach to identify if such schemes are able to achieve net environmental benefits. PES offers monetary incentives to the landholders in exchange for some sort of ecosystem benefit in addition to food production. The idea is to bring otherwise free gifts of nature such as, clean air, climate regulation, pollination and so on, more in synchrony with the market, and in this way signal their importance in decision making. While PES schemes are increasingly being considered in sustainable agricultural practices both in developed and developing countries around the world, a need consistently reported is that of identifying environmental effectiveness of such schemes (Arrigada and Perrings 2009; Farley and Costanza 2010; Hajkowicz 2009; Tallis et al. 2008). A challenge which constrains the environmental assessment of local PES proposals is that of additionality and leakage. Additionality refers to the net impact on the biophysical provision of ecosystem benefits in comparison with the baseline[1] scenario or hypothetical situation where the PES scheme is not in place

[1]For example in Australia's Carbon Farming Initiative baseline refers to the carbon changes one would expect under business-as-usual condition that is those anticipated to occur in the absence of carbon policies or carbon projects. Setting the baselines is important as only carbon sequestered above and beyond the baseline will be counted for crediting purposes.

(Pascual et al., 2010). Leakage occurs when the actions to reduce environmental damages are merely displaced outside the geographic area of the project boundary typically resulting in offsetting or undermining environmental gains. For example, at the farm scale, leakage can potentially occur where project participants alter land use and farming practices in parts of their estate which are outside the technical boundary of the PES scheme. This could occur if land outside the PES scheme is managed more intensively to compensate forgone yields within the PES boundary.

In this paper a life cycle perspective - which is indicative of net environmental outcomes is applied in the assessment of CAMBI (Catchment Action Market Based Instrument) - a pilot project tested at the level of individual farmers and landholders for sequestering soil carbon (C) at the paddock scale. The aim of the CAMBI project is to design and test the cost effectiveness of a market based instrument (MBI) to support land holders adopt practices that increase soil C. This paper builds on previous and on-going work on modelling soil C levels through changed land management practices under CAMBI and considers the changes to above ground carbon emissions from project implementation. In this way the results indicate net potential gains from CAMBI intervention at the project boundary. This paper is organised as follows. In the next section a description of CAMBI and the methods to estimate net environmental impacts are presented. Section 3 and 4 reports and discusses the results of net environmental gains at CAMBI case paddock, followed by a final section on concluding remarks.

2. Methods

2.1. Description of CAMBI (Catchment Action Market Based Instrument)

Soil is a major sink of carbon; the size of the soil carbon pool and the annual flux of carbon passing through the soil are two reasons that soil organic carbon can play a significant role in mitigating GHG emissions. Soil C sequestration has been acknowledged to play an important role in reducing GHG emissions from agricultural systems in Australia (www.daff.gov.au/reducing-greenhouse-gas-fsheet.pdf). In addition to mitigating atmospheric GHG emissions, improving soil C levels has other benefits for increasing soil fertility, minimizing soil erosion, improving water holding capacity and ecosystem services and increasing farm productivity. With this background, the CAMBI pilot project, henceforth referred to as CAMBI, was designed and implemented in the Central West NSW to test the viability and cost effectiveness of a MBI to support landholders to adopt practices that increase soil carbon (Pearson et al. 2012). The premise is that potential changes to soil C occur if changes in land management are made. Accordingly, CAMBI has focused on assessing existing soil C levels under different combinations of land management, climate and soil landscapes. The predictions for soil C sequestration are based on the best available scientific knowledge and consider specific environmental conditions on specific soil types under different land holder defined actions and land uses (Murphy et al. 2012). Accordingly the CAMBI pilot scheme is also a test case to identify whether the current state of soil C science can support the practical implementation of MBI. The CAMBI pilot project was concentrated on the Cowra trough of NSW that has a temperate climate with a seasonally uniform rainfall distribution and porphyry-derived clay loam soils. The net soil C sequestered at the paddock scale from changed land management is the unit upon which payments were based. Contracts were finalized for eligible farmers through a reverse tender auction which provided best value in terms of soil C sequestered per dollar. The contract was between a farmer entity (proponent) and the Catchment Action NSW for a period of 5 years - from 2012 to 2017.

2.2. Data collection and analysis

Information was collected through a face-to-face interview from a CAMBI participant – a mixed farming enterprise with cropping and grazing of sheep on improved pasture. The farm is located in the Cowra region of NSW, Australia. Data was gathered on: 1) general information of the farm such as total land area, crop types, typical yields, irrigation availability, soil types and so on; 2) land management history of paddocks contracted under the CAMBI project – area, type of enterprise, typical calendar of operations, energy and material inputs used, typical yields; and 3) land management under CAMBI contract and the resources used therein.

Net environmental benefits of CAMBI intervention at the contracted paddock were estimated as the balance between GHG emissions from land management changes and predicted soil C sequestration rates expressed as t

CO_2-e ha^{-1} yr^{-1}. GHG emissions from cropping were modelled using LCA Simapro software (version 7.3) and both the Australasian LCI database and the Swiss Ecoinvent database (version 2.2) were used. Nitrous oxide emissions factor from N fertilization in cropping was estimated to be 1% (Australian Government 2011; IPCC 2006). Nitrous oxide emissions from crop residues (which are not burnt) is based on the National Inventory Report (Australian Government 2012) and takes into consideration factors such as yield, dry matter content and C:N ratio. GHG emissions from sheep grazing included GrassGro® modeled enteric methane and nitrous oxide emissions from excreted N and unutilized plant material. Historic climate information and data on-farm were used to model GHG emissions for an average year for the case farm.

Modelling soil C sequestration in CAMBI paddocks is part of the work based on SCaRP (Soil Carbon Research Program) – the largest and most extensive Australia wide program undertaken to measure stocks of soil carbon. As a part of this project a consistent method for sampling and a rapid and cost-effective way of analysing soil samples for soil organic carbon has been developed. Specifically, SCaRP-NSW was intended to assess the potential for agricultural land management practices (including emerging “carbon farming” practices such as the pilot CAMBI project considered in this study) to influence soil carbon on cropping and grazing land in NSW agricultural systems (Cowie et al. 2013). Sampling scheme for CAMBI project was developed to estimate the initial level of soil carbon in a paddock being assessed for a contract and its change after management actions have been undertaken (Murphy et al. 2012). This led to the development of a soil carbon metric that was used to assess rates of soil carbon sequestration for land managers which received payment under CAMBI contract.

3. Results

3.1. Historical GHG emissions on CAMBI paddocks (cropping)

The case farm is typically a mixed enterprise with cropping (wheat, canola, alfalfa) and sheep grazed on improved pasture. The property is not irrigated and is dependent on an average annual rainfall of 520 mm. Soil type is a combination of sandy and red clay loams. The paddock contracted under CAMBI is 80 ha, historically managed under a wheat-canola rotation for over a decade. Typically canola and wheat are sown in April and May and harvested in November and December respectively. The GHG emissions from wheat and canola in a typical cropping cycle are presented in Table 1. Typically wheat and canola yields are 3.5 t ha^{-1} and 1.75 t ha^{-1}. The stubbles for both wheat and canola are grazed and not incorporated into the soil prior to the next crop being sown.

3.2. Current GHG emissions under CAMBI contract

In summary, land management at CAMBI case paddock was converted from a wheat-canola cropping to sheep grazing on improved pasture. The improved pasture is sown once every 20-30 years with a mixture of grasses in combination with legumes. Typically, grasses included *phalaris, fescue, cocksfoot* and *prairie grass sp.* respectively, while the legume is *sub-clover sp.* Lime application of 1 t ha^{-1} was undertaken at the time of sowing, with a re-application frequency once every ten years. The stocking rate on the CAMBI paddocks was 3.8 ewes and 4.98 lambs per ha typically grazed for three months of the year. Total CO_2-e emissions for the above number of animals allocated over the time of year spent grazing on the CAMBI paddocks is estimated using GrassGro model to be 0.54 t ha^{-1} (Table 1).

Table 1. Net effect of CAMBI intervention at the paddock scale (project boundary)

GHG emissions before CAMBI - cropping			GHG emissions under CAMBI	Soil C sequestration
	GHG emissions			
Activity	**Wheat**	**Canola**	**Grazing**	**From cropping to grazing**
	t CO_2-e ha^{-1} yr^{-1}	t CO_2-e ha^{-1} yr^{-1}	t CO_2-e ha^{-1} yr^{-1}	t CO_2-e ha^{-1} yr^{-1}
Production and transport of fertilizers	0.25	0.4	0.10	
Production and use of diesel on farm	0.15	0.16	-	
Production and transport of pesticides	0.023	0.023	-	
Production of machinery	0.009	0.005	-	
Production of seed	0.008	0.002	-	
Soil nitrous oxide emissions from fertilizer application	0.140	0.116	-	
Nitrous oxide emissions from crop residues	0.007	0.003	-	
GHG emissions from livestock	-	-	0.44	
	0.58	0.70	0.54	1.27

3.3. Net environmental benefits at CAMBI paddocks

The predicted net changes to soil C sequestration under land management changes from cropping to improved pasture is estimated to be 1.27 t CO_2-e ha^{-1} yr^{-1} based on the soil C level monitored in the paddock and the equilibrium rate for the pasture system. The results suggest that soil C sequestration from changed land management under CAMBI paddocks did offset the emissions from project implementation (net sink of 0.73 t CO_2-e ha^{-1} yr^{-1}). In addition, changed land management from cropping to grazing under CAMBI further avoided 0.62 t CO_2-e ha^{-1} yr^{-1} (average emissions considering crop rotation of two wheat crops followed by a canola) which would have otherwise occurred under wheat-canola rotation. Thus, soil C sequestration from conversion of cropping to grazing was a net sink of GHG emissions considering the project implementation (grazing) and the avoided practices (cropping). This implied that the land management changes under CAMBI resulted in overall net benefits at the paddock scale.

4. Discussion

4.1. CAMBI - net environmental outcomes at paddock scale

The individual results for GHG emissions under business-as-usual scenario (wheat-canola cropping) are comparable with the published literature. For example previous work on carbon footprints undertaken in the same region of NSW reported between 0.56 to 0.70 t CO_2-e ha^{-1} (Brock et al. 2012) for wheat cropping as compared to 0.58 t CO_2-e ha^{-1} estimated in this research. Similarly for canola carbon footprints estimated in this study (0.70 kg CO_2-e ha^{-1}) are comparable with previous reported studies of 0.61 to 0.98 t CO_2-e ha^{-1} (Gan et al. 2012). Sheep grazing sector usually correspond to a higher above ground carbon footprints compared to white meats (pigs, poultry) and even with beef (Ledgard et al. 2011). The carbon footprint for sheep is dependent upon the management such as stocking rate, soil type, grass or grain-fed, climate characteristics and has been reported to vary widely ranging from 0.4 to 3 t CO_2-e ha^{-1} yr^{-1}(Edward-Jones et al. 2009). With the current stocking rate and the amount of time spent in the CAMBI paddocks used in this study suggested that carbon footprint for sheep grazing was lower than wheat-canola cropping on an area basis (Table 1). It is anticipated that similar number of stock would be grazed for an entire year in CAMBI paddocks in the future which will affect the GHG emissions; however the reason for short period of grazing (3 months) as was the case in this research was due to the establishment phase of CAMBI paddocks which were sown ten months earlier. On the other hand transitioning land management from cropping to grazing resulted in higher soil C sequestration than business-as-usual. This is consistent with the generally acknowledged understanding that soil C sequestration increased with management in the order: continuous cropping < crop-pasture rotation < pasture grazed by sheep and cattle (Chan et al. 2011). The result that grazing had net environmental gains at the CAMBI paddock scale is thus consistent with the above insights.

Based on the empirical work undertaken in this research, CAMBI intervention resulted in an overall net sink of GHG emissions at the paddock scale as compared to business-as-usual scenario. The system boundary for assessment used in this research was the paddock to coincide with the CAMBI project's system boundary. However, the paddock is not a stand-alone area and there is continuous exchange of information and resources between different areas of the farm. For example sheep grazed on the CAMBI paddocks for three months of the year; however the rest of the time they were dependent upon other areas of the farm. Hence it is important to understand the dynamics of GHG emissions outside CAMBI paddocks to identify whether CAMBI intervention has net environmental benefits at the farm scale. This means identifying 'leakage' in terms of GHG emissions from changed sheep numbers at the farm scale as compared to business-as-usual. Similarly information on land management changes to other areas of the farm from CAMBI intervention also needs to be identified.

4.2. Application of life cycle approach for assessing net environmental impacts of PES schemes

Although it is not unusual for empirical research to not develop hand in hand with the theory, policy design and implementation, the current state to measure environmental effectiveness of PES schemes is a cause of concern (Pattnayak 2010). For example the Australian Government's Carbon Farming Initiative in principle requires that the project participants discuss the issue of leakage. This implies that the project must not cause material increases in emissions outside the project's boundary, which nullify or replace the abatement that would otherwise result from the project. In theory this would involve estimation of a leakage deduction in the calculation of the net abatement or sequestration quantity (Australian Government 2010). In practice however, there is a need to include the criteria of LCA in the operational assessment of projects eligible under the CFI if the net benefits from such schemes are to be assessed. There are several potential advantages of life cycle approach implemented through LCA can offer in operationalizing environmental assessment of PES schemes. Firstly, LCA can handle environmental trade-offs across system boundary; this is especially relevant to agriculture where specific policy measures which are directed towards a single goal can lead to trade-offs elsewhere. For example the aim of CAMBI project is to test the implementation of MBI by paying farmers to adopt land management practices which enhance soil C sequestration. An application of life cycle thinking at the CAMBI paddock scale suggested that although for every ton of soil C sequestered there are 43% emissions from project implementation, there was a net benefit from CAMBI intervention. Secondly, LCA can assist to identify trade-offs with other environmental indicators such as water use and land use footprint; this enables overall environmental assessment of PES schemes. In this way, LCA can be a useful tool to identify the consequences of a decision such as PES intervention at the farm scale and beyond by considering off-site environmental impacts. Thirdly, life cycle approach can be potentially useful in discussing the issue of 'permanence' usually associated with sequestration projects. For example, the CAMBI participants have to comply with the project activities for a period of five years only. Potential land management changes beyond the temporal scope of the project using a life cycle approach can help to further identify net consequences of PES intervention in the longer term.

5. Conclusion

PES is an important and increasingly considered policy tool to encourage conservation from agriculture. However, continued poor evaluation in terms of additionality and leakage suggest paucity in the evidence of PES program's net environmental effectiveness. Life Cycle thinking applied through Life Cycle Assessment can offer advantages by considering net environmental gains from changed land management practices associated with PES schemes. The application of LCA suggests that GHG emissions from project implementation were not sufficient to undermine environmental benefits from CAMBI at the paddock scale. The CAMBI project resulted in being a net sink of GHG emissions as compared to business-as-usual scenario at the contracted paddock scale. However, the effect of CAMBI intervention on net environmental benefits at the farm scale and beyond needs to be considered in future studies under LCA framework. This would include the identification of tradeoffs with other ecosystem benefits from PES intervention such as reduction in food production or increased use of water and land resources. Thus future studies should reflect as closely as possible the consequences of changes to ecosystem services on other areas of the farm and elsewhere resulting from PES intervention. This implies using LCA to identify whether provision of ecosystem benefit at the farm scale is offset by a reduction in ecosystem benefit: 1) from project implementation; 2) in another area of the farm and beyond; 3) upstream in the farming input supply chain (from potential intensification); or 4) from trade-offs with other environmental impact categories.

ABSTRACT

The FLONUDEP project carried out an environmental LCA « from cradle to grave » of processed tomatoes made in France and Turkey. We compared the environmental impact of tomato sauce made in France with French tomato paste, with that made with Turkish tomato paste. Data have been collected through surveys among a sample of farms (France=4; Turkey=4), processing plants (France= 2; Turkey=4), logistic organization (France=2), 1 supermarket and consumers (n=800), Findings show that French tomato sauce is slightly less impacting than the Turkish one for GHG emissions and human toxicity, whereas results are similar for eutrophication. Critical points are mainly packaging, energy used and steam production at plant level, fertilization and phytosanitary treatments at agricultural level, and finally, consumer behavior (shopping by car) and packaging recycling.

Keywords: Environmental impact, LCA, Tomato sauce, France, Turkey

1. Introduction

Studies on the environmental impact of agricultural products are now frequent; those on processed industrial products are rare. However, these are very useful as a European regulation regarding the display of the environmental impact of food products is currently under course. Industrials and supermarket chains (Casino, Auchan, and Leclerc) have already anticipated the regulation and present now a display of GHG emissions or water consumption related to the product's manufacturing. Environmental LCAs are fragmentary and often concern only one of the sectors of the food chain. However, several studies have been carried out on processed tomato products, with different system boundaries. Andersson's (Andersson et al., 1998) measured the environmental impacts associated with ketchup's life cycle, from "cradle to grave" and showed that the "hot spots" in the whole system were represented by packaging and food processing. Other two very recent studies (Del Borghi et al., 2014; Manfredi and Vignali, 2014) carried out an LCA on processed tomato from "cradle to the factory gate" (including packaging disposal) and from "cradle to the retailer" respectively , and highlighted the importance of packaging. Findings of the first study show that the impact of the agricultural stage is also considerable, whereas in the second, processing and transport to the retail center are also in cause.

The FLONUDEP project carried out an environmental LCA on the entire food chain, "from cradle to grave", for processed tomatoes in France and Turkey. The latter exports very few industrial products to France but has a huge potential. Turkey is in fact the 4th processed tomatoes producer in the world and holds 6% of the global market.

The purpose of the study is to conduct an environmental LCA of two processed tomato's value chains with the aim of identifying the environmental "hot spots" for each of them. The selected products are concentrated tomato paste and tomato sauce made in France and concentrated tomato paste made in Turkey and exported to France to be used in making sauce.

2. Methods

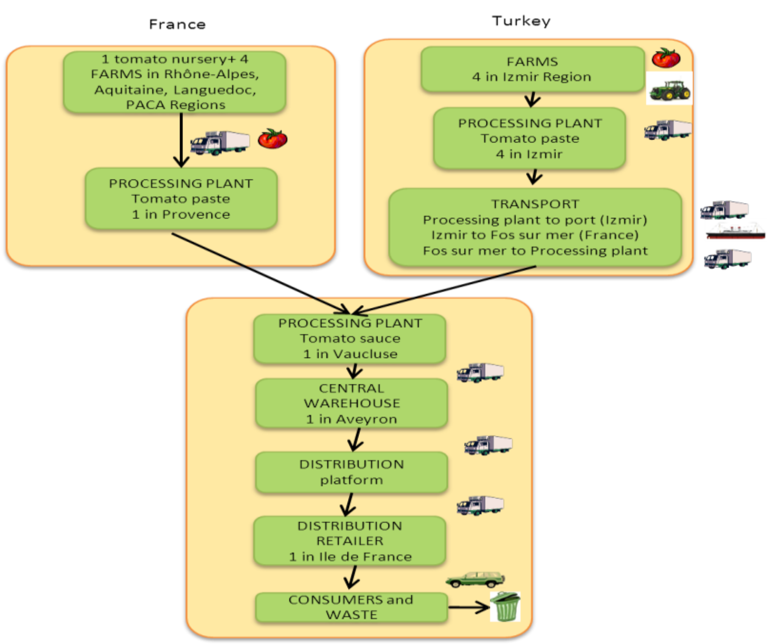
2.1. System boundaries

An LCA approach, from "cradle to grave" has been applied to both chains, that of French and that of Turkish tomato paste exported to France. For France, the system boundaries include: two tomato nurseries, four farms, a first (tomato paste) and a second (tomato sauce) processing plant, the warehouse, the distribution platform, the supermarket, the final waste, as well as transports between these. In Turkey, the study considered four farms, four first processing plants, as well as transport from the field to the plant and from the plant to France. Then the second processing plant in France, the warehouse, the distribution platform, the supermarket and final waste, as well as all transports between these. At agricultural level, allocation methods have not been necessary, as data was collected exclusively for tomatoes. Instead, at plant level, a mass allocation was applied in France and an economic one in Turkey; finally, at logistic and consumer level a mass allocation was applied. Logistics includes storage in the warehouse, the distribution platform, and the supermarket, as well as all the materials used for transport (further packaging), and type, consumption and fill rate of trucks used for transportation. The end of life of intermediate packaging (such as plastic bins and metal drums used to carry tomato paste to the second processing plant) and that of organic waste of fresh tomatoes, have not been taken into account, as the first are often recycled and waste from tomatoes are usually fed to animals. Finally, according to the consumer survey that was carried out during the study, consumers drive to supermarkets and recycle the tin can containing tomato sauce.

Comparison between the two systems taken into consideration in this study is possible, as much of the life cycle is in common (from the second processing plant onwards) (Figure 1). Furthermore, at plant level, whether in France or Turkey, the same flows necessary for tomato processing (energy, water and packaging-excluding its end of life-and storage) were considered in the inventory analysis. However, at agricultural level some differences exist: in France, the tomato nursery and the transport from the nursery to the farm have been studied, whereas this has not been possible for Turkey, as some producers grow the plants themselves.

Three impact categories were selected for the environmental measurements: GHG emissions, eutrophication and human toxicity. The first two are in fact among the criteria taken in consideration by the ADEME (French Environment and Energy Management Agency) regarding the regulation on the display of the environmental impact of consumer products, whereas human toxicity was chosen for its relevance. The environmental LCA was carried out using the SIMAPRO software and the CML 2 baseline V2.05 world method and Ecoinvent database.

Figure 1. System boundaries in France and Turkey



2.2. Functional unit

At agricultural level, in France and in Turkey, the Functional Unit (FU) is 1 Kg of tomatoes. At industrial level, the FU is 1 packed product at the plant's gate (1 metal drum or 1 plastic pouch for concentrated tomato paste, 1 can for sauce); for logistics and consumption the FU is 1 Kg of packed processed tomatoes. In spite of these FU differences between agricultural and post-agricultural levels, the system has been studied as a whole by converting all results in 1 Kg of packed processed tomatoes. The functional unit is therefore 1 kg of packed processed tomatoes using different reference flows for the different stages. We considered two cases: tomato sauce made with French tomato paste and the other with Turkish tomato paste exported to France.

2.3. Quality of data

Most of the data are issued from surveys conducted or from direct observations. To complete missing information, a literature revue and interviews with experts were conducted. In order to be representative, the 4 farms surveyed in Turkey have been chosen in the Egee region which produces 24% of Turkish tomatoes. We do not have the exact number of farms in this area but the choice is justified by the fact that the chosen farms supply the industrial plants under study, which buy 31% of Turkish industrial tomatoes. In France, industrial tomato production systems are very homogeneous, therefore the 4 farms chosen are considered as representative. The first processing plant buys 38.5% of the total industrial tomato production (SONITO, 2009) and the second processing plant is the first French firm of ready-made meals. The logistic taken in consideration is that of the two firms surveyed. Finally, at consumer level, the LCA is carried out with data from a survey among a sample of 800 people (men and women, 20 to 65 years old). It would have been desirable to carry out a sensitivity analysis; this had in fact been initially planned, but finally had to be postponed.

3. Results

The comparison between the two supply chains shows that environmental impacts associated with a can of 1 kg of tomato sauce as purchased by the consumer and then recycled is slightly lower for the strictly French chain, with regards to GHG emissions and human toxicity. The Turkish supply chain and the French one are identical for eutrophication (tables 1 and 2).

Table 1. Contribution analysis of the environmental impacts of 1 kg of processed tomatoes (sauce) produced in France from French tomato paste, by impact category

	Farm	Transport	Plant Tomato paste	Logistics	Plant Tomato sauce	Logistics to Supermarket	Supermar-ket	Consumers	TOTAL
GHG kg CO2 eq	0.0511	0.0063	0.0668	0.0032	2.2472	0.1219	0.0221	0.1800	**2.6987**
Human toxicity kg 1,4-DB eq	0.0307	0.0016	0.9727	0.0029	0.8478	0.0217	0.0358	0.4500	**2.3633**
Eutrophication kg P eq	0.0004	0.00001	0.0001	0.000001	0.0028	0.0001	0.0000	0.0002	**0.0037**

Table 2. Contribution analysis of the environmental impacts of 1kg of processed tomatoes (sauce) produced in France from Turkish tomato paste, by impact category

	Farm	Transport	Plant Tomato paste	Logistics	Plant Tomato sauce	Logistics to Supermarket	Supermar-ket	Consumers	TOTAL
GHG kg CO2 eq	0.0823	0.0259	0.3756	0.0086	2.2472	0.1219	0.0221	0.1800	**3.0635**
Human toxicity kg 1,4-DB eq	0.0247	0.0283	1.2374	0.0031	0.8478	0.0217	0.0358	0.4500	**2.6488**
Eutrophication kg P eq	0.0005	0.00003	0.0001	0.000011	0.0028	0.0001	0.0000	0.0002	**0.0037**

Regardless of the supply chain, the highly critical points are clearly the companies, particularly the 2nd stage processing plants. Indeed, it is at this stage that most of the emissions (¾) are generated, especially for GHG and eutrophication with the tin can and the energy used to produce steam (mostly natural gas) being the main causes. Regarding human toxicity risks, the 1st stage processing factory is also a critical point because of the metal drums used. Interestingly, the agricultural stage, whether in France or Turkey, has very limited responsibility with regards to all impact categories, with the exception of eutrophication (around 12% of the impacts).

At agricultural level, the impacts are quite similar between the two countries: GHG emissions are 1.6 times higher in Turkey, human toxicity is slightly higher in France, whereas eutrophication levels are practically the same. On the contrary, Turkey features much higher environmental impacts if we consider transport from the field to the first processing plant (an average of 70 km by tractor and 110 km by truck) for all 3 impact categories, as well as higher impacts for GHG emissions generated by the first processing plant alone. Regarding transport, findings highlight that rather than distance, it is the mean of transport that influences environmental impacts: for example, pollution (per kg of tomato sauce) due to transport between the field and the first processing plant (by tractor and truck) in Turkey is much higher (for example, 3 times for GHG emissions) than that between the Turkish processing plant and France (an average of 120 km by truck and 1225 km by ship). In France the shorter distance between the production sites and the processing plants (an average of 76 km) coupled with a rationalization of transportation of fresh tomatoes, makes GHG emissions 4 times lower than in Turkey.

Both in France and in Turkey, among technical operations, fertilization has the highest impact, compared with soil preparation, planting, protection, harvest and post-harvest work. This is true for 2 out of three impacts categories: global warming (F=62.7%, T=61%) and eutrophication (F=95%, T=93%). In France, an average of 106 kg of nitrogen, 134 kg of phosphorus and 223 kg of potassium are used per hectare, with great differences among the four farms. In Turkey, these are respectively, 133 kg, 90 kg and 184 kg. Yields are much higher in France than in Turkey, being 102.5 tons per hectare for the first and 72.5 tons per hectare for the latter. The second activity that impacts the most is soil preparation and harvest (36% of human toxicity and 30% of GHG in France). However, regarding human toxicity, phytosanitary treatments also play an important role in France.

In France, differences can be observed between the agricultural practices in the South-East and in the South-West. Due to different soil and climate conditions, use of fertilizers is higher in the South-East, whereas the opposite is true for pesticides. Therefore, eutrophication levels are 1.4 times higher for tomato production in the South-East. However, GHG emissions and human toxicity levels are similar.

The consumer stage also has a significant impact on the whole supply chain: 6% of GHG emissions, 19% of human toxicity and 5% of eutrophication. This is mainly due to the can recycling. Shopping also holds a part of the responsibility, as the majority of consumers drive to supermarkets. This generates a significant amount of impacts, especially with regards to global warming.

The main objective of an LCA is to compare the environmental impact of a product with that of another, in order to decide between the two. Therefore, we decided to compare the environmental impacts of two methods of tomato sauce preparation: the first one from fresh tomatoes and the second one from processed tomatoes. The consumer effectively choses between products that have the same function. At home it takes 2 Kg of fresh tomatoes, 30 minutes of cooking on an electric stove to obtain 1 Kg of sauce (according to our survey, the electric stove is the most common cooking method). The results show that at consumer level, both types of sauce have a similar impact on global warming. Differently, eutrophication is 1.5 times higher for home-made sauce while human toxicity is 10 times higher for sauce made with processed tomatoes. In the first case, the use of water is in cause, whereas for the second one it is rather the impact associated with the can.

4. Discussion

Very few studies take in account the whole system, including production, processing and distribution. The FLONUDEP project can be considered as the first of its kind in France. Results regarding Turkey are similar to others carried out in the same country (Karakaya and Özilgen, 2011).

Comparison with recent literature shows a certain consistency with results from the FLONUDEP project. In his study (Brodt et al., 2013), Brodt highlights the importance of transport rather than distance by making a comparison between a local supply chain of processed tomatoes and a national one. In this study, the choice of environmental impacts is also important because it can significantly change the results. Furthermore, an Italian study (Marletto and Silling, 2010) indicates that the impact of transport by car between the supermarket and home is a critical point which generates a significant amount of impacts. Another recent study in Turkey (Karakaya and Özilgen, 2011) highlights the responsibility of transport by tractor between fields and processing plants in generating impacts, as well as very different impacts depending on the energy source used in the plants. However, the supply chain stages which appear as the most impacting ones are not the same in this latter study as in the FLONUDEP study. This would require further research.

At farm level, if we refer to other LCAs for the same product (fresh field tomatoes) and with the same system boundaries, general results are similar: if eutrophication is higher in the production systems in Turkey (Karakaya and Özilgen, 2011), GHG emissions and acidification are higher in Spain (Martinez-Blanco et al., 2011). The French farms hold an intermediate position for all impact categories.

Table 3. Comparison of environmental impacts at the agricultural stage for industrial tomatoes (for 1kg of fresh tomato)

Category of impact	Unit	France	Turkey	Spain
GHG	kg CO2 eq	0.03424099	0.07951771	0.150
Acidification	kg SO2 eq	0.00058862	0.00049713	0.000888
Eutrophication	kg PO4 eq	0.00030962	0.00037501	0.000234

Source: Our study Flonudep, 2013; Karakaya and Özilgen, 2011; Martinez-Blanco et al., 2011

5. Conclusion

The advantage of such a study taking into consideration all the components of a system is to put into perspective the importance associated with some factors. Often agriculture is regarded as the most impacting sector. However results show that the main critical points are at plant level and more specifically packaging. It is therefore necessary to rethink packaging solutions and take into account their environmental impact associated with manufacturing and recycling. At plant level, two critical points clearly appear: the kind of energy used (there is a big difference between France which essentially uses nuclear energy and Turkey which uses fuel oil and gas) and the production of steam (with gas). A debate on production processes and “clean” energy is needed. . Furthermore, we should rationalize logistics according to environmental criteria rather than economic criteria. This would imply, for example, using local grouping platforms, closer to the production sites. We should also rethink transport for food products, as findings show that transport by truck in highly polluting. At agricultural level, as well as in all the other case studies taken in consideration, fertilization is the most polluting activity, followed by soil preparation and harvest for GHG. Phytosanitary treatment has also a significant role in terms of human toxicity. If ferti-irrigation is a partial solution, it would be useful to consider organic production or choose more energy efficient and less polluting agricultural equipment. Finally, it would be necessary to promote more “environmentally friendly” purchasing and consumption behavior among consumers. However, isn’t the modern supply and consumption system responsible? This is particularly true regarding consumption of ready-made, processed food, and supermarkets placed far out of the city centre.

The FLONUDEP research has been carried out on a limited sample of farms and processing plants in France and Turkey. Therefore, caution must be taken in interpreting results. However, the project highlights the critical points in the supply chain, and shows that according to environmental criteria, local products are not necessarily “better” than imported ones.

ABSTRACT

Food LCA should include salinization. Salinization is a threat not only to arable land but also to freshwater resources. Nevertheless, salinization impacts have been rarely and partially included in LCA so far. First, a comprehensive overview of salinization mechanisms is presented and highlights its multiple causes, which affect soil and water, and ultimately human health, ecosystems and resources. Second, adopting the ILCD analysis grid, we analyzed the scientific relevance and accuracy of existing published methods addressing salinization in LCA. Although interesting, these seminal approaches are often incomplete with regards to both the salinization pathways they cover and their geographical validity. Third, we analyzed how to consistently integrate salinization within the methodological frameworks for impacts modeling in LCA, and raised questions to address towards a comprehensive integration of salinization.

Keywords: Salinization, Life Cycle Assessment, Agriculture, Soil, Water.

1. Introduction

Salinization is a global and major environmental concern. Although we commonly think this issue is limited to arid and semi-arid regions, it appears that no climatic zone is free from salinization (Rengasamy 2006). Furthermore, both agricultural and non-agricultural areas, both irrigated and non-irrigated lands can be prone to salinization (Wood et al. 2000). The FAO estimates that 34 million hectares of irrigated land are salt-affected worldwide, and an additional 60-80 million hectares are affected by waterlogging and related salinity (FAO 2011). Although reports of secondary salinization, i.e salinization due to human beings, continue to appear in the literature, there is a lack of recent assessment of the level of anthropogenic salinization (Flowers 1999). Salinization is a threat not only to arable land (EEA, 1997) but also to water resources (freshwater lakes and wetlands, rivers and streams), particularly in the arid and semi-arid regions of the world (Williams 1999). Salinity becomes a major issue in global agriculture when it adversely affects crop production (Rengasamy 2010).

As a global and multicriteria environmental assessment tool, Life Cycle Assessment should account for one of the major threats of food production. Research on including salinization in LCA is of high priority (JRC-IES 2011). Evaluating salinization impacts is particularly relevant in food LCA, because agricultural systems are both the main affected targets and causes of salinization. Sustainable irrigated agricultural production is seriously threatened by salinization (Aragüés et al. 2011).
So far, a few methods evaluated salinization impacts in the LCA framework: Amores et al. (2013); Feitz and Lundie (2002); Leske and Buckley (2003; 2004a; 2004b). However, these methods were rarely or never applied and focus on one salinization type or on a specific location. A comprehensive approach to salinization in the LCA framework is lacking.

The goals of this work are (1) to provide a comprehensive and structured overview of secondary salinization mechanisms and cause-effect chains, (2) to review LCIA methods modeling salinization impacts and (3) to identify methodological issues to build a consistent framework for salinization impacts in LCA.

2. Salinization: environmental mechanisms, cause and effect chains

2.1. A definition of salinization(s)

Salinization is the accumulation of salts, not exclusively NaCl as it is frequently assumed, but also many other types of salts such as carbonates, sulphates and other salts (calcium, magnesium and potassium) (Rengasamy 2010). Salinity is described as Total Dissolved Salts (TDS) (Leske and Buckley 2003). Although common ions are classified as non-toxic inorganic constituents, they may cause toxic effects at high concentration. Soil and water salinization are often studied separately: "*Salinization is the process that increases the salinity of inland waters*" (Williams 1999). "*Salinization is an accumulation in the soil of dissolved salts*" (Wood et al. 2000). But soil and water salinization are inter-related, water being the main vector of salts. Salts are conservative and resistant to degradation (Schnoor 2013) but they are mobile: they can either stay in a soil at a given location or they can migrate with water.

Soil salinization includes also sodization and alcalinization, while salt-affected soils include saline soils, saline–sodic soils and sodic soils (Ghassemi et al. 1995). Salinization is an accumulation of salts, and sodisation is an accumulation of sodium on the soil exchange complex causing soil clays dispersion, thus altering soil structure. Saline conditions are usually characterized by measuring the Electrical Conductivity (EC) and the Sodium Adsorption Ration (SAR) in soil extracts (Rengasamy 2010). EC measures the ability of water to conduct electrical current and is correlated with the total dissolved solids in soil water (Corwin and Lesch 2005) and thus salinity. SAR is the ratio of sodium ion on calcium and magnesium ions and is correlated with sodicity. Both salinity and sodicity are associated with more alkaline (basic) soils (Wood et al. 2000). Several salt-affected soil classifications exists (e.g. Rengasamy (2010)), and it is important to note that SAR and EC thresholds values are not the same in different soil classification systems (Rengasamy 2006).

Water quality in relation to salt abundance can be classified in 4 classes: fresh, brackish, saline and eventually brine water. On an operational point of view, farmers usually classify irrigation water according to EC and SAR measurements because it represents an easy way to estimate the salinization and alcalinization hazard of soil associated with its use (Richards 1954).

2.2. Causes of salinization in space and time

This paper does not consider natural salinization and focuses on anthropogenic salinization because LCA addresses impacts of human interventions. Salinization results from various causes which are often inter-related (Williams 2001). Salinization involves physico-chemical mechanisms at local scale and hydrological mechanisms at regional (catchment) scales. We distinguish for analysis between salinization associated with land use change and salinization associated with irrigation.

2.2.1. Salinization associated with land use change

Land Use Change (LUC) modifies hydrological processes and then water cycle at the catchment level. In particular, clearance of deep-rooted perennial native vegetation with high transpiration rates, and replacement with shallow-rooted crops with lower transpiration rates, will increase the water infiltration rate and mobilize salts stored in soil. Thus, the underlying groundwater tables can rise and reach the near soil surface in lowland, leading to temporary surface waterlogging and then deposition of salts through capillary action after evaporation (Williams 1999). In addition, the infiltrated salts increase the salinity of the aquifer. Many examples have been documented in Australia (Scanlon et al. 2007; Williams, 1999). Classical factors, as topography, acts on soil and water salinization at catchment scale. Specificities associated to LUC are directly linked to modifications of the water balance at the landscape scale: a modification of amounts of precipitations, a modification of groundwater table level, a modification of evapotranspiration rates, a modification of soil geochemical and hydrodynamic profiles, and salt stock variation in soil.

2.2.2. Salinization associated with irrigation

Salinization associated with deposition of ions - Irrigation is "*the salt concentration and mobilization machine*" (Smedema and Shiati 2002). The development of irrigation influences the local geohydrological regime, mobilizes salts stored in the underlying substrate, and contributes to the concentration of salts in land and water resources (Smedema and Shiati 2002). Irrigation water always contains some salts that may eventually accumulate in the soil, unless the irrigation management allows the salt leaching (Flowers 1999). However, the leached salts from the root zone may induce salinization of water bodies, such as the underlying groundwater, if drainage is not carefully managed (Mateo-sagasta and Burke 2010). Salts have a higher tendency to accumulate in semi-arid and arid areas because of the conjunction of low rainfall and high evapotranspiration rates (Marlet and Job 2006). The combined effect of the withdrawal of fresh irrigation water from a water body and the return of saline drainage water to this water body leads to salinity increase (Smedema and Shiati 2002). Furthermore, changing climatic conditions are worsening salinization with the use of low quality water to compensate the increased scarcity of freshwater (Duan and Fedler 2013). Irrigation's controls on salinization are those associated to local dependencies: salinization associated with deposition of ions through irrigation. Salts are also derived from fertilizers (Scanlon et al. 2007). Embedded key parameters are salt content in irrigation water, fertilizer use intensity, precipitation levels and irrigation doses, evapotranspiration rates, soil hydrodynamic profile, and salts reservoirs in the soil.

Salinization associated with shallow groundwater table or poor drainage - When an area is irrigated, the hydrologic balance is modified, and is often causing groundwater table rising. This rise may be noticeable after only a few years (Smedema 1993) cited by (Marlet and Job 2006). Areas having shallow water tables usually have soil salinity issues (Corwin and Lesch 2005). In this case, good drainage is required to avoid waterlogging and salts deposition through capillary action. More generally, poor irrigation management and inadequate drainage often lead to salinization and waterlogging (Wood et al. 2000). When the groundwater rising is saline, it may in turn induce salinization of some fresh waters (Williams 2001). Nested scales are involved in this salinization context: if spatial extend and structure of groundwater tables are regional, associated salinization processes are expected to act at a local scale; the key parameters are water table depth, drainage rates, salts content in irrigation water, precipitation levels, evapotranspiration rates, irrigation doses, and salts reservoirs in the soil.

Salinization associated with overuse of a water body: saline intrusion - In many coastal regions, excessive withdrawal of groundwater leads to marine intrusion: the decreasing aquifer table level and the proximity of seawater induces sea-water inflow in the aquifer. Some aquifers are already permanently salinized (FAO 2011; Flowers 1999; Scanlon et al. 2007). Deltas are also prone to marine intrusion when the freshwater flow of the river is reduced because of excessive water withdrawal upstream or the construction of impoundments (FAO 2011; Williams 2001). Sea-level rise induced by climate change is an aggravating factor of marine intrusion (FAO 2011). In non-coastal areas, saline intrusion may result from saline water transfer from a saline aquifer to an overused aquifer. Salinization associated with saline intrusion involves mechanisms at catchment scale; the key parameters are volume of freshwater withdrawal, distance to the coast, water body (river or aquifer) exploitation rate and presence of saline aquifer.

2.2.3. Salinization causes are often inter-related

Although we can establish a typology of salinization contexts, in many cases the situation is complex because salinization results from several causes. Many freshwater lakes, wetlands and rivers become saline because of the replacement of natural vegetation by agricultural crops upstream, together with the discharge of saline agricultural wastewater (Williams 2001). Groundwater salinization can be due to both sea-water intrusion and the agricultural return flows (Bouchaou et al. 2008). In addition, water and soil salinization are intimately related. The degradation of freshwater sources (surface or groundwater) has concomitant effects on the systems using these sources, and soil salinity affects in return water resources (D'Odorico et al. 2013).

2.3. Water and soil salinization damages to ecosystems, human health and resources

Salt-affected soils and waters have many effects and ultimately damage the areas of protection (AoP) as defined in LCA: ecosystems (or natural environment), human health and natural resources. Figure 1 depicts the salinization cause and effect chains, emphasizing the inter-relation between the multiple causes.

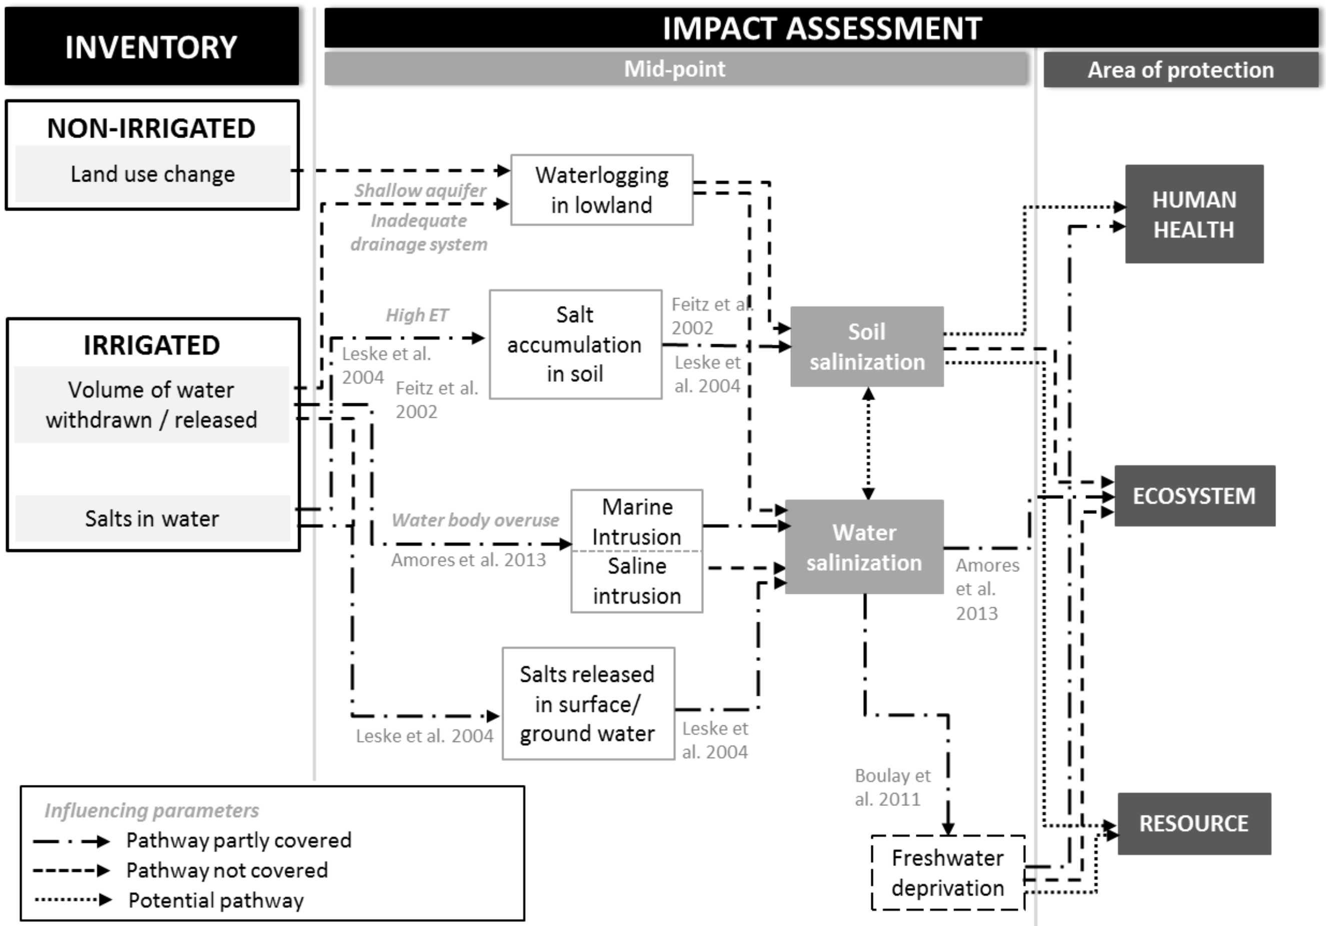

Figure 1. Human-driven salinization cause and effect chains and positioning of approaches proposed in the literature

Soil salinization not only reduces vegetation or crop growth, but also degrades land more or less permanently (D'Odorico et al. 2013). Salt-affected soils have a lower productivity through three potential effects on plants: i) reduction of plant water uptake by lowering the osmotic potential, ii) toxic effect by different ions depending on the pH, and iii) plants nutrients uptake imbalance (Flowers and Flowers 2005). Sodic soils also have indirect effects due to soil structure degradation, permeability reduction and possible waterlogging (D'Odorico et al. 2013; Rengasamy 2010; Suarez et al. 2006). Thus, by reducing crop yield, salinization of crop land could result in malnutrition for poor populations who rely on this production to feed themselves. Soil salinization is also considered as a driver of desertification because it affects terrestrial ecosystems and is closely related to land degradation processes such as soil erosion (D'Odorico et al. 2013). Land degradation might be considered as a damage to soil resource. It should be noticed that ecosystems may not lose diversity per se but simply replace the halosensitive biota with a halotolerant one (Williams 1999). Measures to reduce soil salinity and sodicity exist, but salinization can be irreversible: in arid regions where there is not enough freshwater available to leach the accumulated salts (Rozema and Flowers 2008), or in lowland areas of endorheic basins with shallow and saline groundwater (D'Odorico et al. 2013).

Salinization of a water-body not only affects the aquatic and riparian ecosystem, but also reduces the water availability for further use. An increase of water salinity causes change in species composition of algae, zooplankton, and benthic communities and leads to the disappearance of macrophytes and riparian trees (Schnoor 2013; Williams 1999). In addition, saline freshwater lakes, wetlands, rivers or aquifers are unfit to serve as supplies for domestic, agricultural and other uses (FAO 2011; Williams 1999), thus resulting in water deprivation for humans and ecosystems. This water resource quality alteration may be irreversible, for example for a permanently saline aquifer, and thus affects the water resource for future generations.

3. Review of salinization impact assessment methods in LCA

3.1. Overview of the methods

Three methods have been developed assessing salinization impacts in the LCA framework so far (Table 1). These approaches are either mid-point oriented (Feitz and Lundie 2002), end-point oriented (Amores et al. 2013), or near-endpoint oriented (Leske and Buckley 2003; 2004a; 2004b).

Mid-point oriented approaches - The soil salinization potential developed by Feitz and Lundie (2002) assesses the propensity of irrigation water to damage soil structure and the accumulation of sodium in the soil. The volume of irrigation water and sodium concentration are multiplied by a soil sodisation hazard characterization factor (CF). The soil sodisation hazard is assessed through the ratio between the EC threshold representing the limit of soil structure integrity for a given SAR, and the EC of the irrigation water. The SAR calculation is based on the irrigation water composition.

Table 1. Salinization impacts assessment methods overview

Publication	**Feitz and Lundie 2002**	**Leske and Buckley 2003;2004a; 2004b**	**Amores et al. 2013**
Inventory requirement	Irrigation water volume (L), [Na] (mg/L).	kg TDS released	Evapotranspiration of the crop: ET_{crop} (m^3)
Characterization factor (CF)	$CF=EC_{threshold}/EC_{iw}$ With: $EC_{threshold}=0.121xSAR+0.033$ linear equation representing the clay flocculation - dispersion threshold. SAR calculation requires: [Ca], [Mg], [SO4], [$CaCO_3$], pH, EC of irrigation water. If CF<1, no soil degradation hazard from sodisation.	Total salinity potential (TSP) for salt release in a given compartment: TSP= Σ potential effects on environmental target. With: potential effect $=\Sigma_i^N PEC_i-PEC_i^0$ / PNEC.M PEC_i=predicted concentration in the compartment during day i after an emission of total mass M; PEC_i^0=predicted concentration in the compartment during day i without an emission; PNEC=predicted no-effect concentration; N=number of days in the simulation	Change in PAF of species due to a change in groundwater consumption: - Fate Factor $=\Delta FGW/\Delta\ ET_{crop}$ x $\Delta C_N.V_N/\Delta FGW$ With: FGW=fresh groundwater inflow to Lagoon, C=salinity and V=volume of the lagoon, ET_{crop}=crop ET, Δ symbolizes the change between years. - Effect Factor $=\Delta PAF_{sal}/\Delta C_N.V_N$ $=0.5/HC50_{sal}$ With: $HC50_{sal}$=concentration at which ≥50% of the species are exposed to concentrations above their EC50
Indicator	$\sum_i CFi.[Na]i.Vi$ For irrigation water i. **Unit:** kg $Na+_{eq}$	TDS released x TSP **Unit:** kg TDS $_{eq}$	ET_{crop}. CF **Unit:** PAF.m^3.year, converted into species.year considering a 7.89 x 10^{-10} species.m^{-3} freshwater species density

Near-endpoint oriented approaches - Leske and Buckley (2003; 2004a; 2004b) developed a salinity impact category for South African LCA. They provide salinity potential CFs for salts release in atmosphere, surface water, natural surfaces, and agricultural surfaces compartments, and account for potential effects on aquatic ecotoxicity, materials, natural wildlife, livestock, aesthetic, natural vegetation and crop. Inspired by a risk assessment approach, salts fate factors are calculated with an atmospheric and hydrosalinity catchment model, thus assessing the predicted salt concentration in the different compartments. Effect factors are calculated using the predicted no-effect concentration for each environmental target.

End-point oriented approaches - Amores and colleagues (2013) evaluated the impacts on biodiversity associated with a salinity increase in a Spanish coastal wetland caused by the use of groundwater for agriculture. The water consumed by the crop (withdrawn from the aquifer) is multiplied by fate and effect factors. The fate factor represents the freshwater that lacks in the wetland system due to withdrawal, leading to increased concentration of salt due to increased sea water infiltration into the wetland. It is calculated from seasonal water and salts balances for the wetland Albufera de Adra. The effect factor is obtained from the fitted curve of the potentially affected fraction of native wetland species due to salinity. It is focused on plants, fishes, algae, and a crustacean.

Apart from the applicability test done by the authors themselves (Amores et al. 2013; Feitz and Lundie 2002), literature provides only one case study implementing Feitz and Lundies's method. Muñoz and colleagues (2010) calculated soil salinization potential as one indicator for soil quality impacts (besides soil organic carbon deficit), to compare the impacts of systems using treated wastewater, groundwater, or desalinated water for irrigation.

3.2. Critical analysis of the methods

We analyzed the methods against criteria of the ILCD Handbook procedure for methods analysis (JRC-IES 2011): completeness of scope, environmental relevance, scientific robustness and certainty, documentation, transparency and reproducibility, applicability and potential stakeholder acceptance.

Completeness of scope - Feitz and Lundie (2002) and Amores et al. (2013), focus on one single salinization pathway: soil sodisation and salinization from poor irrigation practices and seawater intrusion in a groundwater-fed wetland, respectively. Leske and Buckley (2003; 2004a; 2004b) cover several pathways of water and soil salinization induced by salts release. The methods are providing good methodological approaches to salinization impact modeling but with a limited geographical validity. Moreover, the methods cover only a part of salinization mechanisms within the pathway they are modeling. Figure 1 positions the contributions of these approaches on the global salinization cause and effects chains.

Feitz and Lundie (2002) do not account for waterlogging. Leske and Buckley (2003, 2004a, 2004b) do not consider salinization induced by a LUC or a saline intrusion, and Amores et al. (2013) do not consider groundwater salinization. All methods have site-specific CFs, emphasizing that salinization impacts are highly site-dependent; especially regarding the hydrology, the climate and irrigation water quality. However, their geographical extend validity is limited. The soil salinization impact of Feitz and Lundie (2002) depends on the validity domain of the electrolyte threshold curve which «*may not be appropriate for some soils*», and the estimation of the Sodium Adsorption Ratio of the soil drainage water is assumed for an Australian red-brown earth. Leske and Buckley (2003; 2004a; 2004b) fate factor is calculated with a South African catchment atmospheric deposition-hydrosalinity model, and the effect factor is based on the South African Water Quality Guidelines. Amores et al. (2013) fate factor is based on water and salts balance relying on the specific hydrologic functioning of the wetland and local hydro-climatic parameters, and the effect factor is based on specific native species of the Albufera de Adra wetland. It would be time-consuming and data-intensive for one who wants to apply the methods in other contexts.

Environmental relevance - Feitz and Lundie (2002) indicator is based on a relatively ancient approach but very common and generally well accepted. However, the soil type is not accounted for, although soil texture is a key parameter in the sodicity sensitivity. Indeed, sandy soils do not have soil structural problems caused by high SAR, whilst clayey soils are likely to be sodic with soil structural problems (Rengasamy 2010). Besides, the quality of the soil solution is buffered by slow physico-chemical mechanisms occurring over several years (Condom et al. 1999). Leske and Buckley (2003; 2004a; 2004b) fate model predicts environmental concentrations in all the compartments relevant to the calculation of salinity potentials. The land use distribution of the model is simplified through one single urban area, one single rural area and one single rural agricultural area. The calculated characterization factors for salts emissions onto the agricultural surface by far outweigh the CFs for releases into other compartments. This warrants further research to better model agricultural systems. The salts effect factors are based on the Predicted No-Effect Concentrations, a conservative approach compared with the HC50 (50% hazardous concentration), assuming that sensitivity of an ecosystem depends on the most sensitive species. Effect factors are not calculated as a function of the background salt concentration, except for aquatic ecotoxicity. Amores et al. (2013) fate and effect factor calculation are simplifying the salinization mechanisms. The effect factor is linear: calculated as the average gradient at the HC50 but does not account for background concentration. The Species Sensitivity Distribution are not based on EC50s describing the same effects (e.g., survival or growth inhibition). The fate factor is not utilizing any model but is based on simple water and salt balance equations.

Scientific robustness and certainty - These methods were published in peer-reviewed journals. Model uncertainty is not provided by Feitz and Lundie (2002), but is provided through a sensitivity analysis of the fate model by Leske and Buckley (2003, 2004 a&b), and through confidence intervals and CF standard error by Amores et al. (2013).

Documentation, transparency and reproducibility - Model documentation, characterization model and results published are available for the three methods. Reproducible for LCA studies located in areas where CFs are available.

Applicability - CFs are not straightforward to apply for the three methods. CFs have to be calculated by the practitioner because they are either irrigation-water dependent (Feitz and Lundie, 2002), or require re-developing the whole modeling approach because of its narrow geographical validity. The indicator units Na^{+}_{eq} and TDS cannot be compared with other methods as they are salinity-specific units. In contrast, the common end-point unit PAF from Amores et al. (2013) can be compared with other methods.

Potential stakeholder acceptance - The acceptance among LCA practitioners is limited with no or a single application (Leske and Buckley, 2003; Feitz and Lundies, 2002). Amores et al. (2013) method is young and remains to be implemented for validation in other contexts; further developments are required to ascertain if CF with global coverage can be calculated.

4. Perspectives toward a consistent framework for salinization impacts assessment in LCA

The purpose in this section is to analyze how salinization impacts should be modeled within the methodological framework of LCA. Answering this question raises several methodological issues: where to set the boundary between technosphere and ecosphere? What is the status of the AoP resource? A holistic approach is adopted to identify the methodological questions and risks of double counting to be addressed for future developments.

4.1. Methodological framework of LCA

We can distinguish two environmental impact modeling types in LCA: the first in relation to impacts due to the emission of a substance and the second in relation to the consumption of a resource. If tracing a substance in the environment has been historically addressed in LCA through the modeling of his fate and effect on the receiving environment, the modeling of impacts due to biotic resource consumption, especially for water and land resources, has only been studied recently (Finnveden et al. 2009).

Water and land as resources are inventory flows, which may be consumed or altered by the human activity under study. Modeling the damages caused by a resource use is complex because its function depends on the quality required by the user. Regarding water, if impacts from pollutant emissions into water are accounted for in LCA, impacts from water unavailability are not yet fully quantified (Boulay et al. 2011b). Boulay and colleagues (2011a; 2011b) developed a method to fill this gap: a functionality-based water impact assessment considering that water quality degradation can lead to water deprivation if not suitable anymore for specific users. In this method, the water quality is related to a functionality; assessing to which users the water is functional. This method assesses the impacts from water deprivation on the AoP human health. The same approach could be adopted to assess impacts of water deprivation on the AoP ecosystems, but the water categories should be based on ecosystems uses instead of human uses. Regarding the impact of water deprivation on the AoP resource, the framework proposed by the UNEP-SETAC “Water Use in LCA” (WULCA) working group considers that only fossil water use or renewable water overuse can affect the resources, thus water quality alteration is not addressed (Kounina et al. 2013). Yet, a permanently degraded freshwater represents a loss of water resource for future generation. There is no risk of double counting if we clearly define the AoP resource as the protection of a resource (in sufficient quality and quantity) for future generation, while the AoP human health and ecosystems reflect the protection of current people and ecosystems. The fact that the new IMPACT World^{+TM} LCIA methodology is considering an AoP "resource and ecosystems services" raises the question of the status of this AoP.

Although it has sometimes been considered as an impact indicator, land use is an inventory flow that leads to a group of impact categories, directly affecting ecosystems and resources, and indirectly affecting human health (Finnveden et al. 2009; Koellner and Geyer 2013a). The open research question is which midpoint categories should be defined to support an integrated impact assessment accounting for land use impacts alongside those from chemical emissions, water use and climate change (Koellner and Geyer 2013b). The UNEP-SETAC Life Cycle Initiative project LULCIA recommends for each impact pathway the determination of the optimal resolution of land cover types and regionalization, and the development of CFs for all relevant combinations of land use type and location (Koellner et al. 2013a). Several pathways were recently developed, within a structure of the LCIA in accordance with the typology of ecosystem services of the Millennium Ecosystem Assessment (Millennium Ecosystem Assessment 2005). Indeed, the framework distinguishes between two intermediate end-points: biodiversity damage potential and ecosystem services damage potential. Brandão and Milà i Canals (2012) characterized land use impacts on biotic production potential (representing an ecosystem services damage potential) using deficit of Soil Organic Carbon (SOC) as an indicator. They developed CFs for eight land use types at the climate region level. Saad et al. (2013) address land use impact on three ecosystem services: erosion regulation potential, freshwater regulation potential, and water purification potential. They calculated CFs per land use type (seven) specific to each biogeographic region (tested at different regionalization scales), using LANCA® model which assesses the influence of different land use activities on soil ecological functions. Developing such CFs requires the availability of land-use-specific and biogeographically differentiated data on the indicator selected: SOC for Brandão and Milà i Canals (2013) or soil properties, landscape and climatic conditions for Saad et al. (2013).

4.2. Perspectives for integrating salinization in LCA

Regionalization - The fate of salts depends on climate, agricultural practices, soil, and hydrological context, and their effects depend on the sensitivity of the target (species, capacity to desalinate water). Therefore a regionalized approach is paramount. The methods developed by Leske and Buckley and Amores and colleagues are regionalized, but with a very limited coverage. Regionalized impacts in LCA are supported by geographic information systems (e.g. (Boulay et al. 2011b; Núñez et al. 2012; Núñez et al. 2009; Saad et al. 2013).

Midpoint - For water and soil salinization, two pathways modeling can be differentiated: on the one hand salinization induced by a LUC, which inventory flow is a land use transformation, and on the other hand irrigation-driven salinization, which inventory relies on a volume of water withdrawn (for saline intrusion) or released (waterlogging) and salts contents in water (salts released in soil and water bodies) (Cf. Figure 1). While LUC and saline intrusion result from a modified hydrologic (and thus salt) balance at regional or catchment scale, direct salts emissions through irrigation water occur at local scale. The system limit definition, and thus the consistency between LCI and LCIA modeling, is a crucial issue because salinization mechanisms occur at different spatial and temporal scales. In particular, the soil status is critical because it is both an environmental target and a part of the agricultural system. If soil is excluded from the technosphere, a salt emission is the salts content in irrigation water, while if soil is partially included in the system, a salt emission depends on soil conditions and practices. If soil is totally included in the system, no soil salinization would be accounted for and salt emissions would occur in the aquifer or river. Setting the system limit will determine which parameter has to be accounted for in the inventory or to be part of the CF.

We analyze in the following the modeling options for each AoP.

Ecosystems - Salinization affecting ecosystems could be modeled through aquatic ecotoxicity assessment for water salinization. Although salts are not classified as toxic substances, salts have toxic effects at high concentration. Amores et al. 2013 adopted this type of modeling in a specific context. Salts are not yet modeled in the USEtox model (Rosenbaum et al. 2008), but future developments of this tool could include freshwater ecotoxicity CFs for salts. Another future improvement of USEtox model is to develop regional versions because no spatial differentiation of location of the emission was considered so far (Henderson et al. 2011). Water salinization may also damage ecosystems through reduced water availability: a functionality-based approach could be adopted for this pathway. Similarly to water salinization, soil salinization affecting ecosystems could be modeled through terrestrial ecotoxicity assessment. The development of terrestrial ecotoxicology CFs is part of future developments of the USEtox model (Henderson et al. 2011).

Human health - The modeling of water salinization affecting human health could be approached by Boulay and colleagues framework. Total Dissolved Solids, Bicarbonate, Chloride, Chlorides/nitrites, Sodium and Sulfate in water are already parameters accounted for in this method to define the water categories for users (Boulay et al. 2011a). However, Boulay et al. (2011) method cannot be applied in its present form due to a scale modeling issue: the water salinized should be an inventory flow which is the result of a balance between water input and water output (with associated salinity increase). Boulay’s method can only be applied in the case of salinization of drainage water induced by irrigation, and if the soil is included in the technosphere; i.e the saline drained water is considered an “emission”. Soil salinization affects human health through reduced food supply. This is linked with the ecotoxicological effects of salts on crops, but also to soil physical degradation. Feitz et al. (2002) method is the mid-point step contributing to this pathway.

Resource - Water and soil salinization affecting water and soil resources are debatable pathways. In the case of permanently saline aquifers, we can consider that future generations will be deprived of water in that specific location. But as noticed previously, water quality alteration affecting resource is not considered in the water use impact framework. Regarding soil salinization, permanent degradation of soil or a loss of soil through erosion reduces soil availability as a future resource (Núñez et al. 2012). The UNEP SETAC Land use working group considers that a high salinity area in a very dry climate could be barren for an indefinite time period and corresponds to a permanent impact (Koellner et al. 2013b).

The land use impacts framework could cover soil salinization pathways, but within this framework, the inventory flux is a land use type, and not a salt release. According to JRC-IES 2011 “*soil salinization may be included in a completed/revised land use category”*. Soil salinization and waterlogging could be included in the global land use impact assessment on biodiversity and ecosystem services. Salinization, together with other mid-points, has an impact on the potential for biotic production (Brandão and Milà i Canals 2012). Also, salinization may impact freshwater regulation, erosion regulation and water purification, but this soil parameter is not accounted for in the method developed by Saad et al. (2013). To include salinization impact potential, a refinement of the land use types would be required to account for soil and agricultural practices and their effects on salinization. However, it is important to notice that accounting for salts emission through the land use framework reduces the frontier with the salt emission modeling framework, thus increasing double counting risks. Moreover, it is important to notice the link between land use and water use categories, especially for irrigated agriculture. Indeed, irrigation is part of the land use practices, and LUC can lead to changes in the water cycle (Koellner et al. 2013c).

5. Conclusion

Including salinization impacts in LCA is of high priority, especially for agricultural systems. Although the existing methods addressing salinization in LCA are important and relevant contributions, they are incomplete in terms of spatial and environmental mechanisms coverage. The modeling complexities lie in the inter-relations between salinization mechanisms, at both local and regional scales, and the status of soil and water in LCA which are both resources and living environments. An analysis of the modeling options in agreement with the LCA framework has been proposed in this paper. Much research effort is still required to include salinization impacts in a global, consistent and operational manner in LCA.

ABSTRACT

There is an increasing demand for LCA applied to the food and beverage sector. However, major limitations in doing LCA studies in this sector are currently the lack of inventory data and processes, and the absence of consistency among existing food datasets. There is a need to develop detailed, transparent, well-documented and reliable data in order to increase the accuracy and comparability of LCA in the food sector. This need is being addressed by the World Food LCA Database (WFLDB) project. The main aim of the WFLDB is to create a basis to assist companies and environmental authorities to assess and reduce ("eco-design") the impacts of food and beverage products, in initiatives like Environmental Product Declarations (EPD) or product labelling and also for academic research.

Keywords: Agriculture; database; environmental product declaration; inventory; LCI.

1. Introduction

Agricultural production and food processing contribute significantly to environmental impacts on global warming, eutrophication and acidification (Pardo and Zufia 2012; Ruviaro et al. 2012; Saarinen et al. 2012). The use of LCA for the assessment of these impacts is steadily increasing in the last decade (Notarnicola et al. 2012). However, major limitations to such assessments are the lack of reliable and consistent inventory data.

Existing libraries of LCA data on food are most often:

- Not transparent enough
- Incomplete: only few inventory flows are accounted for, which leads to an incomplete overview of the impacts of food products and misleading interpretations and conclusions
- Inconsistent among each other, due to different approaches and assumptions
- Outdated and consequently unreliable
- Not regionalized: country-specific data are rarely available

Therefore, it is critical to develop detailed, transparent, well-documented and reliable data to allow for more accurate and comparable LCA in the food sector.

In this context, Quantis and Agroscope launched early 2012 the World Food LCA Database (WFLDB) project which will be completed in 2015, in collaboration with, as of April 2014, ADEME, Bayer, Swiss Federal Office for the Environment, General Mills, Kraft Foods, Mars, Mondelēz International, Monsanto, Nestlé, Syngenta and Yara.

The main aim of the WFLDB is to create a basis to assist companies and environmental authorities to assess and reduce ("eco-design") the impacts of food and beverage products, in initiatives like Environmental Product Declarations (EPD) or product labelling and also for academic research.

2. Methods

A new set of food inventory data is being developed from existing LCA studies on food products (project partners' past LCAs, Agroscope and Quantis existing databases), literature reviews, statistical databases of governments and international organizations (such as the Food and Agriculture Organization of the United Nations), environmental reports from private companies, technical reports on food and agriculture, information on production processes provided by the project partners as well as primary data. Background datasets from the ecoinvent database are being used as a basis and compatibility with ecoinvent will be ensured.

The developed datasets include, when relevant, different production schemes (such as conventional, integrated or organic production), regional specificities and deforestation impact.

To guarantee its transparency, the inventory database is fully documented, unit processes are visible (except for confidential data) and all sources are referenced. The end-user will be able to differentiate among different stages of the process (e.g. agricultural production vs. food product manufacturing) and to identify the main impact contributors for each dataset (e.g. pesticides, fertilizer use, etc.).

Datasets created within the project will initially be solely available to the project partners and they will become public through their integration in ecoinvent.

The scientific modelling principles of the WFLDB are at a first instance based on:

1. ISO standards14040 and 14044 (ISO, 2006a; ISO 2006b)
2. ecoinvent quality guidelines (ecoinvent, 2013; Weidema et al, 2013)
3. ILCD guidelines (JRC, 2010)

The project managers collect data and define the methodological guidelines for modelling the WFLDB datasets. These rules are based on the above-mentioned documents and on other existing guidelines for modelling agricultural processes. By doing this, it is ensured that all datasets within the WFLDB are modelled according to internationally accepted standards and are fully consistent with each other. Furthermore, the project managers follow the developments within other international initiatives and organizations such as The Sustainability Consortium (TSC), the Food and Agriculture Organization of the United Nations (FAO), the Sustainable Agriculture Initiative Platform (SAI), the EU Food SCP Roundtable and the EU Product Environmental Footprint. Scientific guidelines used in other database initiatives such as Agri-BALYSE (Van der Werf et al., 2010) and ACYVIA (Bosque et al, 2012) are also considered for the definition of the WFLDB modelling principles (developments are considered as they occur).

The methodological guidelines of the World Food LCA Database will be reviewed by a selected panel of external and independent experts and will be published in 2014.

The aim is to be as compliant as possible with the developments occurring within the above mentioned initiatives and organizations. Compliance with other initiatives is assured by the project advisory board, which has a consultative role and is constituted of members of non-governmental and research organizations.

The WFLDB datasets will be delivered in the most widely used data exchange formats for LCA software (i.e. ecospold v1, ecospold v2, SimaPro-CSV, Quantis SUITE 2.0-excel). This will enable using the datasets in common LCA software: SimaPro, GaBi, OpenLCA and Quantis SUITE 2.0. The datasets are released in three phases, the first release was in summer 2013. Two years after their release to the project partners, datasets will be submitted to the ecoinvent Centre for their integration in the ecoinvent database.

3. Conclusion

The WFLDB will be a comprehensive LCA food database providing detailed LCI data of high scientific quality, reliability and transparency, while being in line with other database developments such as ecoinvent v3.

The database will provide a large number of new food-related inventory datasets with a focus on different production schemes and regional specificities.

As an illustrative example, Figure 1 shows the preliminary results for carbon footprint of some processes related to coffee, from processes fairly upstream the life cycle of coffee (e.g., green coffee production) until fairly downstream the life cycle of coffee (e.g., decaffeinated instant coffee), for different technologies (e.g., spray and freeze drying). Furthermore, specific gate-to-gate steps are also modelled (such as roasting and grinding) and could be combined with customized processes (for example regional coffee production that would be modelled with primary data). This gives high flexibility to the final user of the WFLDB.

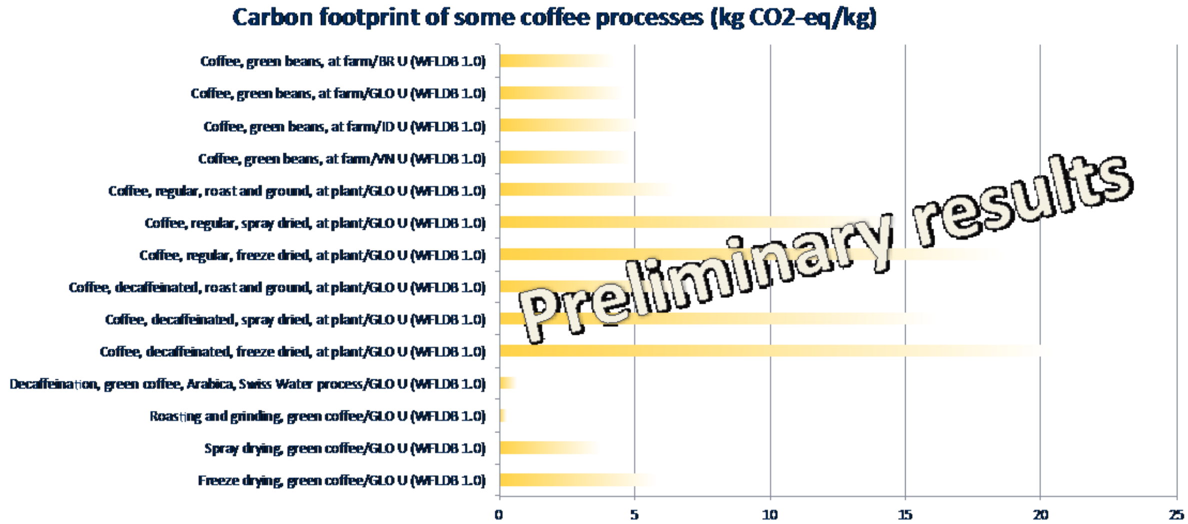

Figure 1. Preliminary results for carbon footprint of some processes related to coffee

Learning obtained in the last 2 years data collection as well as recommendations for any practitioner and company encountering challenges with food data collection will be presented.

ABSTRACT

On April 9th 2013, the European Commission published a communication to the European Parliament and the Council to Build a Single Market for Green Products to facilitating better information on the environmental performance of products and organisations. An open call for volunteers was announced by the European Commission for the Product Environmental Footprint (PEF) and the Organisation Environmental Footprint (OEF), inviting companies, industrial and stakeholder organisations in the EU to participate in the development of product-group specific and sector-specific rules. A group of public and private organisations has been selected by the European Commission to develop the guidance for surveying and reporting environmental impacts in the European retail sector. The Technical Secretariat which is responsible for developing the OEF sector rules in two years (official launch in November 2013), is composed by four retailers: Carrefour SA, Colruyt Group, Oxylane Group (Decathlon) and Picard; three public agencies: Environment Agency Austria (EAA), French Environment and Energy Management Agency (ADEME) and Italian National agency for New Technologies, Energy and Sustainable Economic Development (ENEA); one non-governmental organization: Global 2000; one association PERIFEM; and one Life Cycle Assessment (LCA) consultant: Quantis. The project, challenges and preliminary results and benefits of this pilot test will be presented highlighting feedback in reference to specific modelling issues related to the application of LCA to a sector as vast as the retail sector such as defining system boundaries (e.g., direct, as well as upstream and downstream indirect contributions) and choosing life cycle impact assessment methods (e.g. which indicators are relevant, which weighting scheme to use). These points also include the issue pertaining to consistency with the product approach for a sector as interdisciplinary as the retail sector.

Keywords: Organisation Environmental Footprint (OEF), Sector rules (SR), Product category rules (PCR), European Commission (EC)

1. Introduction

On April 9th 2013, the European Commission (EC) published the following: "Communication from the Commission to the European Parliament and the Council: Building the Single Market for Green Products, facilitating better information on the environmental performance of products and organisations" [1].

An open call for volunteers was announced by the EC for the Product Environmental Footprint (PEF) and the Organisation Environmental Footprint (OEF), inviting companies, industrial and stakeholder organisations in the EU to participate in the development of product-group specific and sector-specific rules.

A group of public and private organisations has been selected by the ECn to develop the guidance for surveying and reporting environmental impacts in the European retail sector [2]. The Technical Secretariat which is responsible for developing the OEF sector rules in two years (official launch in November 2013), is composed by three retailers: Carrefour SA, Colruyt Group and Oxylane Group (Decathlon); three public agencies: Environment Agency Austria (EAA), French Environment and Energy Management Agency (ADEME) and Italian National agency for New Technologies, Energy and Sustainable Economic Development (ENEA); one NGO: Global 2000; and one LCA consultant: Quantis.

2. Methods

The approach used to develop the OEFSR will encompass the four following principles: (1) life cycle-based approach; (2) multi-criteria; (3) physically realistic modelling; (4) reproducibility /comparability.

This pilot will test how approaches such as Product Environmental Footprint Category Rules (PEFCRs) and the "Chain OEF" (approach covering the indirect/upstream part of the value chain) will interact with or benefit the proposed OEFSR. The Chain-OEF aims primarily to allow the assessment of the environmental footprint based on the product portfolio of retailers, produced or not by them, using a cascade system; and to involve progressively more and more companies in the supply chain, enhancing primary data collection and building transparent partnerships. This sub-pilot strives to develop a cost-efficient approach to analyse, link and reduce the impact of each player in the value chain.

3. Results

Table 1 presents the preliminary results in terms of scope of the OEFSR.

Application	Use of an OEFSR		
	Optional "May"	*Recommended "Should"*	*Mandatory "Shall"*
In-house: improvement of the organisation's environmental performance	✓		
Reporting without comparisons or comparative assertions		✓	
Reporting with comparisons or comparative assertions			✓
Any OEF study declared to be in compliance with the OEF Guide	✓		

Table 1: Preliminary scope of the OEFSR (scenarios that does and does not necessitate the use of OEFSRs)

Building upon OEF studies already carried out, several aspects are identified as being challenging, including the definition of (i) the representative organisation model, (ii) benchmark and classes of environmental performance, or (iii) a weighting scheme different from the one proposed by the EC.

Figure 1 presents the system boundary of the OEFSR in general.

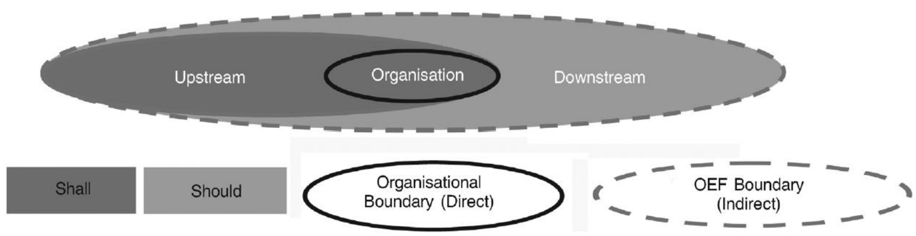

Figure 1: System boundary of the OEFSR in general

Figure 2 presents the system boundary of the OEFSR adapted to the retail sector (initial proposal for discussion).

Figure 2: System boundary of the OEFSR adapted to the retail sector

4. Conclusion

The project, challenges, preliminary results and benefits of this pilot test will be presented highlighting feedback in reference to specific modelling issues related to the application of LCA to a sector as vast as the retail sector such as defining system boundaries (e.g., direct, as well as upstream and downstream indirect contributions) and choosing life cycle impact assessment methods (e.g. which indicators are relevant, which weighting scheme to use). These points also include the issue pertaining to consistency with the product approach for a sector as interdisciplinary as the retail sector.

Numerical results of overall retailer OEF as well as proposed rules to assess the OEF of retailers will be available for public consultation for four weeks starting around December 2014. Final rules and generic results should be available by February 2015. Preliminary results and rules will be presented at LCAFood2014 (but not presented here as they are being calculated until end of September) to invite interested experts to engage in the public consultation that will occur at the end of the year and allow them to start considering strength and weaknesses of the proposed approach as well as technical, political, reputational and financial implication for the different economical sectors.

Grass as a C booster for manure-biogas in Estonia: a consequential LCA

Sirli Pehme[1,*], Lorie Hamelin[2], Eve Veromann[1]

[1] Institute of Agricultural and Environmental Sciences, Estonian University of Life Sciences
[2] Department of Chemical Engineering, Biotechnology and Environmental Technology, Faculty of Engineering, University of Southern Denmark

ABSTRACT

The aim of this study was to assess the environmental consequences of using grass (from both unused and cultivated boreal grasslands) as a co-substrate to dairy cow manure for biogas production. Environmental impact categories assessed were global warming, acidification and nutrient enrichment (distinguishing between N and P). Scenarios studied were: traditional management of dairy cow manure, mono-digestion of manure, manure co-digestion with reed canary grass and manure co-digestion with residual grass from semi-natural grasslands. The latter scenario showed the best environmental performance for the global warming category, for other categories it did not show clear benefits. Using reed canary grass specially produced for biogas purpose resulted in a climate change impact just as big as the reference manure management, mainly as a result of indirect land use changes. Increased impacts also occurred in the acidification and eutrophication (N) categories for the reed canary grass scenario, reflecting the impacts of the cultivation process. The main conclusion was that future strategies for manure-biogas production in Estonia should not rely upon land-dependent biomass, even if the availability of arable land in Estonia is, under current conditions, not considered to be an issue.

Keywords: anaerobic digestion, land use changes, dairy manure, reed canary grass, natural grass

1. Introduction

Biogas production from manure has a good potential to simultaneously produce a renewable and flexible energy carrier, while reducing the environmental impacts of manure management (mainly due to the reduced emissions from raw manure storage) and recycling biomass macronutrients (as well as the slowly degradable carbon) (Hamelin 2013). Although the energy produced from manure-biogas in the European Union (EU) is currently far below its full potential (Hamelin et al. 2014), a drastic increase of biogas production is nevertheless planned in the EU (Beurskens and Hekkenberg 2011), as well as in Estonia (Melts et al. 2013).

However, due to the too low carbon (C) and carbon-to-nitrogen (C/N) content of animal manure, it is usual practice to supplement manure with C-rich co-substrates for anaerobic digestion. Grass, especially reed canary grass, has been considered to have great potential for biogas production mainly due to its relatively high yield and the fact that arable land resource is available in Estonia (Ministry of Economic Affairs and Communications 2010; Värnik et al. 2011).

Two grass options were considered in this study: i) reed canary grass (this being one of the dedicated energy crops suggested to grow in Nordic countries) and ii) the residual grass from semi-natural grasslands, which is clearly underused currently but has a considerable biogas potential (Melts et al. 2013).

The goal of this consequential life cycle assessment (LCA) study was to quantify the environmental consequences of implementing, in Estonia, a manure-biogas strategy relying on grass as a co-substrate (options i) and ii), as opposed to managing manure conventionally and not harvesting the grass from semi-natural areas, nor producing energy grass. The focus is on dairy cow manure, this being presenting the highest share from all manure types in Estonia (Luostarinen 2013).

2. Methods

2.1. LCA approach

The life cycle impact assessment methodology used for this study was the EDIP2003 method described in Hauschild and Potting (2005) and the functional unit upon which all input and output flows were expressed was ”the management of 1 tonne of dairy cow manure ex-animal (i.e. the manure as freshly excreted by the animals)”. Four impact categories were considered: global warming, acidification and nutrient enrichment (distinguishing between N and P). Background data were based on Ecoinvent v.2.2 database (Frischknecht and Rebitzer 2005). Foreground data were mainly based on the Estonian situation, partly combined with Danish data.

The life cycle inventory and process flows are detailed in Pehme (2013), and the assessment was facilitated by the software SimaPro 7.3.2. The geographical scope was considered to be Estonia, i.e., inventory data for biomass composition, technologies and emissions were specific to the Estonian/Baltic conditions.

In this study, biogenic carbon flows (both removals from atmosphere by plants and also emissions) were fully accounted for each process.

2.2. System boundaries and description of scenarios

Four different scenarios are considered in this study: one reference scenario (conventional management of dairy cow manure) and three biogas alternatives (mono-digestion; co-digestion with energy grass; and co-digestion with grass from semi-natural areas).

In the reference scenario, dairy cow manure is handled as slurry after excretion, pumped towards outdoor storage at least once per day, stored outside in a concrete slurry tank covered by a naturally-forming crust layer and applied to fields when suitable. The life cycle inventory of the reference manure management is detailed in Hamelin et al. (2013), including details on the manure composition. The process flow diagram of this scenario is presented in Figure 1, reflecting the mass changes of manure due to emission losses and water addition in-house and at the outdoor storage through precipitation. The dry matter (DM) content of dairy manure ex-housing (i.e. as it leaves the housing unit) considered in this study is 11.5%, the volatile solids (VS) representing 82.0% of the DM (Hamelin et al., 2013).

In the biogas scenarios, manure is instead collected from the animal houses and used in biogas plants, digested in a mesophilic 2-steps digestion process. The biogas was considered to be used for combined heat and power production (CHP). The marginal energy sources displaced by the biogas were natural gas for the heat and oil shale for the electricity. The digestate was assumed to be stored and used as a fertilizer, displacing the marginal mineral nitrogen, phosphorus and potassium fertilizers for Europe (respectively taken as calcium ammonium nitrate, diammonium phosphate and potassium chloride; Hamelin 2013). The rationale behind this fertilizer substitution is, based on the Estonian context, that if the farmer would not have had the manure or digestate, the farmer would have applied mineral fertilizers up to the crop needs and national regulations. Yet, this does not mean that 100% of the N, P and K applied with the raw manure (reference scenario) and digestate (biogas scenarios) correspond to avoided mineral fertilizer; only the portion available to plants was considered to avoid the production and use of mineral N, P and K. The full calculation of avoided fertilizers is detailed in Pehme (2013).

For the 2 scenarios involving co-substrates, it was considered, based on Hamelin et al. (2011), that these were added to manure in order to get an input mixture with a DM content of 10% after the first digestion step. Fugitive CH_4 losses from the anaerobic digestion process were taken as 1% of the overall CH_4 produced, based on Hamelin et al. (2014) and assuming the implementation of state-of-the-art biogas technologies. Further life cycle inventory data, details and mass balances for all biogas scenarios are detailed in Pehme (2013).

The co-digestion with energy grass scenario, here referred to as the “Reed canary grass (RCG) scenario”, is based on co-digestion of dairy cow slurry and reed canary grass silage. RCG is here produced specially for biogas purpose, fertilized and harvested twice per year. The average grass yield for a 15 years plantation is considered as 8.23 t DM/year. RCG production data were based on Värnik et al. (2011). The production of RCG is considered to displace the use of land for cultivating barley, thus this barley cannot be produced on the same land and has to be produced somewhere else, thus involving land use changes emissions (expansion and intensification). Different life cycle assessments have identified spring barley as the marginal crop displaced by an increased demand for other crops (e.g. Hamelin et al. 2012; De Vries et al. 2012). Barley is mostly produced in areas with lower soil quality and its gross-margin value is lower compared to other crops. Thus, production of energy grass instead of barley has been presented as an attractive choice for Estonian farmers from the economic and agronomic point of view (Värnik et al. 2011). In this study, indirect land use changes (ILUC) emissions of 357 t CO_2 eq. per ha of barley displaced were considered on the basis of (Hamelin et al. 2014), which corresponds to 18 t CO_2 eq. ha per year (20 years annualization). Hamelin et al. (2014) derived that estimate from the results of Kløverpris (2008) for a marginal increase in wheat consumption in Denmark. Process flows for the RCG scenario are illustrated in Figure 2.

The co-digestion scenario involving natural grass (NG) is based on co-digestion of dairy cow slurry and natural grass silage. Grass is collected once per year from semi-natural grassland (alluvial meadows) where no soil cultivation is practiced and no agrochemical inputs are used. The grass yield is assumed to be 5.5 t DM/ha according to Melts et al. (2013). Currently there is no use for most of the biomass from those areas, so harvesting the grass prevents it to decompose and cause CO_2 emissions to the atmosphere. This (avoided) decay process was modeled following a first order ($C_t=C_oe^{-kt}$) decay, assuming that 100% of the above-ground biomass is transferred to the soil, and using the decay rates of Freschet et al. (2013). On the basis of this, it was considered that 100% of the C in the above-ground grass biomass would have been emitted as CO_2, if the grass would not have been harvested. In this system, this translates to avoided CO_2 emissions of 9.5 t CO_2 eq. ha per year (20 years annualization), considering a C content in the grass biomass of 0.47 kg C kg^{-1} DM. Of course, as the grass C ends up to be emitted through the biogas scenario (among others in the biogas and through the application of the digestate), this credit is, at the end, essentially counterbalanced. Production, cutting, chopping and transport of grass are accounted in the analyses for both grass co-digestion scenarios.

More straightforward, the mono-digestion scenario is based on the anaerobic digestion of dairy cow slurry ex-housing, this being the only substrate. The digestate then undergoes the same processes as for the other biogas scenarios.

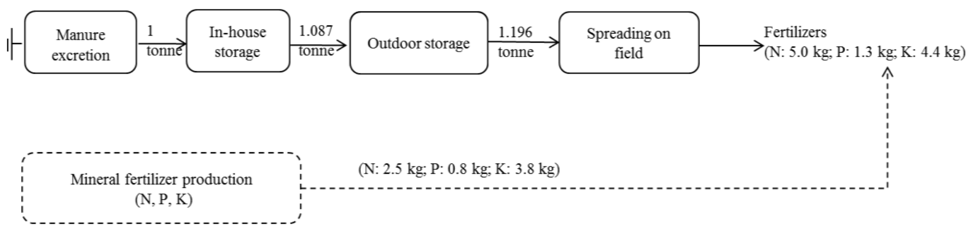

Figure 1. Process flow diagram for the reference manure management scenario per 1 tonne of manure ex-animal

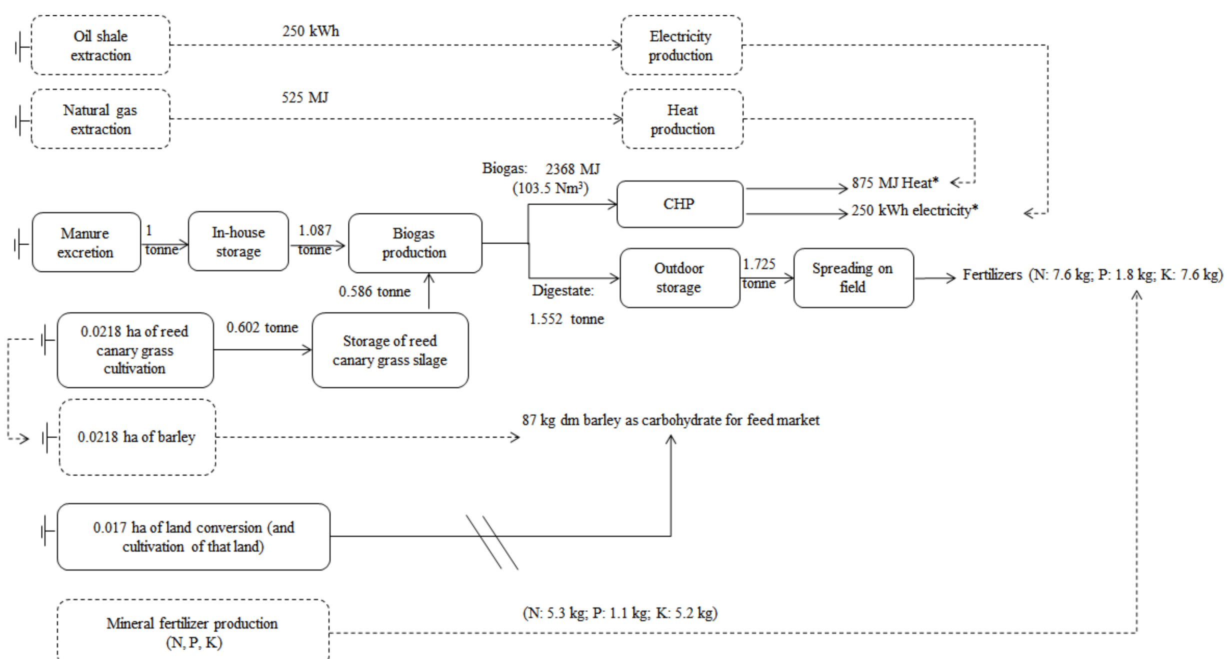

Figure 2. Process flow diagram for the reed canary grass scenario per 1 tonne of manure ex-animal

3. Results

The natural grass scenario had the best reduction potential for the global warming impact category (Table 1). The reed canary grass scenario showed equal result compared to reference scenario; the main reason for this was indirect land use changes. Mono-digestion displayed a good potential to reduce the global warming impact, but its energy production is significantly lower.

Most of the induced greenhouse gas (GHG) emissions originated from field application of manure and digestates, and from the burning of the biogas in the biogas engine prior to CHP. For all scenarios, the main reduction of GHG emissions was caused by the avoided oil shale-based electricity.

For the rest of the impact categories, natural grass did not show clear environmental benefits in comparison to the reference scenario (conventional manure management without biogas) (Table 1).

Table 1. LCA results, per 1 tonne of dairy cow manure ex-animal.

Impact category	**Reference manure**	**Mono-digestion**	**Co-digestion with RCG**	**Co-digestion with NG**
Global warming, kg CO_2 eq.	314	155	314	-207
Acidification, m^2 "unprotected ecosystems eq." (UES)	43	37	60	48
Aquatic Eutrophication, N eq.	0.40	0.28	0.89	0.38
Aquatic Eutrophication, P eq.	-0.02	-0.02	0.01	0.04
Grass input to digester per FU, tonne	-	-	0.586	0.407
Energy produced per FU, MJ	-	860	2368	1916

The highest contributions to the acidification category were caused by the field application and outdoor storage for all scenarios, reflecting essentially the losses of nitrogen as ammonia. For the RCG scenario, additional emissions were caused by the grass cultivation process. For the N and P eutrophication, the main contributions came from field application and the main emission reductions originated from the avoided mineral fertilizers production and application.

4. Discussion

The results of this study highlighted the important potential environmental impacts related to the use of land-dependent biomass, when implementing a national renewable energy strategy (in this case based on manure-biogas). In this study, co-digesting dairy cow manure with dedicated RCG resulted in an overall worse environmental performance than not producing biogas at all (i.e. the reference scenario where heat and power are based on fossil fuels and manure is managed conventionally). Similar conclusions are presented in some studies (De Vries et al. 2012; Hamelin et al. 2014), but very often bioenergy studies exclude the land use change impacts. In the Estonian context, in can indeed be debated whether it is reasonable to consider that cultivating RCG would lead to the displacement of barley, given the great availability of uncultivated land. However, if the Estonian stakeholders are really serious about a manure-biogas strategy relying upon the supply of dedicated energy grass, it seems reasonable to assume that the frontier between the availability of arable land (supply) and the demand for it will be reached. This situation is exactly what this LCA endeavored to model, in the aim of preventing eventual misleading decisions.

Residual biomass from nature conservation areas as it is illustrated by the natural grass scenario results of this study should be preferred to cultural grass to achieve the target for increased biogas production reflected in the National Renewable Energy Action Plan of Estonia 2020 (Ministry of Economic Affairs and Communications 2010). Natural grass shows great reduction potential especially in global warming category, but there are technological issues to solve connected to the access to harvesting mainly due to the seasonal flooding (Heinsoo et al. 2010). Managing natural areas has also other benefit not reflected in the LCA results– it would ensure to maintain their high biodiversity value. Grass yield from floodplain meadows in Estonia have been estimated to

113,349 tonne of DM (Heinsoo et al. 2010). If half of the biomass is considered to stay unused currently and would be used for anaerobic digestion in mixture with manure as presented in this study, it would result in a biogas amount of 11.4 x 10^{-6} Nm^3, which would correspond to a greenhouse gas emissions reduction of approximately 28,000 t CO_2 eq.

However, this study did not reflect the practical aspects of using grass for anaerobic digestion. Economic aspects of grass collection, feasibility of harvesting, possible impacts on the digestion process (e.g. corrosion) need further investigation.

It can also be debated whether the alternative use of the natural grass would, on a long-term perspective, be to be left on land. If, for example, this grass has a high protein value and could become competitive enough to be used for animal feed, then a protein feedstuff is displaced. In such case, it is likely that no environmental benefits would be obtained from using the grass as a co-substrate to manure-biogas, as e.g. shown in De Vries et al. (2012) for agro-industrial residues with high protein value.

5. Conclusion

Manure-biogas does, for the Estonian context, lead to significant benefits. In this study, manure-biogas strategies were shown to yield overall environmental benefits if based on grass co-substrates from natural areas, or if simply based on mono-digestion. Yet, a strategy relying on the use of dedicated reed canary grass was shown to lead to an overall worse environmental performance than not producing biogas at all. This was essentially due to the impacts of the cultivation process itself, as well as to the cascading effects involved when considering the use that the land would have otherwise had, if not used for dedicated energy grass cultivation.

ABSTRACT

This paper presents the approach used to develop a model predicting fuel consumption according to the different agricultural practices and the results obtained for wheat production. Results showed that the largest variations were caused, not by production systems, but by soil preparation and fertilization operations. Average fuel consumption was 55.6 L/ha regardless of the production system, the soil preparation and fertilization strategies and the type of wheat. On average, soil preparation consumes 32% of the fuel, but it can reach more than 50% if conventional tillage is used. Grouped by tillage system, instead of production systems, no-till plots consume 39.6 L/ha, reduce tillage 55.6 L/ha and conventional 76.0 L/ha. Fuel consumption due to fertilization varies according to the type of fertilizer used. The amount of fuel used seems to be related to the concentration of nitrogen in the fertilizer. Winter wheat production used less fuel than spring wheat.

Keywords: life cycle assessment, wheat production, greenhouse gas, environmental impact, fuel consumption

1. Introduction

Life cycle assessment (LCA) performed on agricultural products generally use average values of fuel, fertilizer and pesticide consumption per hectare of land. These average values are close to reality when the LCA results are used to inform consumers about the environmental impact of products like milk or flour that have been produced on more than one farm using different agricultural practices. Such values are, however, less relevant for agricultural producers who want to improve the environmental impact of their farm.

Several factors may influence fuel consumption: production systems, soil and fertilizer management and technical factors such as the width and weight of equipment, as well as the power of the tractor used during farm operations.

A model predicting fuel used for specific farm machinery and operation was developed while performing a “cradle-to-farm gate” LCA of wheat production. The aim of this LCA was to assess the environmental impact of four production systems (intensive, conventional, integrated and organic) for spring and winter wheat.

This paper focuses on the approach used to develop the model and the results obtained for fuel consumption according to the different agricultural systems.

2. Methods

2.1. Inventory data

Four production systems for spring and winter wheat were considered in this study. Difference in production systems were observed in the management of fertilizer and pesticide use. Organic producers had to be accredited by a certified organic body. Integrated producers were obliged to follow a book of specifications provided by the grain buyer. They were not restricted with the use of mineral fertilizer alongside manure, but they were encouraged to respect a fertilization management plan. They were only allowed to use herbicide before seeding, but not during the growing season. Conventional and intensive producers were not restricted in the use of fertilizers or pesticides. Intensive producers tended to use more pesticides in combination with a growth regulator. Regardless of the production system, soil management practices were not limited.

Data used in the project come from plots established on farms that were accustomed to sell their wheat to a grain buyer. Producers provided data for soil cultivation, like tillage, seedbed preparation, seeding, fertilizers and pesticides application, harvesting and on-farm transportation. They were asked to provide, for every operation, the main characteristics of the implement (e.g., width and weight), the tractor used (e.g., type and power) and the working conditions (e.g., yield, soil texture, travel speed and working depth). Producers with information such as fuel consumption and field capacity, recorded by the GPS of their tractor or combine were invited to provide them. These values were thereafter used to validate the model.

Based on the list of equipment provided by the producers, a data base of equipment has been developed alongside the model. This database includes the following equipment:

- Chisel
- Combine (auger or draper head, rigid or flexible)
- Disk gang
- Disk harrow
- Field cultivator
- Grain drill (rows or no-till)
- Grain wagon
- Loader
- Manure pump
- Manure spreader (solid and liquid)
- Mounted fertilizer spreader
- Plow (semi-mounted and mounted)
- Rod weeder
- Roller packer
- Sweep plow
- Pesticides sprayer (trailed)

2.2. Fuel consumption

The methodology used for the calculation of fuel consumption was based on the equations presented in the following two standards produced by the American Society of Agricultural and Biological Engineers: Agricultural Machinery Management Data (ASAE D497.7 Mar2011; ASABE, 2011) and Agricultural Machinery Management (ASAE EP496.3 FEB2006; ASABE, 2006). The methodology estimates fuel consumption of an operation using the equipment characteristics (e.g., width, mass and tillage depth) as well as the characteristics of the tractor used (e.g., mass and travel speed).

The methodology has been simplified according to the available data. A summary of the main calculation is presented here. The calculation of fuel consumption can be summarized by the following equation:

$$Q_{fuel} = \frac{P_{total} \times Q_{sfc}}{C_{field}} \qquad \text{Eq. 1}$$

Where Q_{fuel} is the fuel consumption (L/ha), P_{total} is total power requirement for an operation (kW), Q_{sfc} is specific fuel consumption (L/kWh) and C_{field} is field capacity (ha/h).

Total power (P_{total}) requirement for operating implements is the sum of implement power components (Eq. 2).

$$P_{total} = \frac{P_{db}}{E_m E_t} + P_{pto} + P_{hyd} + P_{el} \qquad \text{Eq. 2}$$

Drawbar power (P_{db}) is power developed by the drive wheels or tracks and transmitted through the hitch or drawbar to move an implement through or over the crop or soil (ASABE, 2006). It is primarily a function of the width of the implement and the speed at which it is pulled. It also depends upon soil texture, depth and geometry of the tool. Drawbar power is the sum of motion resistance and soil and crop resistance multiply by the travel speed. Mechanical efficiency (E_m) and tractive efficiency (E_t) are coefficients specific to tractor characteristics.

Power-takeoff power (P_{pto}) is the power required by the implement from the PTO shaft of the tractor or engine and it is a function of the width of the implement and the material feed rate or yield.

Hydraulic power (P_{hyd}) is the fluid power required by the implement from the hydraulic system of the tractor or engine. Electric power (P_{el}) is required to operate components of implements. Hydraulic and electric power are difficult to assess and were not considered in the survey, they were replaced by a factor ($F_{Phyd\ +\ Pel}$) representing an additional 25% of the power requirement.

Total engine power must be greater than the total implement power required. Additional power is required to accelerate and overcome changes in topography, soil and crop conditions (ASABE, 2006). An additional 20% of the power requirement has been allowed for reserve power (F_{Pres}).

For the purpose of the project, Equation 2 has been simplified and can be presented as:

$$P_{total} = \left(\frac{P_{db}}{E_m E_t} + P_{pto}\right) \times F_{P_{hyd}\,+\,P_{el}} \times F_{P_{res}} \qquad \text{Eq. 3}$$

Specific fuel consumption (Q_{sfc}) is the fuel requirement based on the actual power required. For a particular operation it can be found by multiplying specific fuel consumption volume by current power delivery. It takes into account the ratio of equivalent PTO power required by the current operation to rated power available and the ratio of partial throttle engine speed to full throttle engine speed.

Effective field capacity (C_{field}) is a function of field speed, machine working width, field efficiency and unit yield of the field.

3. Results

Average fuel consumption was 55.6 L/ha with a standard deviation of 21 L/ha for the 80 plots regardless of the production system, the soil preparation and fertilization strategies and the type of wheat. There was lot of variation in the results, the minimum value was 27.5 L/ha and the maximum value was 108.0 L/ha. Table 1 presents the average fuel used per operation according to production and tillage systems. Results showed that the largest variations in fuel consumption were caused, not by production systems, but by soil preparation and fertilization operations.

Table 1. Average fuel used for wheat cultivation per operation in function of production and tillage systems

Production and tillage systems	n	Yield (t/ha)	Soil preparation (l/ha)	Fertilization (l/ha)	Pulverization (l/ha)	Seeding (l/ha)	Harvesting (l/ha)	Transportation (l/ha)	Total (l/ha)

Reduce	6	3.6	12.8	13.2	0.6	8.6	13.8	3.7	52.6
Conventional	6	3.5	41.0	6.7	0.9	9.2	16.1	3.6	77.5
Average		3.6	16.3	7.6	1.1	11.3	14.4	3.7	54.5
Conventional									
No-till	8	4.4	-	4.3	2.4	14.9	13.5	4.5	39.6
Reduce	5	4.0	14.2	15.5	2.3	9.1	14.1	4.1	59.4
Conventional	6	4.2	41.0	6.7	2.5	9.2	16.1	4.3	79.8
Average		4.2	16.9	8.0	2.4	11.6	14.5	4.3	57.8
Intensive									
No-till	8	5.0	-	4.7	4.9	14.9	13.5	5.2	43.2
Reduce	12	4.4	10.7	13.5	5.0	7.9	13.3	4.5	54.9
Conventional	6	4.9	37.4	7.5	3.9	8.7	15.0	5.0	77.5
Average		4.7	13.7	9.4	4.7	10.2	13.7	4.8	56.7
Average		4.0	17.6	7.7	2.4	10.1	13.7	4.1	55.6

On average, soil preparation consumes 32% of the fuel, or 17.6 L/ha, but it can reach more than 50% or 41 L/ha. Grouped by tillage system instead of production systems, no-till plots consume 39.6 L/ha, reduce tillage 55.6 L/ha and conventional 76.0 L/ha. Conventional tillage system used roughly the same amount of fuel regardless of the production system. Soil preparation consisted, on average, of 2.3 operations, using a plow and one or two passes of field cultivator. For integrated, conventional and intensive production systems, reduce tillage consumed approximately one third of the fuel used by conventional tillage. An average of 1.6 operations was done by the producers combining a chisel, a field cultivator, a disk harrow or a rod weeder. Soil preparation was performed with an average of 3.8 operations for organic producers using reduce tillage. They consumed approximately the same quantity of fuel than those using conventional tillage (33.3 L/ha vs 34.0 L/ha). The exact reason for all these operations was not specified, but it may be due to a related operation such as weed control.

Fuel consumption due to fertilization varies according to the type of fertilizer used. Fertilization with ammonium nitrate averaged 1.8 L/ha or 0.9 l/ha per pass. Spreading of liquid cow manure averaged 14.7 L/ha while mixing and loading accounted for 16.4 L/ha for a total of 31.1 L/ha. Spreading of liquid pig manure averaged 7.7 L/ha while loading accounted for 4.8 L/ha for a total of 12.5 L/ha. Spreading of solid poultry manure averaged 3.6 L/ha while loading accounted for 2.1 L/ha for a total of 5.7 L/ha. The amount of fuel used seems to be related to the concentration of nitrogen in the fertilizer (Figure 1).

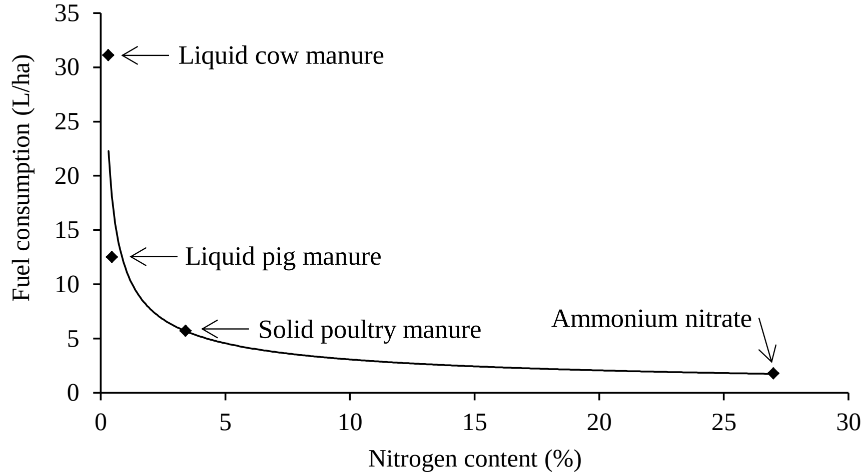

Figure 1. Fuel consumption of fertilization operations according to the concentration of nitrogen in the fertilizer

Winter wheat production used less fuel than spring wheat. Major differences were observed because more producers used no-till and fertilized with manure. Average fuel consumption for winter wheat was 53.6 L/ha with no-till representing 60% of the plots. Fertilization consume 11.4 L/ha and seeding 11.8 L/ha. Average spring wheat fuel consumption was 57.5 L/ha with no-till representing only 3 plots out of 40. Fertilization consume 4.1 L/ha and seeding 8.4 L/ha.

Pesticides pulverization consumed less fuel than any other operation. Integrated production system consumed 1.1 L/ha, conventional 2.4 L/ha and intensive 4.7 L/ha.

No-till seeding consumed approximately 5 litres more per hectare than seeding done after reduce or conventional tillage. Organic farming consumed less fuel for seeding because, for most of the plots, the operation was done using a tractor smaller than 100 kW. The same conclusion can be drawn for harvesting; the combines used in the organic plots were smaller.

4. Discussion

Sensitivity analysis should be performed to investigate the impact of farm equipment use. Efforts to reduce fuel use during farm operations would contribute to reduce greenhouse gas emissions, but this parameter has little influence on the whole farm emissions. Fuel consumption of 55 L/ha is equivalent to approximately 150 kg CO_2e/ha, which is not an important parameter compare to the emissions produced on a hectare of land. Furthermore, results observed in this study showed a variation corresponding roughly to 20 L/ha or 50 kg CO_2e/ha. In another vein, at the end of the year, an economy of 20 L/ha can represents a substantial amount of money for a producer.

If the objective is to reduce the environmental impact, the choice to use a machine or another must take into account all the operations of the farm. For example, the use of manure instead of mineral fertilizer increase greenhouse gas produced by the use of machinery on the farm but may contribute to reduce greenhouse gas outside the farm.

It should be considered to use the method to evaluate the impact of agricultural operations on more than a year in order to cover an entire rotation. The sequence of crops in the rotation has an impact on the operations and ultimately on greenhouse gas emissions and other impact categories. For example, analyzing operations for an entire rotation could solve interrogations like, in what year and on what culture is associated the environmental impact of seeding a cover crop?

5. Conclusion

This paper presented the approach used to develop a model predicting fuel consumption according to the different agricultural practices and the results obtained for wheat production.

Results showed that the largest variations were caused, not by production systems, but by soil preparation and fertilization operations. Average fuel consumption was 55.6 L/ha regardless of the production system, the soil preparation and fertilization strategies and the type of wheat. On average, soil preparation consumes 32% of the fuel, but it can reach more than 50% if conventional tillage is used. Grouped by tillage system, instead of production systems, no-till plots consume 39.6 L/ha, reduce tillage 55.6 L/ha and conventional 76.0 L/ha. Fuel consumption due to fertilization varies according to the type of fertilizer used. The amount of fuel used seems to be related to the concentration of nitrogen in the fertilizer. Winter wheat production used less fuel than spring wheat. Differences were observed because more producers used no-till and fertilized with manure.

ABSTRACT

In current LCA guidelines and most LCA studies of land-based systems, soil carbon is the "elephant in the room". Taking it into account is essential for many reasons, and yet it is still ignored. The lack of soil carbon data, as well as the site specificity of soil carbon stocks, makes the estimates highly uncertain. Actual monitoring of soil-carbon stocks is therefore necessary. In this study, we show that monitoring soil carbon at the scale of an apple orchard block is practically feasible at a cost of less than 1% of the price of export apples at the ship side. Furthermore, LCA studies should use measured, site specific, soil-carbon stock input data if meaningful results are sought. For transparency, the related uncertainty should always be expressed. Finally several actions for all stakeholders are presented for the implementation of soil-carbon stock monitoring.

Keywords: LCA, soil carbon, carbon footprint, monitoring, land use

1. Introduction

Soil-carbon is essential to maintain and enhance soil fertility; it also makes a contribution to many other ecosystem services (Victoria et al. 2012). Furthermore, the temporal changes in soil-carbon stocks could play an important role in mitigating climate change (Lal 2004). Therefore, soil-carbon change has been suggested as the main indicator in Land Use Impact Assessment in LCA (Koellner et al. 2013). However, most LCA studies include an incomplete consideration of the carbon balance because they omit total soil-carbon stocks and their changes in the calculations (Hamelin et al. 2012). Existing Life Cycle Assessments (LCA) and Carbon Footprint (CF) studies that account for or discuss soil-carbon stocks and their temporal changes suggest that the inclusion of soil-carbon can have a huge impact on the climate change results for land-based products. This effect can be over 100% for a change in land management (Land Use, LU) (e.g. Galdos et al. 2010) and over 2000% for land conversion (Land Use change, LUC) (e.g. Gelfand et al. 2013). Despite this substantial impact and its potential consequences for interpretation, LCA and CF guidelines such as the recent ISO TS 14067 generally exclude soil-carbon from the compulsory part of the assessment. As a result, many LCA and CF studies have excluded this essential parameter when assessing the impact of land based systems on the environment (Plassmann et al. 2010).

However, studies that consider or discuss soil-carbon change in the context of LCA and CF highlight three major issues. Firstly, there is a critical lack of soil-carbon data for all land-based systems and at all spatial scales (e.g. Smith et al. 2012). Secondly, they report the enormous uncertainty (e.g. Malca and Freire 2012; Meisterling et al. 2009), although rarely quantified, associated with the use of available soil-carbon data. Thirdly they demonstrate the site-specificity of soil-carbon stocks and their temporal changes, due to the complexity and inherent variability within and between land based systems (e.g. Bessou et al. 2011).

The role of soil-carbon stocks and their temporal changes in land-based systems as well as their potential influence on LCA and CF results suggest that soil-carbon should always be taken into account in LCA and CF studies assessing land-based systems. Furthermore, the important issues highlighted in the literature show the necessity of collecting site-specific data on soil-carbon stocks and changes and monitoring these changes over time.

The main objectives of this research were:

- To determine the practical and economic feasibility of monitoring changes in soil-carbon stocks at the field scale in commercial apple orchards.
- To propose guidelines for integrating soil-carbon in LCA, as well as actions for researchers, LCA specialists, businesses and policy makers to enable soil-carbon stock monitoring in agriculture, in order to improve the reliability and credibility of soil-carbon accounting in LCA.

2. Methods

Four commercial apple orchard blocks of different ages (Latitude: -39.588125, Longitude: 176.800076), were intensively sampled for soil-carbon to one meter depth to determine the spatial variability, and to assess the sampling requirements to observe a statistically significant change over time. The four apple orchard blocks of a chrono-sequence were chosen to be as similar as possible, in an effort to minimize non-age differences between these blocks. The apple variety, as well as the rootstocks, the soil texture to one meter depth and the depth of the water table were similar for the four orchard blocks. Furthermore, the management of the orchard blocks was very similar, being integrated fruit production, similar irrigation, and similar treatment at replanting. Finally, the previous land use was similar for the four orchard blocks. All blocks had been converted from grazing pasture and planted with apple trees more than 20 years before sampling, and more than 30 years for the four-year-old block. Figure 1 shows the spatial arrangement of the orchard blocks, to emphasize their proximity.

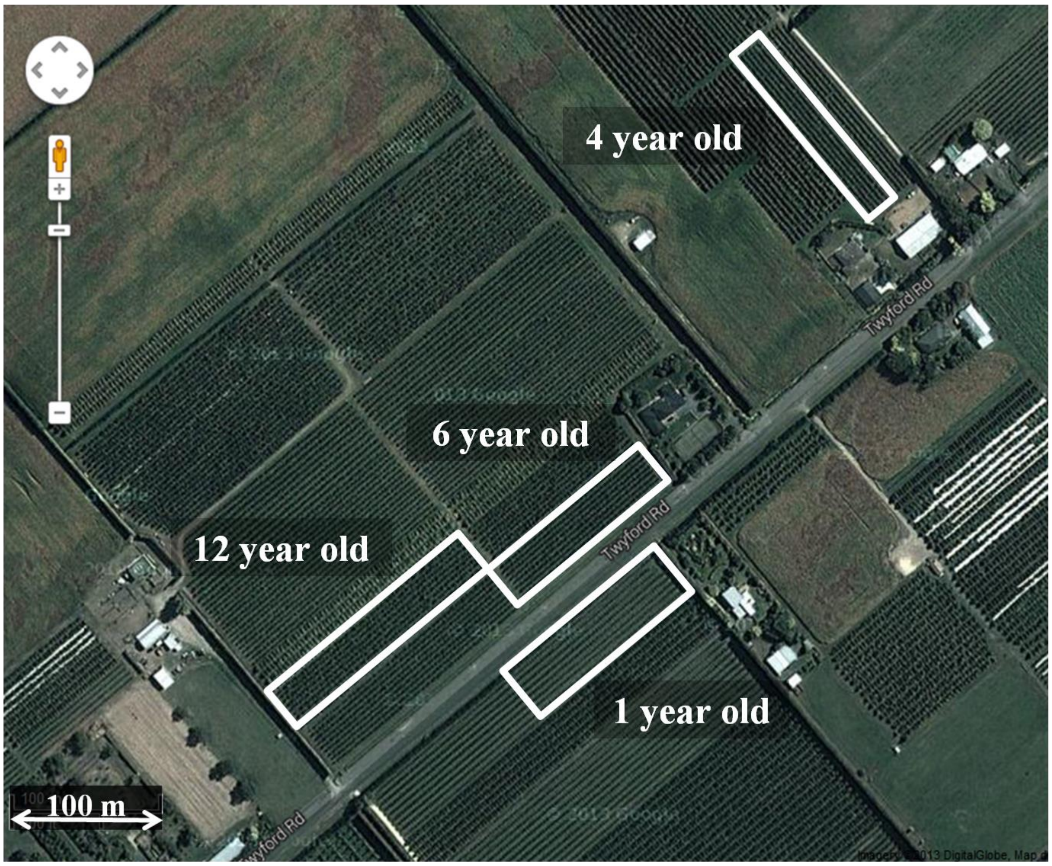

Figure 1: Map showing the proximity of the four orchard blocks. All blocks are within 500m of each other.

2.1. Sampling procedure

Within each orchard block, 10 sampling sites, or clusters, were randomly selected. For each sampling cluster, one bulk density (BD) profile (10 cm depth increments to one meter depth) was sampled. Furthermore, 16 soil samples to one meter depth were laid out in a 4 by 4 systematic grid within each sampling site. All %C samples were collected between 16/04/2012 and 24/08/2012. All BD samples were collected as soon as practicably possible, and within approximately one year of the % C samples. Following collection, all samples were kept in a cold room below 4 °C until further processed. The %C samples were sieved with a 2mm mesh and the fine-earth fraction was sent to a laboratory for total carbon content determination using a LECO TruSpec CN analyser (LECO Corporation, St. Joseph, Michigan, USA). The BD samples were oven dried at 105 °C until constant weight. Stones, roots and pumice rocks were removed and weighed separately for soil bulk density correction, in order to determine the weight of soil per unit volume.

The total carbon stock of the fine earth fraction, $C\ stock$, in tons of carbon per hectare (tC/ha) was determined for each depth increment according to the following formula:

$$C\ stock = BD_{fine\ earth} \times \%C_{fine\ earth} \times depth \qquad \text{Eq. 1}$$

The Genstat software was for the statistical analyses to determine the statistical significance of differences between orchard blocks.

In order to calculate the minimum number of samples, n, to observe a given change, δ, in soil-carbon stocks , and assuming that the same variance is found when re-sampling, the following formula from Steel et al. (1997) was used:

$$n = \frac{(Z\alpha_{/2} + Z_\beta)^2 \sigma_D^2}{\delta^2} \qquad \text{Eq. 2}$$

Here $Z\alpha_{/2}$ and Z_β are the values of the Z table with α the type-I error (statistical significance, α=5%) and β the type-II error (statistical power=1- β=0.8), respectively and where σ_D^2 is the variance of the difference between the two sample sets.

Therefore, the calculated number of samples required to observe a statistically significant change in soil-carbon stocks of 10% over 20 years in the top meter of soil was used to determine the economic feasibility of monitoring changes in soil-carbon stocks at the field scale in commercial apple orchards. The cost of routine minimum sampling (2 sampling campaigns: at year 0 and year 20 and each costing NZ$1590) was balanced against the price of export New Zealand apples at the ship side, taken as NZ$20/ carton equivalent (18kg of apples). The cost of routine minimum sampling was also used to calculate the price that a ton of carbon on the carbon market should reach in order to compensate for the cost of the sampling campaign. This analysis guided the identification of actions for the implementation of soil-carbon stock monitoring, including guidelines of how to take soil-carbon into account in LCA.

3. Results & discussion

3.1. Soil-carbon stocks

As shown in Figure 2, the carbon stock of the top meter of soil did not follow a particular trend along the chrono-sequence i.e. with regard to the time since the establishment of the current apple trees. There was no statistically significant difference at the 5 % level between the 1-year-old, the 6-years-old and the 12-years-old orchard block. This can be interpreted in several ways. First, one can deduce that the differences between soil-carbon stocks over 12 years are too small and the rate of change is too slow compared to the sampling campaign carried out. In other words, not enough samples were taken in order to reach a high enough precision of the average soil-carbon stock for each of the orchard blocks that would allow detecting a statistically significant difference between them. Secondly, it is possible that the four orchard blocks are different in a way not captured by the experiment, even though many factors were thoroughly evaluated to ensure a high degree of similarity between the four orchard blocks. Lastly, it is possible that no change in soil-carbon stocks took place over the twelve years along the chronosequence. In this case, current management practices in these three orchard blocks achieve the maintenance of the soil-carbon stocks over time.

However the soil-carbon stock of the 4-year-old orchard block had a much higher soil-carbon stock than the three other orchard blocks and was therefore significantly different (in a statistical sense) from the other blocks at the 5 % level. This large difference suggests that something happened to this orchard block that is different from the three other blocks. Two phenomena are potentially responsible for this difference. First, the 4 year old orchard block was converted from dairy farming to an orchard at least 10 years earlier than the three other blocks. Due to the fact that root turnover in the soil represents the main input of carbon into the soil, especially at depth (Schmidt et al. 2011), it is possible that having trees on the land for a longer time period favored soil-carbon sequestration. Secondly, a flood occurred in the area in the mid 1980s, and the deposition of alluvial sediments that were probably rich in carbon could have modified the carbon content of the soil, therefore increasing the soil-carbon stock. However, this second possibility remains uncertain, as the apple grower is not sure if the flood reached this part of the orchard block. And so far, no aerial photograph of the area affected by the flood was found.

Finally, the variation in soil-carbon stocks within each orchard block is equivalent to two standard deviations and is represented by the error bars on Fig. 2. It is important to note that this variation can be very different for different orchard blocks, even though the same sampling procedure was carried out on all orchard blocks. This indicates that generalizing a particular level of variation to any orchard blocks, from the four orchard blocks in this study, is not possible. In other words, each orchard block is affected by its specific level of variation, and sampling at this level is necessary in order to estimate it.

Overall, very different soil-carbon stocks with very different levels of variability were found in very similar orchard blocks, situated within less than 500m of each other. This has important implications for soil-carbon monitoring: The site specific factors, including the long-term land-use history for management and natural events means that monitoring soil-carbon stocks should be done specifically at the orchard-block level. Furthermore, using an average for all the blocks, even within one orchard comprising several blocks of various characteristics (variety, rootstock, time since first planting), is most likely to show a variability too high to allow observing statistically significant differences, even over long time periods such as several decades.

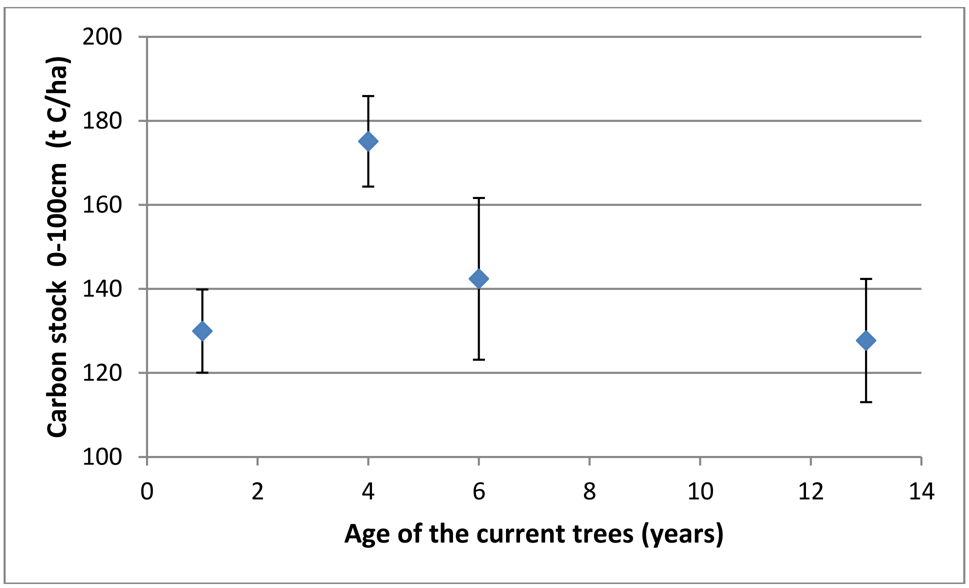

Figure 2: Chronological sequence of the soil-carbon stocks averages of the four orchard block. The error bars indicate two standard deviations (i.e. approx. 95% confidence interval)

3.2. Number of samples required

In order to estimate an indicative minimum sampling effort for monitoring, the 4 year old orchard block was selected for this calculation, as the variability of soil-carbon stocks within this orchard block is the smallest when compared relatively to its carbon stock. In other words, this orchard block has the smallest coefficient of variation in this study. The average soil-carbon stock for this orchard block is 175 tons of carbon per hectare.

In order to detect a 10% change over the top meter of soil, assuming an average rate of soil-carbon stock change of 0.5% per year, only 32 samples would be necessary and arranged in nine clusters with four samples per cluster. [This assumes that when sampling is repeated at the end of the 20 year period, the same level of variability compared to the initial sampling is found within the orchard block, which is uncertain, since root growth over this time period may affect soil-carbon distribution patterns.] However, observing a change of 5 % in the soil-carbon stock under the same conditions would require 240 samples (30 sites, eight samples per sites) for each sampling campaign. This highlights that monitoring soil-carbon stocks can be costly over short (less than 20 year) time periods.

3.3. Feasibility of monitoring

Several assumptions are necessary to determine the cost of sampling. First, it is assumed that a cost of NZ$1590 per sampling campaign can allow observing a change of 10% of the initial soil-carbon stock, and that the soil-carbon stock is measured twice, initially and 20 years later in the same orchard block. Secondly, it is assumed that an orchard block of one hectare that fits the first assumption, produces 50 tons of export quality apples per year from year 4 of the 20 years period. Thirdly, it is assumed that the sampling campaigns are conducted by a trusted independent organization, and no further sampling to verify the results is required. Fourthly, the value of apples at the ship side in New Zealand before export is assumed to be NZ$20 per carton (equivalent to 18kg) of apples.

According to these assumptions, which are believed by the authors to represent roughly the reality, one can calculate the value of a ton of carbon on the carbon market needed to compensate for the cost of monitoring, as well as the cost of monitoring associated with each carton of apples.

Value of a ton of carbon on the carbon market needed to compensate for the cost of monitoring:

$$= \frac{\text{Cost of two sampling campaigns}}{\text{tons of carbon stock change in the soil over 20 years (10\% of 175 tons)}}$$

$$= \frac{1590 \times 2}{17.5} = 182\text{NZ\$/ ton of carbon on the carbon market}$$

Cost of soil carbon monitoring per carton of apples:

$$= \frac{\text{Cost of two sampling campaigns}}{\text{number of cartons of export apples over the orchard block producing life (17 years)}}$$

$$= \frac{1590 \times 2}{\frac{50.10^3}{18} \times 17} = 0.07 \text{ NZ\$ per carton of apples}$$

This simple analysis shows that in order to compensate for the cost of monitoring soil-carbon stocks at the site specific level of an orchard block, relying on the carbon market is unrealistic, as it would require the price of carbon to be at least NZ$182 per ton of carbon. Even the optimistic forecast of the Intergovernmental Panel on Climate Change (IPCC) is based on a value of US$100/ton of carbon, which is roughly equivalent to NZ$120.

However, compensating for the cost of monitoring soil-carbon stocks every 20 years is largely feasible, as the price increase per carton of apples would have to be NZ$0.07, which represents less than 1% of the price of a carton of apples at the ship side. However, immediately this raises the question as to who should bear this extra cost. The benefits of monitoring soil-carbon reach far beyond the orchard, as soil carbon sequestration represents carbon taken out of the atmosphere, as well as improved soil health and fertility which helps keeping land use sustainable. It seems unfair that this cost should fall solely on the apple grower.

4. Conclusions

4.1. Implications for LCA

These results have three major implications for carbon footprint and LCA studies. First, perennial systems such as apple orchards may not always be associated with increases in soil carbon, as nevertheless suggested, for example, by reference documents such as the 2006 IPCC Guidelines for National Greenhouse Gas Inventories[1].

[1] Under Tier one of the 2006 IPCC Guidelines for National Greenhouse Gas Inventories, the combination of soil-carbon stocks change factors relevant to the orchard blocks in this study (perennial cropland management, no till, medium residue input) indicate a carbon sequestration over time.

This study has indicated that no statistically significant change in soil carbon stocks could be observed over twelve years in a chronosequence of three orchard blocks. In addition, a decrease in soil-carbon stocks in perennial orchard systems is unlikely, due to the growth and turnover of tree roots, which represents the main input of carbon into the soil, especially at depth (Schmidt et al. 2011). As a general guideline, then, if site specific data on changes in soil-carbon stocks are not readily available, zero soil-carbon change should be assumed. Secondly, the fact that one orchard block of the chronosequence shows significantly different soil-carbon stocks compared to very similar and proximal orchard blocks demonstrates the high local specificity of soil-carbon stocks, and the high variability that can be presumed to underlie soil-carbon averages for land-based systems that are found in the literature. This suggests that ranges of data should be used to represent soil-carbon stocks and their changes and/or maintenance in LCA and carbon footprint studies. Thirdly, land-based systems that maintain soil-carbon stocks keep carbon out of the atmosphere. It is therefore reasonable to consider that, as well as accounting for changes in soil-carbon stocks, also the maintenance of soil-carbon stocks over time in agricultural systems should be recognized in LCA and carbon footprint studies.

4.2. Feasibility of soil carbon monitoring

Soil-carbon stocks monitoring can be realistically implemented, in the case of New Zealand apples, for less than 1% addition to the price of export apples at the ship side. The industry body seems to be the appropriate stakeholder to coordinate field monitoring and to communicate results to export retailers, because of their close interactions with both farmers and retailers. The implementation of a price premium for apples coming from an orchard block where soil carbon is monitored could be a solution to finance soil carbon monitoring. The cost would not be borne by apple growers, and would not involve politically unpopular measures such as making soil carbon monitoring a requirement for market access.

4.3. Actions for stakeholders to implement soil-carbon monitoring

The following actions would support implementation of soil-carbon monitoring:

- Researchers improve and develop standard, crop-specific, statistically representative, rapid and inexpensive measurement methods to collect data in order to capture the changes in soil-carbon stocks and parameterize biophysical models.
- LCA specialists favor and advocate using site specific, statistically representative soil carbon input data, as well as quantify and report the uncertainty associated with using non site-specific soil-carbon stock data from databases and literature in LCA studies, together with their potential impact on the LCA results.
- Industry bodies introduce and organize monitoring schemes as well as their promotion to export markets.
- Farmers are recognized for their efforts to monitor and maintain soil-carbon stocks.
- Policy makers and retailers facilitate and promote schemes such as price premiums for food products from land based systems involving monitoring, maintaining and improving soil-carbon stocks.

4.4. Guidelines to integrate soil-carbon in LCA

The maintenance of soil-carbon stocks needs to be considered as having a beneficial, rather than neutral, impact on the climate change and soil quality impact categories. Furthermore, using measured, site specific (and geo-localized) soil-carbon stock data in LCA is necessary if meaningful results are sought. Even nearly identical and proximal sites can have very different soil-carbon stocks as a result of different past land use and/or natural events. If this is not possible, and because of the large potential impacts of soil-carbon input data on LCA and CF results, the inherent variability and the uncertainty associated with literature or model estimates of soil-carbon stocks and changes should be quantified and communicated. Finally, these soil-carbon input data should be accompanied by sets of data describing the environmental and management conditions in which they were collected, or, by default, the related assumptions associated with the choice of a particular estimate. This will improve the transparency and the reliability of LCA results of land-based systems.

5. Acknowledgements

The authors would like to thank Massey University and Plant and Food Research Ltd for providing the funding for this research. Two apple growers who contributed time, knowledge and allowed access to and sampling on their properties are also thanked. Two reviewers are thanked for their comments that helped improve this paper.

ABSTRACT

In this paper, we discuss different methods to calculate greenhouse gas field emissions from fertilization and soil carbon changes to be integrated into Carbon Footprint (CFP) of food and biomass products. At regional level, the simple Tier 1 approach proposed in the IPCC (2006a) AFOLU guidelines is often insufficient to account for emission variability which depends on soil type, climate or crop management. However, the extensive data collection required by Tier 2 and 3 approaches is usually considered too complex and time consuming to be practicable in Life Cycle Assessment. We present four case studies to compare Tier 1 with medium-effort Tier 2 and 3 methodologies. Relevant differences were found: for annual crops, a higher Tier approach seems more appropriate to calculate fertilizer-induced field emissions, while for perennial crops the impact on CFP was negligible. To calculate emissions related to soil carbon change higher Tiers are always more appropriate.

Keywords: agricultural production, GHG accounting, regional variability, field emissions, soil carbon change

1. Introduction

During the last decade, the interest of companies and policy makers in Carbon Footprint (CFP) as a supporting tool to assess the global warming impact of food and biomass productive processes and to design impact reduction plans has grown. All greenhouse gas (GHG) emissions occurring within the established boundaries of such a study have to be taken into account, as instructed in the ISO 14067 (2013), the most recent international reference standard for the development of CFP studies.

Land-based CO_2 and N_2O emissions from fertilization and crop residues management can account for a considerable amount in the GHG balance of food and bioenergy products, together with CO_2 fluxes due to soil carbon change (Brentrup et al. 2000; Petersen et al. 2013), but they are often disregarded in CFP studies. IPCC guidelines for National GHG Inventories (IPCC 2006a) provide, within the fourth volume dedicated to Agriculture, Forestry and Land Use sector (AFOLU), three calculation pathways (Tiers) for the accounting of these land-based emissions characterized by different degrees of complexity: Tier 1 level includes the less accurate methodologies, which can be applied by using the provided global emission factors; the Tier 2 level methodologies require using emission factors specific for the region which is subject of the study, while Tier 3 level methodologies are based on measurements or simulations performed by models. The mentioned IPCC guidelines suggests always using a more accurate methodology if possible, and provides decision trees to support the identification of the suitable Tier.

At regional and sub-regional level, Tier 1 level methods are not always sufficiently accurate to account for geographical variation of emissions dependent on different soil, climate or management practices. Conversely, field measurements and extensive data collection required by higher Tiers (Tier 2 and Tier 3) are usually considered too complex and time consuming to be practicable in the development of Life Cycle Assessment (LCA) studies.

The first aim of this paper is to test assessment methods at Tier 2 and Tier 3 level to calculate land-based GHG emissions from crop cultivation with medium efforts for stakeholders. The selected Tier 2 method consists of calculating N_2O emissions from fertilization in consideration of pedoclimatic and crop management conditions based on Bouwman et al. (2002) and the Tier 3 method of simulating CO_2 fluxes occurring as consequence of soil carbon stock change based on Petersen et al. (2013). The second aim is to assess and compare the influence of the variability of regional inventory data on CFP results, depending on the adoption of Tier 1 or Tier 2 and Tier 3 accounting methods. We performed analysis in four case studies: two wheat croplands in Germany and one peach orchard in Italy managed with two different regimes. The choice of case studies was based on different soil characteristics, climate conditions and crop types (annual and perennial), to test how different methodologies may represent this variability.

2. Materials and Methods

2.1. Methodologies for the assessment of fertilization induced emissions on field

The simple IPCC Tier 1 method (IPCC 2006a) for calculating the emission of nitrous oxide (indirect and direct N_2O) from managed soils only takes into account 1% of the anthropogenic N inputs on the field. This approach disregards differences of crop type, fertilizer type, management system and local climate conditions. In contrast, considering all these agricultural relationships to calculate N_2O, NO and NH_3 emissions, the heterogeneity of environmental and management conditions occurring in agriculture would be reflected more accurately.

We have chosen the model approach from Bouwman et al. (2002) for direct and indirect N_2O emissions and the approach from FAO and IFA (2001) for NH_3 volatilization. These methods are more performant on the local scale and under different agricultural management systems to reduce the uncertainty range within the global emission Tier 1 factors (IPCC 2006a). Implementing this Tier 2 approach more detailed data are required. The multivariate empirical model of Bouwman et al. (2002) divides the parameters which have an influence on the N_2O and NO emissions into specific categories (fertilizer type and application rate, crop type, soil texture, soil organic carbon (SOC), soil drainage, soil pH and climate type), for each factor. NO and NH_3 emissions were converted to N_2O based on IPCC (2006a) by the factor 0.01. For the NH_3 emissions induced from organic fertilizer (mature and liquid manure, digestate, poultry manure) we made an exception and used the model approach based on KTBL (2009). CO_2 emissions from the application of urea and liming on soil were calculated based on Tier 1 IPCC (2006a) factors.

2.2. Methodologies for the assessment of emissions from soil carbon stock change

To include the soil carbon change into the CFP accounting the Tier 1 and the Tier 3 methodology have been tested and compared.

The simple Tier 1 is explained in Chapter 5 of Volume 4 (cropland remaining cropland) of IPCC guidelines (IPCC 2006a). The soil organic carbon reference (SOCref) under native vegetation, has to be selected depending on six soil types and nine climate regions, together with three relative stock change factors: F_{LU} related to land use, F_{MG} related to tillage regime and F_I related to carbon input level. These factors are characterized by different error ranges (between ±5% and ±50%) and have to be selected, based on the climate region, for both conditions before and after the management or land use change occur.

The Tier 3 methodology consists in a simulation of the turnover of carbon in soil with the model Roth C 26.3 (Coleman and Jenkinson 1999), integrated with the Bern Cycle Model as suggested by Petersen et al. (2013); the Bern Cycle Model (IPCC 2007) simulates the decay of CO_2 in the atmosphere in order to represent the release of CO_2 into the atmosphere over several years. The outputs of the Roth C simulation are the CO_2 emissions and removals related to soil organic carbon change. The Roth C simulations were run for both scenarios (baseline and changed) for a number of years sufficient to reach the equilibrium (n), and the resulted emissions and removals were divided by the same number of years in order to obtain the yearly figures. The following equation was used to calculate the Tier 3 results:

$$\Delta CO_{2\,(n)}\ [t\ CO_2\ year^{-1}] = [(CO_2\ E_{CS} - CO_2\ E_{BS}) + (CO_2\ R_{CS} - CO_2\ R_{BS})]/n \qquad \text{Eq.1}$$

where $\Delta CO_{2\,(n)}$ represents the net balance of CO_2 in the atmosphere after *n* years, related to crop management change; E_{CS} and E_{BS} are the emissions resulting from soil organic matter decomposition after *n* years, respectively in changed scenario and in baseline scenario; R_{CS} and R_{BS} are the removals resulting from carbon stored in soil after *n* years in the changed scenario and in the baseline scenario.

2.3. Field experiments

Four field trials were selected based on crop type (annual crops and perennial crops), soil and climate conditions. Characteristics of experimental sites are presented in Table 1. The two winter wheat experiments were cultivated as sole-food-crop at two different sites in Germany (Site 1 and 2). They were sown at the end of September after ploughing and harvested in the following summer (end of June), leaving the straw at field. The rate of nitrogen fertilizer was determined site-specifically and split into 50% mineral and 50% organic N-fertilizer (digestate).

The perennial crop field trials were conducted on a peach orchard located in Southern Italy (Site 3). The orchard was divided in two plots, one cultivated with local management practices and one converted to improved management practices. The local management regime consisted of: no tillage, micro-jet sprinkler irrigation, pruning residues mulched and left on field, chemical weed control with glyphosate and mineral fertilization based on experience. The improved management regime introduced some innovative: drip irrigation based on daily water balance, spontaneous grass cover mowed twice per year, precision fertilization based on periodic monitoring of soil nutrient availability and organic fertilization with 10 tons of compost per hectare and year.

We assumed that no land use change occurred in our four case studies, but the cultivation management changed. In the winter wheat case studies the straw management was changed. Before the change all straw was harvested to be used for energy production or animal feeding. However, after the change it was left at field and incorporated later. In peach orchard experimental site managed with local regime the change occurred after the orchard establishment, when pruning residues started to be incorporated in the field instead of being burned (as in the past orchard). In the plot converted to improved management one more change occurred: compost and grass cover were added to the soil to increase the quantity of the carbon input comparing to the local management regime.

Table 1: Characteristics of experimental sites

Site number	**1**	**2**	**3 (Local and Improved)**
Crop	winter wheat (*Triticum aestivum L.*)	winter wheat (*Triticum aestivum L.*)	Peach (*Prunus Paersica*) Variety Big Bang/ GF/677 Trained to delayed vase Layout: 5,50 x 4
Name	Ascha	Dornburg	Scanzano Jonico
Period of data collection	2011-2013	2011-2013	2006-2013
Country	Germany (south)	Germany (central)	Italy (south)
Geographical location	48°59´N 12°39´E	51°00´N 11°39´E	40°14´N 16°42´E
Height above sea level (m)	431	247	16
Soil type	Stagnic Cambisol	Luvisol	Eutric Vertisols
Soil texture	Loamy sand	Silty clayey loam	Sandy clay loam
pH-value	5,1	7,4	7,4
Bulk density (g/cm³)	1,7	1,5	1,5
SOC (%)	0,5	0,5	1,3
Total annual precipitation (mm) (long term mean)	957	582	550
Mean temperature (°C)	8,3	9,6	16,8

2.4. Goal and scope, Life Cycle Inventory and Impact Assessment

Greenhouse gas emissions of the four crop cultivations were investigated according to the standards ISO 14040 (2006), ISO 14044 (2006) and ISO 14067 (2013).

The focus in the case studies was on the agricultural activities during the food production, which is why the selected functional unit was the unit of cropland (1 hectare). System boundaries were fixed from cradle to farm gate, starting with production of all inputs (seeds, fertilizers, pesticides, agricultural machinery and fuels) and ending with harvesting the crop, encompassing all direct and indirect emissions

For peach case studies, the whole life cycle of the orchard has been included within the time boundaries, from the first year of orchard establishment till the last year before removal, coherently with the most common practice of LCA sectorial studies about fruit production from perennial tree crops (Cerutti et al. 2010; Milá i

Canals and Polo 2003). The considered impact category was the Global Warming Potential (GWP) – 100 years with the characterization factors from the "CML, 2001" method (Ecoinvent 2013).

The calculation of CFP have been divided in three main parts: land based emissions from fertilization, CO_2 fluxes from soil carbon change, and all other impacts from agricultural operations.

Consequences of methodological choices have been analyzed by comparing the CFP results based on IPCC Tier 2 and Tier 3 approach with the reference CFP results based on IPCC Tier 1.

3. Results and discussion

Applying the approach from Petersen et al. (2013) it is possible to evaluate if the change in crop management practices results or not in a net saving in terms of CO_2 released to the atmosphere. For the wheat case studies (Site 1 and 2), the CO_2 removed from atmosphere caused by soil carbon stock change is much lower using Tier 3 than using Tier 1. This means that for changes in management practices of annual crops (straw added to soil) the Tier 1 overestimates the benefits in terms of carbon stored in soil (Figure 1 B). This result is determined by the stock change factor related to carbon input level F_I. Performing the calculation with Tier 3, the real quantity of straw added to soil is considered, which results in a lower saving of CO_2 linked to soil carbon stock change. In both case studies of winter wheat (site 1 and 2) the Tier 3 estimates are outside the error range indicated in Tier 1.

For the peach orchard case study the situation is opposite. The amount of CO_2 stored in soil is much higher using Tier 3 than using Tier 1(Figure 1 D). The stock change factors from Tier 1 are not sufficient to represent the real entity of soil carbon change in a perennial crop. Even if the Roth C model does not consider the effect of tillage on CO_2 emission from soil organic matter decomposition, the Tier 3 methodology gives higher results in terms of soil carbon change than Tier 1 in the case of perennial crops. In the peach case studies the results of Tier 3 methodology are inside the error range forecasted for Tier 1.

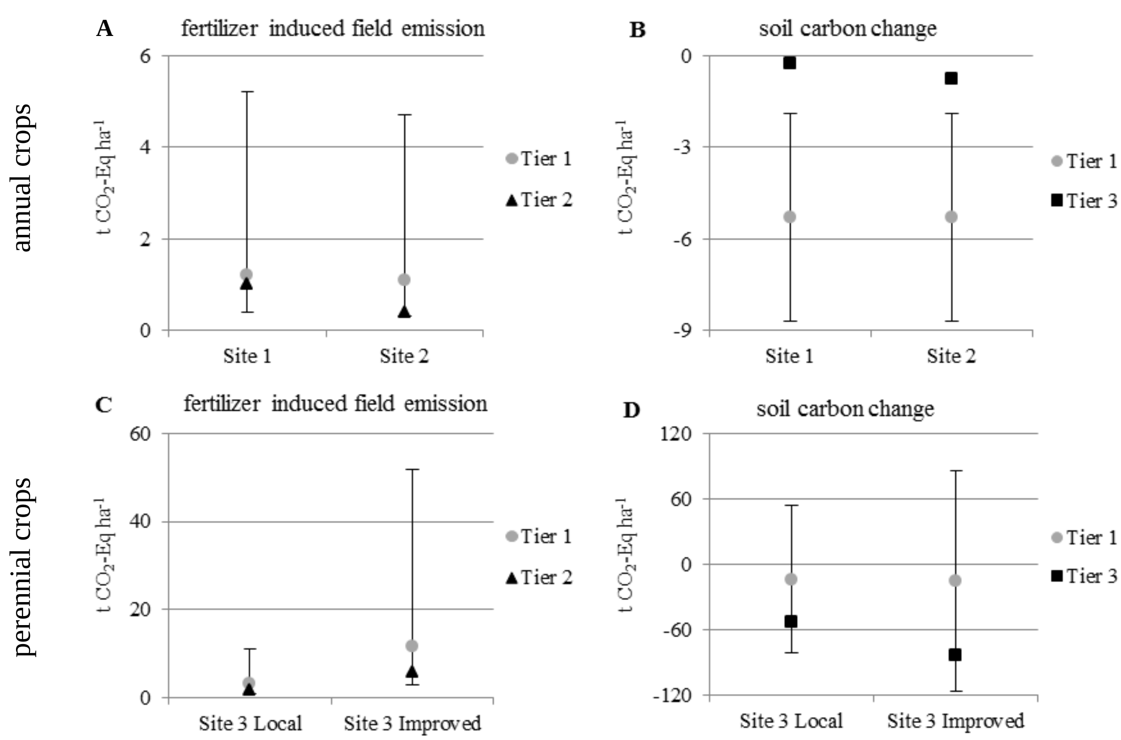

Figure 1. Comparison of the emissions from fertilizer applied on field and soil carbon change calculated with Tier 1 and Tier 2/3 approaches for the four case studies (Site 1 and 2: mean values from two cultivation years at each site, Site 3: values are summed up over 13 years)

For annual crops (wheat cropland), field emission from fertilizer application is an important factor, accounting for almost 50% of the whole CFP-emissions calculated with Tier 1 at Site 1 and 2. In contrast, for perennial crops (peach orchard) the amount of emissions from fertilizer application is less than 25%. Using a higher Tier (Bouwman et al. 2002) to calculate GHG emissions from fertilizer application on field, the CFP is reduced by −8% for wheat production in Site 1, −28% for wheat production in Site 2, −6% for peach production in Site 3 with local management and −12% with improved management. Looking at the Tier 2 fertilizer induced field emissions (Figure 1 A, C), the estimated values are in any case study lower than the Tier 1 approach, and are within the uncertainty range of ~ -70% to +350% reported for the default global emission factor from Tier 1.

As reported in the IPCC (2006a) guidelines, in many cases the global default values (Tier 1) are adequate to determine the field emissions like in one of our wheat case study (Site 1). But in most cases these factors have to be more specified based on environmental conditions (climate and soil characteristics) like in our wheat case (Site 2) as well as on crop management conditions like in our peach cases (Site 3 local and improved management). Considering these fertilizers induced field emissions a higher Tier approach will allow to detect more specific mitigation potentials.

4. Conclusion

We identified appropriate assessment methods on Tier 2 and Tier 3 approach level with medium efforts for stakeholders and explored the consequences of these methodological choices on CFPs of annual and perennial crops for land-based GHG emissions from crop cultivation. The results for fertilizer induced field emission calculation were consistent among studies, using the higher Tier (Tier 2) led to a reduction of the GHG emissions. We have observed that using the Tier 1 approach overestimates the field emissions from fertilization.

To include field emissions related to soil carbon stock change into CFP of agricultural products is challenging. A wide difference was found between results calculated with Tier 1 and Tier 3 methodologies.

A more shared consensus within the LCA practitioners community is needed about how to perform the calculation using higher Tiers, in order to improve the assessment of agriculture´s mitigation potential and support the development of GHG reduction plans in the primary sector. Using the Tier 1 approach can lead to wrong estimations, due to the qualitative nature of the relative stock change factor. This is why we suggest using the Tier 3 approach for perennial crops where CO_2 emission savings related to soil carbon change are more relevant and for annual crops to avoid an overestimation caused by the use of Tier 1.

Variability in methods can considerably affect the CFP from agricultural productions. A harmonization and more transparency in methods are necessary to distinguish between actual differences of case studies and differences caused by methods. For annual crops the higher Tier approach is very important to perform the fertilizer induced field emissions, for perennial crops on the other side the fertilizer induced field emissions have just a minor impact on the CFP. The soil carbon change is negligible because of the short cultivation period of annual crops. However, for perennial crops the soil carbon change should be considered in the CFP. Only a few more site-specific data are needed to perform these higher Tier approaches, which can be used in both methodological improvements.

5. Acknowledgement

The authors want to express their gratitude to the member of the following projects who provided the observed data used for the CFP calculations. “Development and comparison of optimized cropping systems for the agricultural production of energy crops” (FKZ 22013008), funded by the German Federal Ministry of Food, Agriculture and Consumer Protection through the Agency of Renewable Resources (FNR) and

ABSTRACT

Odorous emissions are a key concern for intensive livestock industries, wastewater treatment and other industries due to growth and increasing overlap with urban areas. Relatively little effort has gone into the development of methods for odor within the field of life cycle assessment (LCA). Traditionally, the mass of gas emitted and its detection limit by humans are considered. So there is a simple effect model, but no transport model. Detailed approaches for odor transport modeling exist outside LCA but they are difficult to apply in strategic environmental assessments. To support debate around the development of a midpoint indicator with transport aspects for odor, we calculated characterization factors for an "odor footprint", using data on the rates of diffusion and reaction to model persistence and spreading. We suggest that a simplified approach to transport modeling is reasonable within the LCA context.

Keywords: odour, footprint, midpoint

1. Introduction

Many food production systems involve components that generate odor, particularly those where animal wastes are involved. Management systems for some textile factory wastewaters, sewage, sludge and other organic materials have similar challenges exacerbated by urban encroachment. Odor entering domestic and commercial buildings reduces the amenity of indoor working and home environments. Strategic environmental comparisons between production systems or between odor management systems should preferably take odor into account but approaches for doing this in a life cycle assessment (LCA) framework have received little developmental attention over the last 20 years. Perhaps the first attempt was described in the original "Guide and Backgrounds" to LCA (Heijungs, 1992) where odor threshold values (OTVs) were the key element in a life cycle impact assessment (LCIA) for "malodorous air", a characterization approach based on critical volumes. The OTV is the concentration ($kg.m^{-3}$) at which a chemical is detectable by 50% of the population. Thus, for the mass *m* of each odorant *i*:

$$\text{malodorous air} = \sum_i \frac{m_{i,air}}{OTV_{i,air}}$$

What this means is that an emission of a mass of an odorant is characterized as the volume of air it would occupy if instantly diluted to its OTV. Heijungs (1992) proposed that this could be the basis for future development of a "smell creation potential" indicator, including transport and fate considerations. But this has been a long time coming: Heijungs' original approach and the 60 characterization factors (CFs) he obtained from an older document (Roos, 1989) were duplicated in the subsequent Nordic LCA guidelines (Nord, 1995) and the updated Backgrounds document (Guinee, 2002). The method is suggested (without providing data) in the popular Hitch Hiker's Guide to LCA (Baumann and Tillman, 2004). The recent International Life Cycle Data System (ILCD) Handbook (JRC, 2010), does not provide any guidance on odor, so the most recent consensus guidance documents on odor use a life cycle impact assessment (LCIA) approach that has not changed in 22 years, using data which is 25 years old. One could call Heijungs' method the established approach since it has been reproduced as described, and has been used in several LCAs, but with the qualification that no odor method has been widely applied in the LCA literature.

Perhaps the most interesting thing to happen recently in this area is a proposal to modify the USEtox model as a basis for fate modeling of odorants (Marchand et al., 2013). USEtox is a consensus-based box-model for the calculation of LCIA factors for chemical contaminants, but it is feasible to extract steady-state concentrations for different atmospheric compartments from it and compare these with OTVs. Marchand's proposal involves a number of adjustments to the environmental descriptors in the standard USEtox model to make it more relevant to the environmental assessment of a particular local area. It also suggests OTVs should be placed on a fuzzy scale, with potential effects below the nominal OTV. Another innovation on Heijung's approach was the suggestion that the ultimate odor burden be expressed in terms of 11 different midpoint indicators, one for each different type of smell (sweet, rancid, fecal etc.).

Balancing parsimony with accuracy is an important consideration in the development of LCIA (Hauschild et al., 2008). It is a consideration which is the more challenging when LCIA attempts to characterize emissions with local (as distinct from global) impacts. To encourage further discussion around this balance, the aim of this work was to develop a simple method for odor midpoint assessment in LCA.

2. Methods

We considered the cause-effect sequence between emission of an odorant and the reduction of the value of the protection objects typically included in LCA: human health, ecological systems and resources (e.g.: Kounina et al., 2013). That overview suggested the potential for a midpoint of "odor footprint" which does not represent the actual area disturbed by odor, but the relative potential of different emissions to cause odor problems. A more detailed description of the method will be provided in a journal article recently accepted after peer review (Peters et al., 201x) but salient details are summarized here.

The key decision to be made in developing an odor LCIA method may be what approach to take to wind dispersion. In normal odor dispersion modeling as applied to the assessment of single and mixed odorants, wind speed is a key input in the calculations and also determines dispersion parameters. The time step in the input meteorological data and subsequent modeling may be hours or even shorter intervals. Such dispersion models are commonly used in regulatory and detailed design processes, for example when decision-makers need to assess whether a particular emission will affect a particular urban area. We felt a simpler approach could be justified in an LCA context, as illustrated in the following example. Imagine that a landowner is considering construction of a facility on her land and commissions an LCA comparing production system 'A' which emits odorant 'X' and system 'B' that emits 'Y'. In either case, the same wind will blow, so the diluting effect of the wind on 1 kg of X or Y will be the same. On the other hand, degradation and diffusion rates, and odorant potency (OTV) may distinguish the impacts of X and Y, as these are based on inherent chemical properties. Since LCAs are often performed to compare alternatives, making a *relative* odor impact scale relevant, we chose to take these three factors into account and exclude wind. This will not replace the need for absolute assessments based on dispersion modeling for environmental regulation or detailed design, but may fill the need for strategic LCA assessments.

The approach to odor modeling in this article is illustrated by Figure 1. An initial mass of 1 kg of odorant is assumed to be uniformly distributed within a 1 m diameter hemisphere at ground level (the dashed volume outline in the figure). The gas is allowed to diffuse radially (path 'a' along axis 'r' in the figure), thus the land area at which the concentration exceeds the OTV increases. The increase is counteracted by simultaneous degradation reaction with hydroxyl radicals. Although certain gases may react with other anthropogenic and natural gaseous reagents, the most important route for the destruction of organic odorants is reaction with hydroxyl radicals (Kwok and Atkinson, 1995). The area exceeding the OTV reaches a maximum radius (the solid outline) and then collapses back to the origin (path 'b') due to the continuing degradation process.

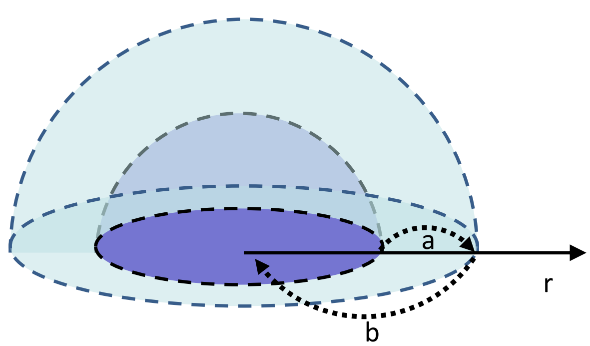

Figure 1. Odor modeling approach

For the calculations, OTV values were taken from Nagata (2003) who measured values for 223 gases using the triangle odor bag method. We obtained estimates of k_{OH} from the NIST database (Manion et al., 2008) and estimated D, the Brownian diffusion coefficient, using Fuller's method (Onken et al., 2008). Atmospheric pressure and 25°C were assumed, consistent with a typical daytime value of the atmospheric concentration of hydroxyl radicals [$^{\cdot}OH$] of 1.5 x 10^6 molecules.cm^{-3} (Allen, 2001). Computational modeling was implemented in Matlab® version 2012a.

3. Results

Figure 2 shows an example of the model output. Hydrogen sulfide diffuses approximately twice as fast as methyl ethyl ketone, and its OTV is a factor of 2000 lower. Both of these factors lead to the steeper, taller curve. The degradation rate of methyl ethyl ketone is a quarter of that of hydrogen sulfide, leading to the longer persistence of concentrations exceeding the OTV. The integral of the curve is the cumulative area x time the OTV is exceeded, i.e. the odor footprint.

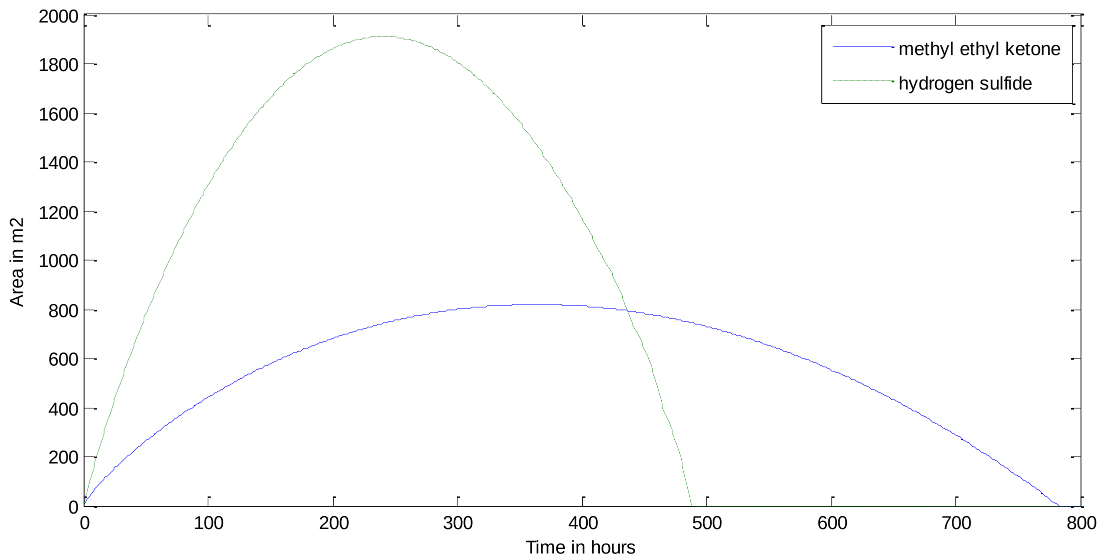

Figure 2. Illustration of footprint growth and decay over time

We have calculated characterization factors for 33 key odorants prioritized on the basis of their presence in LCA literature and the literature on emissions from agriculture and wastewater treatment (Peters et al., 201x). Two of these results are shown in Table 1. As can be seen from this table, the relative significance of a kilogram of the two contaminants is quite different if the analyst was to use Heijungs' method: a kilogram of hydrogen sulfide is equivalent to a volume of "malodorous air" 2267 times greater than a kilogram of butanone, while the odor footprint of the hydrogen sulfide is only 46% larger. The difference in these relationships is due to the more rapid decay of hydrogen sulfide which the new method considers.

Table 1. Sample results from characterization factor estimation

Parameter	**OTV**	**D**[1]	**k_{OH}**	**Odor footprint**	
Odorant	$g.m^{-3}$	$m^2.s$	s^{-1}	m^2s	kg H_2S-eq.kg^{-1}
Hydrogen sulfide	$5.72 x 10^{-7}$	$2.31 x 10^{-5}$	$7.05 x 10^{-6}$	$2.30 x 10^{9}$	1.00
Butanone (methyl ethyl ketone)	$1.30 x 10^{-3}$	$1.29 x 10^{-5}$	$1.80 x 10^{-6}$	$1.57 x 10^{9}$	$6.83 x 10^{-1}$

[1] Diffusion coefficient

4. Discussion

The expression “midpoint indicator” does not exactly describe the location of an indicator on the cause-effect chain between an emission and an impact on a protection object. Both the established metric for odor LCIA of Heijungs (1992) and the recent proposal of Marchand et al. (2013) could be called midpoint indicators, given that neither of them computes an output that is expressed in the terms of common endpoint indicators for human health (e.g.: DALYs), ecosystem quality (e.g.: PDF.m^{-2}.$year^{-1}$) or resources (e.g.: MJ). As suggested by Table 2, our proposal lies somewhere between these two in terms of the level of detail used in the modeling. An analogy can be made between our proposal and the characterization factors for the popular ”carbon footprint” indicator, which do not predict potentially nonlinear consequences of climate change like species extinctions and human fatalities due to sea-level rises, but rather a change in radiative forcing – the gases’ relative potential to cause these effects. This odor footprint model compares odorant’s relative potential to affect air quality, rather than the likelihood of a particular, geographically defined receptor being disturbed.

Table 2. Comparison between established and more recent proposals for odor LCIA

	Heijungs, 1992	Marchand et al., 2013	This proposal
Output	Single indicator: “malodorous air” in m^3	11 indicators (kg-equivalents) based on a key odorant for different smell types	Single indicator: “odor footprint” in kg H_2S equivalents
Transport model	Gas dilutes instantly to OTV	Modified USEtox approach including degradation and removal by a constant wind.	Considers degradation and diffusion
Effect model	Comparison with OTV	Fuzzy interval (uniform factor of 1000) as a safety margin for effects below OTV	Comparison with OTV
Practical operation	Elemental flows easily divided by characterization (OTV) factors	11 factors adjusted in USEtox spreadsheet for each emission location. Model run for each odorant at each location. Steady-state concentrations extracted individually for comparison with effect model.	Elemental flows easily multiplied by characterization (odor footprint) factors.

The new approach we propose has the advantage over Heijungs’ approach of considering the temporal aspect of odorant impact and the advantage over Marchand’s approach of simpler implementation. The question we would like to answer in future research is whether modification of USEtox to describe odorant dilution at a facility and local scale is more meaningful and/or accurate than our simpler approach. Marchand provides an example based on ethylbenzene emissions from a composting facility, which includes initial dilution in a tall rectangular airspace 50 m square at the base and 240 m high, before subsequent dilution in a 6 km square and 1 km high, the latter “based on the average dispersion area of odorous compounds”. In practice, the steady-state concentrations in the facility and local USEtox compartments are directly inversely proportional to volume. On the other hand, if one tests the sensitivity of USEtox by halving and doubling wind speed, rain rate or temperature (factors which Marchand suggests are the most sensitive) a much smaller effect on the steady-state concentration in the local air compartment is observed. This suggests that if adjustments are made to the scale of USEtox compartments in future studies which are not justified by first performing detailed odor dispersion modeling, then comparisons of odorous systems using the results generated by USEtox are unlikely to be more accurate than they would be using the proposed odor footprint method. Alternatively, if detailed odor dispersion modeling is performed for scaling purposes, there may be no need to assess odor in an LCA framework.

Another matter to consider when implementing any of the methods is the appropriate source of OTV data. The available OTV data has been augmented considerably since 1989. Furthermore, a transcription error occurred during production of the Nordic Guidelines (Nord, 1995) so the values in the bottom half of the list in the Guidelines are too large by a factor of 1000. So even if an analyst wishes to use Heijungs’ method, it would be more appropriate to use it with the Nagata (2003) values. For example, in comparison to the data shown in Table 1, the original values of the OTV for hydrogen sulfide and butanone are quite different, 4.3×10^{-7} and 6.8×10^{-4}

$g.m^{-3}$, respectively. The new compilation is superior compared to other available compilations of olfactometry results because the OTVs are corrected for recovery of single compounds and losses in the dynamic olfactometer are avoided (Hansen et al. 2013). Additionally, unlike other compilations of OTVs, the Nagata data all are obtained in the same lab using the same method. These factors are reasons why recent work on OTV prediction by Abraham et al. (2012) is also based on the data we obtained from Nagata (2003).

5. Conclusion

The established method for odor assessment in LCA effectively places emphasis on the detectability of an odor by the human nose. No consideration for the persistence of an odor impact is made. Our proposal is a way of including persistence in LCIA of odorants and gives more weight to slower reagents. We suggest that in practice, alternatives using USEtox to model odors for LCA purposes may lead either to unnecessary work or false precision, depending on whether or not the analyst has previously implemented site-specific dispersion modeling to assist in setting local parameters in USEtox.

The key difference between the LCA odor footprint proposed here and local odor impact prediction using dispersion models is that the disposition of sources and receptors is not known in LCA, so the influence of wind is excluded – the dispersion effect of wind dilutes all odorants equally. So while an odor footprint will not predict impacts which are particular to a site or climate (endpoint modeling), it is an improvement on the traditional LCA approach for ranking odors.

ABSTRACT

Two approaches, nutritional and multi-criteria sustainability, were combined to define Life Cycle Assessment (LCA) of Slow Food Presidia in a new way. Chemical and bromatological evaluation of several plant and animal Presidia products were compared to traditional Italian bromatological references. To assess sustainability, producers were interviewed on four objective areas: environmental, economic, social and cultural. The gathered data were used to value Presidia.

Keywords: Food LCA, Sustainability, Slow Food Presidia Nutritional Value

1. Introduction

Slow Food is a global, grassroots organization, founded in 1989 to prevent the disappearance of local food cultures and traditions. It is also intended to counteract the fast pace of life and people's dwindling interest in the foods they consume, including their sources, production, and how their choices affect the world around us.

Since its inception, Slow Food has grown into a global movement involving millions through its activities:

- saving endangered foods and defending gastronomic traditions through biodiversity projects;
- teaching food pleasure and how to make good, clean, and fair choices through food and taste education;
- connecting young people passionate about changing the food system via the Slow Food Youth network;
- organizing countless daily activities for local Slow Food member groups (convivial) on food, the environment, and food-related sustainability;
- linking food producers, chefs, academics, and community representatives across the world through the Terra Madre network;
- creating the next generation of food and gastronomy professionals at the University of Gastronomic Sciences.

The Slow Food Foundation for Biodiversity was founded in 2003 to support Slow Food projects, defending food biodiversity and traditions. The Presidia project started in 1999 with a recording of hundreds of products facing extinction through the Ark of Taste. Thereafter, Slow Food engaged the production side of the foods (the where, how, and who) to promote the products, work, and wisdom.

The Presidia sustain their production quality while risking extinction of their unique regions and ecosystems, traditional processing methods, native breeds and local plant varieties. There are more than 200 Presidia in Italy and more than 170 International Presidia, involving 2500 small-scale fishers, butchers, shepherds, cheese makers, bakers, and pastry chefs.

2. Methods

2.1. The project

Since 2009, the Slow Food Foundation for Biodiversity (SFFB) in collaboration with Turin and Pollenzo Universities and the Chemical Laboratory of the Chamber of Commerce of Turin, has started a process of chemical and bromatological evaluation of some plant and animal Presidia products. They were compared to usual Italian bromatological references in IEO and INRAN tables.

In 2012, a collaboration of the SFFB, University of Turin, and University of Palermo studied the sustainability of a significant sample of European Presidia from three points of view: agri-environmental, socio-cultural, and economic. Four areas were investigated: environmental (biodiversity preservation, food production sustainability increase, economic (producer income rise, locally-driven activity development, employment increment), social (producer social role improvement, organizational skill consolidation, self-esteem increase), cultural (producer cultural identity consolidation, production area promotion).

Life Cycle Assessment of Presidia food products to determine their value utilized an approach that considered the entire supply chain: before, during, and after food production. To this end, Presidia products were evaluated from two different perspectives: nutritional and multi-criteria sustainability.

Four Italian Presidia were selected for analysis based on food category and available comparative literature: 'Lenticchia di Ustica', a lentil (legume) grown on an island of Sicily; 'Ramasin di Pagno della Val Bronda', a plum grown in southwest Piedmont; 'Manna delle Madonie', natural sweetener harvested from the bark of tree Fraxinus tree in Sicily; and 'Culatello di Zibello,' a crude ham from Parma.

2.2. A model of sustainability

The assessment of the socio-cultural, agri-environmental, and economic aspects of 47 of the 269 European Presidia was performed between 2000 and 2012. Presidia were selected according to risk of extinction, social sustainability, small-scale production, history, and culture.

Four areas were analyzed: environmental (biodiversity defense, food production sustainability improvement), economic (producers' income, locally driven activities development, employment increase), social (producers' role, organizational skills and self-esteem) and cultural (strengthening producers' cultural identity and promoting production areas).

They were clustered into three scales (socio-cultural, agri-anvironmental, and economic) on the basis of an assessment grid discussed and formulated by agronomists, sustainability experts, and producers. Each scale had 10 indicators that, when maximized, reached a score of 100. As an example, biodiversity was analyzed according to variety, processing tecnhnique, landscapes, seeds and intercropping. Soil and water analysis was based on rotation, irrigation, fertilization, organic fertilization; crop protection included pest and disease protection, natural pest and disease protection, weed control, natural weed control, post-harvest treatments, natural post-harvest treatments, certification; energy took into consideration renewable energy and packaging. Each indicator had a different measurement unit (yes/no - % of farms, % producers)

The Slow Food motto of "good, clean and fair" food, formed the basis of each scale. "Good and fair" parameters were mainly considered by the socio-cultural scale (taste, sustainability, link to local culture), "clean" parameters were included in the agri-environmental scale (risk of extinction, soil and water, energy, crop protection), and "fair" was also used by the economic scale (development, efficiency).

Total sustainability was analyzed over time, where T_0 represented the initial status of the Presidium and T_1 represented their status in 2012.

2.3. Nutritional evaluations

The main purpose of this part of the study was chemical analysis of Slow Food Presidia to understand if different production methods, both for animal and plant foods, could lead to different nutrient profiles. A few papers have, in fact, shown preliminary data as to the influence of seeds (native versus traditionally or genetically-modified), space (open versus greenhouses), and production type (small-scale versus intensive) on the final food.

Many of the nutritional components analyzed for each Presidium were common among the foods, but others differed according to food category. Table 1 lists the products and analyses performed for each.

Table 1. Components analyzed for each Presidium product considered.

Component	Lentil	Plum	Sweetener	Ham
Proteins	✓	✓	✓	✓
Carbohydrates	✓	✓	✓	✓
Sugars	✓	✓	✓	✓
Starch	✓	✓		
Polyalcohol (mannitol)			✓	
Dietary fibre	✓	✓		
Fats	✓	✓	✓	✓
Saturated fatty acids				✓
Monounsaturated fatty acids				✓
Polyunsaturated fatty acids				✓
Cholesterol				✓
Calcium	✓	✓		✓
Iron	✓	✓		✓
Phosphorous	✓	✓		✓
Magnesium	✓	✓		✓
Potassium	✓	✓		✓
Sodium	✓	✓		✓
Vitamin C		✓		
Flavouring		✓		

All nutritional analyses were performed in the Chemical Laboratory of the Chamber of Commerce in Torino, Italy over a four-year period (from 2008 till 2012). Table 2 displays the methods used for each analysis.

Table 2. Analytical method used for component analysis of Presidia tested.

Component	Analytical method
Proteins	Kjeldahl Method (ISO 1871:2009)
Sugars	HPLC (high performance liquid chromatography) Electrochemical Detection
Starch	Enzymatic-Spectrophotometric Method
Dietary fibre	Enzymatic-Gravimetric Method (AOAC 985.29)
Fats	Official methods such as Soxhlet Extraction after Acid Hydrolysis
Fatty acids*	Gas-chromatography of methyl esters of fatty acids (ISO 5508:1990 (E) + UNI EN ISO 12966-2:2011)
Cholesterol	HPLC (high performance liquid chromatography)
Minerals**	ICP-AES (Inductively coupled plasma -Atomic Emission Spectroscopy)
Vitamin C	Spectrophotometric method
Flavoring	HS-GC-MS (Head Space Gas Chromatography Mass Spectrophotometry)

* Fatty acids including saturated, monounsaturated, and polyunsaturated fatty acids.
**Minerals including calcium, iron, phosphorous, magnesium, potassium and sodium.

Following the analyses, study results were compared to bromatological values of similar foods reported in IEO and INRAN literature. The comparison was not possible for ‘Manna delle Madonie’ as its traits are not available in the literature.

3. Results.

3.1. ‘Lenticchia di Ustica’

These tiny, dark brown, tender and flavorful lentils grow on the fertile volcanic soil of the island of Ustica. They must be soaked and then cooked for 45 minutes.

The Presidium was launched in 2000 from a point of very good performance. Nevertheless, it attained excellent scores due to the impressive interest and involvement it attracted by young people, as well as its good defense of cultivation, soil, and water. By T_1, post-harvest chemical soil treatments against weevils had been replaced with cold treatments and all producers were adopting organic practices (Figure 1).

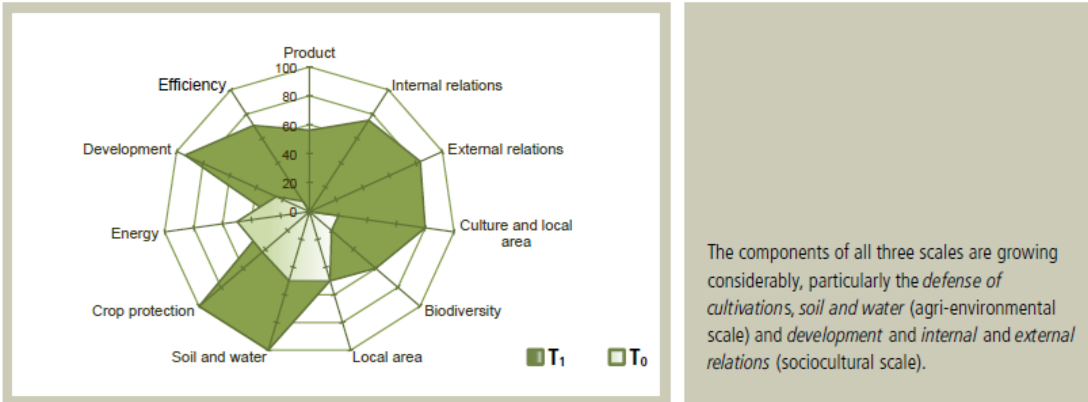

Figure 1. Sustainability performances of ‘Lenticchia di Ustica’: T_0 = initial status of Presidium, T_1 = 2012 status

The results describing the nutritional quality of the lenticchia are displayed in Figure 3. The dietary fiber of ‘Lenticchia di Ustica’ is more than double that of other lentils, which led to a reduced energy value and carbohydrate content. Furthermore, the high Iron content in the Presidium results in a single serving (about 60 g) providing 5.4 mg of iron, or almost 50% of the RDA.

Table 3. Summary of results comparing ‘Lenticchia di Ustica’ and standard lentils (per 100 grams)

	Lenticchia di Ustica	**Lentils**
Energy value (kcal)	252	291
Proteins (N x 6,25) (g)	27,7	22,7
Carbohydrates (g)	32,6	51,1
Fats (g)	1,2	1,0
Starch (g)	29,82	44,8
Sugars (g)	2,78	1,8
Dietary fiber (g)	30,22	13,8
Iron (mg)	9	5

3.2. ‘Ramasin della val Bronda’

The small, dark, and very sweet ‘Ramasin della val Bronda’ plum is familiar to many in the Piedmont (region in northwest Italy), but it is relatively unknown in the other Italian regions. It is a traditional fruit that was typically found along the borders of family orchards.

The Presidium started its activity in 2007 with a very low initial score, but the 2012 evaluations found interesting levels of efficiency and sustainability. The producers now sell their products both fresh and processed (in jam and spirits), promote them collectively, and two producers among the six are women. Organic agriculture has been only partially adopted to-date, and the packaging still requires improvement (Figure 2).

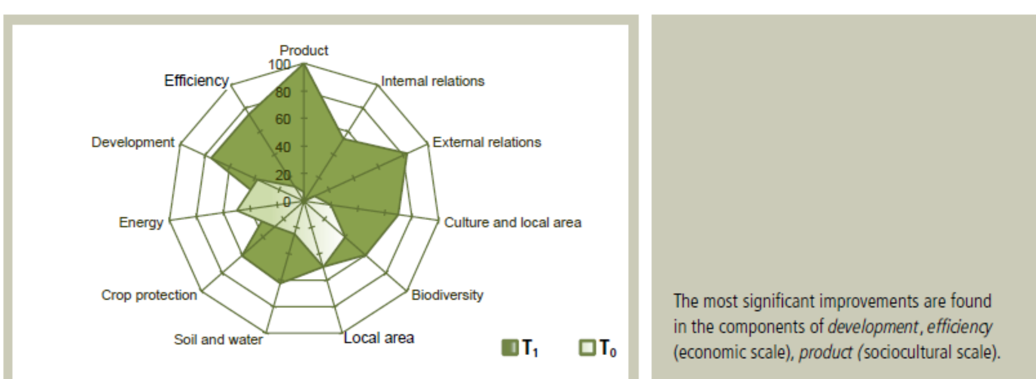

Figure 2. Sustainability performances of ‘Ramassin della Val Bronda:’ T_0 = initial status of Presidium, T_1 = 2012 status

The results of the nutritional quality analysis of the Ramasin are summarized in Table 4. The 'Ramasin di Pagno della Val Bronda' plum is richer in dietary fiber (seven-fold higher) and vitamin C (more than two-fold) compared to the reported standard values for plums. The measured flavoring components explain the organoleptic character that improves the consumption of this fruit.

Table 4. Summary of results comparing 'Ramasin della Val Bronda' and standard plum (per 100 grams)

	Ramasin della Val Bronda	**Plum**
Energy value (kcal)	41	42
Proteins (N x 6,25) (g)	0,7	0,5
Carbohydrates (g)	9,6	10,5
Fats (g)	< 0,10	0,10
Starch (g)	< 0,10	< 0,10
Sugars (g)	2,8	1,8
Dietary fiber (g)	7	1
Phorsphorus (mg)	19	14
Vitamin C (mg)	9,4	5

3.3. 'Manna delle Madonie'

'Manna' is obtained from a resinous substance extracted from the bark of ash trees in Castelbuono and Pollina (Madonie mountains, Sicily), which dries rapidly to form white tubes. It is used as a natural sweetener and has very low glucose and fructose content.

The Presidium, launched in 2002, has improved in its harvest technique. Purity and quality are now continuously monitored and the use of metal wires hung on branches to collect the manna (*versus* manna flowing down the bark) has reduced impurity levels.

Many producers are very young (seven among the 10 are under 35 years). Sustainability, already very high, has remained unchanged even with improved harvest techniques. The quantity of 'manna' produced has increased from 100 to 450 kg/year (Figure 3).

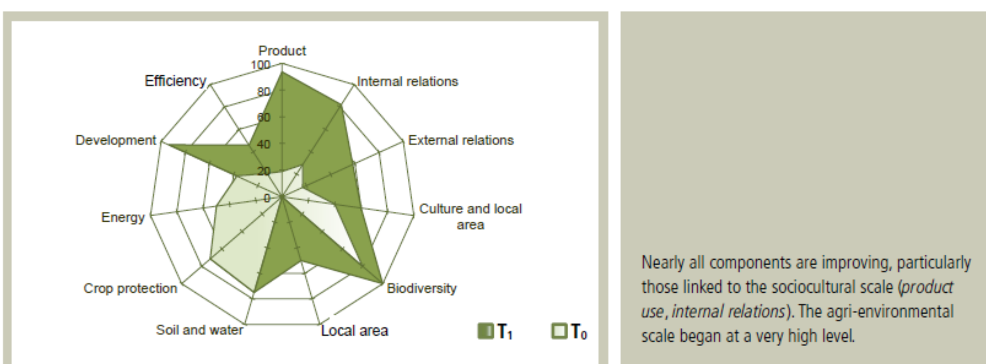

Figure 3. Sustainability performances of 'Manna delle Madonie:' T_0 = initial status of Presidium, T_1= 2012 status

The results describing nutritional quality of manna are mentioned in the Table 5. The 'Manna delle Madonie' main characteristic is its high mannitol and low soluble sugar contents which result in a reduced energy value, but conserved sweetening power.

Table 5. Summary of results 'Manna delle Madonie' (per 100 grams)

Energy value (kcal)	**176**
Proteins (N x 6,25) (g)	< 0,10
Carbohydrates (g)	64
Fats (g)	0,3
Polyalcohol (D-mannitol) (g)	53
Sugars (g)	11

3.4. 'Culatello di Zibello'

'Culatello di Zibello' is among the most highly regarded Italian cured meats due to its long and delicate processing and prized cut of pork. The heritage and richness of the cured ham is amplified by the peculiar climate of the foggy flatland from which it comes near the Po River. The right aging is a key element that has been passed on for generations. The ham embodies the history of a land, a people's tradition, and the particular climate.

In the Protected Designation of Origin (PDO) production, which is mainly industrial one, great efforts have been made in recent years to differentiate traditional producers. In the case of 'Culatello di Zibello,' it has been improved in several ways: it is GM-free, it has shown strong growth on the sociocultural scale, and it has maximized its local area score (agri-environmental) (Figure 4).

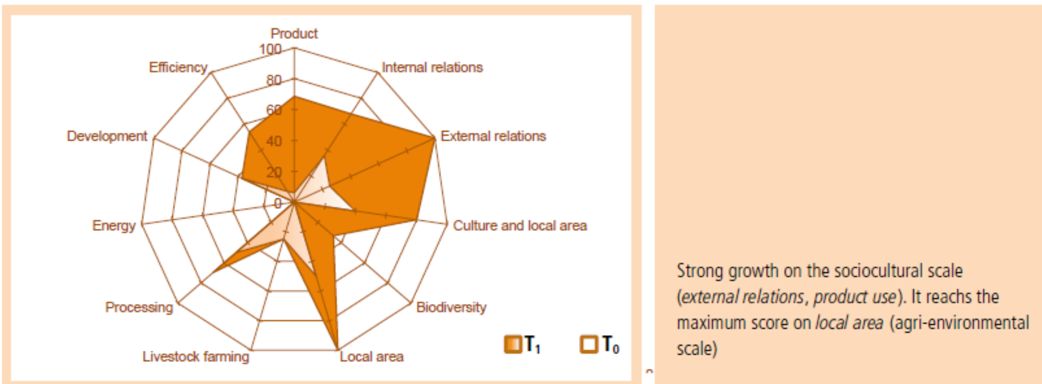

Figure 4. Sustainability performances of 'Culatello di Zibello:' T_0 = initial status of Presidium, T_1 = 2012 status

The analysis of the nutritional components of 'Culatello di Zibello' compared to other cured hams as displayed in Table 6 shows that is a protein-rich animal product. Its monounsaturated fatty acid content is higher than in other crude hams, and its cholesterol value is lower. These characteristics make 'Culatello di Zibello' very similar to low-fat bovine and ovine meat. Other positive qualities are its low sodium content and high phosphorous and potassium contents.

Table 6. Summary of results comparing 'Culatello di Zibello' and standard crude ham (per 100 grams)

	Culatello di Zibello	**Crude ham**
Energy value (kcal)	404	370
Proteins (N x 6,25) (g)	29	22
Carbohydrates (g)	< 0,10	< 0,10
Fats (g)	32	31
Saturated fatty acids (g)	11	10
Monounsaturated fatty acids (g)	16,2	13,9
Polyunsaturated fatty acids (g)	4,4	3,8
Sugars (g)	< 0,10	< 0,10
Cholesterol (mg)	72	92
Sodium (mg)	1544	2378
Phosphorous (mg)	320	177
Potassium (mg)	646	281

4. Discussion

Lifestyle and nutrition health indicators show a pandemic of obesity, type-2 diabetes, some cancers, and many chronic degenerative diseases, including Parkinson's and dementia. Given these data, it is no surprise that there is an increased consumer demand for healthier food choices. While fortified and deeply transformed foods can augment the intake of protective nutrients (fibers, antioxidants, chemo-protective substances, healthy fats, and more), their taste and other aspects often take them far from natural, traditional, and local food products. On the other hand, local and traditional certified foods often suffer from a lack nutritional and bromatological data. Furthermore, there is an increasing concern about the ecological footprint of food. How best to combine sustainability, health, and pleasure deserves consideration. Slow Food Presidia responds to this issue through its focus on several crucial sustainability issues of local communities: small-scale agriculture and farming, mountain pasture protection and pastoral farming, traditional landscape defense, traditional seed selection and propagation by communities, animal welfare, transparent labeling and ecologically sustainable packaging.

Nutritional quality analysis of Presidia confirms a strong consumer health orientation and suggests a new global 'health-oriented LCA' approach. Understandably, the approach is limited to small productions that represent a very small percentage of world food production. However, Presidia present an interesting paradigm that can be applied to other small-scale productions in order to promote LCA analysis in less-industrial settings while taking into account holistic gastronomic aspects that are sometimes forgotten in such studies.

5. Conclusions

The combined approaches represent an interesting example of Life Cycle Assessment (LCA) of food. In order to consider the global impact on the well being of both land and people, the nutritional aspect must be included alongside the usual sustainability markers.

Slow Food Presidia products (both plant and animal foods) performed at high levels of global sustainability and demonstrated extra nutritional value. Our work suggests that when a nutritional evaluation is combined with traditional LCA social, agri-environmental, and economic aspects, an innovative tool emerges that help small scale producers improve product characteristics, as well as support and promote traditional gastronomic activities. Furthermore, the food—health relationship must be considered with a multifactorial approach that encompasses producers, consumers, communities, and environment.

ABSTRACT
So far, land use impacts in life cycle assessment have only been considered in the context of ecosystem quality and ecosystem services. However, in a manner similar to water consumption, land use has the potential to impact food production and thereby human health. In this paper we develop a model to quantify food production losses due to land use and combine the food loss with a socio-economic, trade-based model to account for DALYs from malnutrition due to reduced food production potential in each country. Although high uncertainties occur along the cause-effect chain, a case study involving cotton production demonstrates that impacts can be quantified and are relevant in comparison to impacts associated with water consumption and other life cycle emissions. The paper provides preliminary maps of characterization factors at a high spatial resolution.

Keywords: impact assessment, land use, land occupation, land use footprint, trade-offs

1. Introduction

Land use impacts are an essential consideration when conducting life cycle assessment (LCA) in the agri-food sector. In most cases, without the inclusion of land use impacts it is unlikely that a reliable assessment of overall environmental performance can be achieved and the core principle of *comprehensiveness* (ISO 14040: 2006) satisfied. When considering alternative agri-food production systems and products, land use impacts are also central to the assessment of trade-offs, which frequently exist between land and water use (Pfister et al. 2011; Ridoutt et al. 2013; Stoessel et al. 2012), as well as other impact categories such as greenhouse gas emissions (Müller-Wenk and Brandão 2010). In addition, land use impacts are pertinent to many contemporary policy questions, such as the environmental benefits of sustainable intensification in agriculture (Garnett et al. 2013), bio-fuels (Searchinger et al. 2008), alternative protein sources (Wirsenius et al. 2010), sustainable diets (Heller et al. 2013), and land sparing/sharing strategies (Phalan et al. 2011) to name a few. The criticality of assessing land use in LCA stems from the recognition that from a global perspective land resources are already scarce (Lambin et al. 2013), many of the major global environmental challenges directly relate to land use (Rockström et al. 2009), and the increasing world population and affluence are creating unprecedented demand for food, fibre and bio-energy products.

However, at the present time, impact assessment modelling for land use in LCA is relatively immature (Hauschild et al. 2013; Jolliet et al. 2014). Although numerous land use indicators exist (Mattila et al. 2012), many closely resemble life cycle inventory parameters and others are stand-alone, proxy indicators (e.g. ecological footprint) which lack coherence with the overall life cycle impact assessment framework, making interpretation and assessment of trade-offs difficult. Part of the complication in assessing land use impacts in LCA arises from the multiplicity of cause-effect pathways leading to the various areas of protection. Recently, new frameworks and methods have been proposed for assessing biodiversity impacts (de Baan et al. 2013; Koellner et al. 2013) and ecological functions (Bare 2011; Bos et al. 2012; Saad et al. 2011). In addition, land has been considered from the perspective of a resource which has the potential to be degraded in its productive capability for future users (Garrigues et al. 2012; Núñez Pineda 2011).

Our research involves modelling the impacts of land use related to the area of protection Human Health, which has been completely neglected so far. In particular, we focus on the impact pathway linking land occupation and protein-energy malnutrition (PEM), expressed in Disability Adjusted Life Years (DALYs), taking an approach that builds on previous modelling of human health impacts related to water use (Boulay et al. 2014; Motoshita et al. 2010; 2014; Pfister et al. 2009) The model contributes essential new analytical capability for

LCA studies concerning agri-food and other land-based production systems, and is intended to ultimately be integrated with models addressing land use impacts on ecosystems and resources to enable a complete land use impact assessment capability.

2. Methods

2.1. Model structure

The model structure connecting land use to human health impacts is depicted in Figure 1. The Occupation of land leads finally to DALYs from malnutrition. Land use change was not considered to have an immediate effect on human health other than the effects related to loss of ecosystem services and biodiversity, which are the subject of the methods described above.

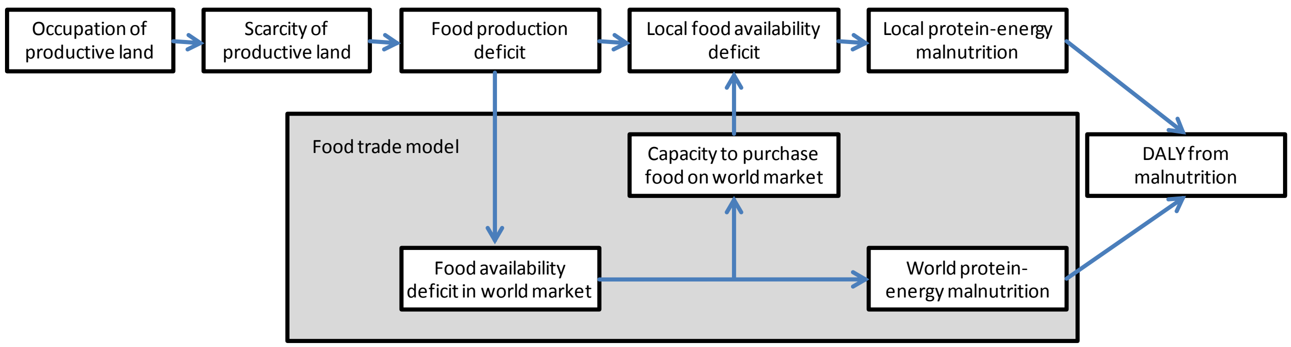

Figure 1. Land use impact pathway leading to protein-energy malnutrition

The first step was a spatially explicit characterization of land use productivity as a proxy for the relevance of a m^2yr of land in global comparison, by applying the land stress index developed in Pfister et al. (2011), which we call hereafter the Land Productivity Index (LPI). Net primary productivity of potential vegetation was used to relate each m^2yr of land occupation to m^2yr of global land unit on 5 arc minutes spatial resolution (~10km).

The subsequent steps were calculated on political units (countries). Scarcity of land within a region was determined in order to quantify the deprivation potential (i.e. the probability that land use deprives another user of land due to competition for productive land as a limited resource within a region). We applied a factor to account for the land competition within a country since some countries have declining agricultural activities and therefore land use might just replace other land use not producing food. For this we developed a Cropland Scarcity Index (CSI) in relation to the share of agricultural GDP to total GDP using data from the CIA World Factbook (CIA 2010) as shown in Figure 2. For countries with agricultural GDP shares of <1%, the CSI was set to 0.05, for shares between 1 and 4% the CSI increases linearly to 0.8, between 4 and 5% the CSI was set at 0.8, between 5 and 10% at 0.9 and for shares >10% the CSI was set to one, assuming full competition.

By combining the LPI_i (on grid cell level) with CSI on national level, the deprivation of land in absolute terms of highest land quality was obtained. This result was normalized by the production weighted average LPI_j in each country *j* derived from Pfister et al. (2011) with application of the national food loss factor (FLF_j) obtained by quantifying food energy production per m^2 yr of land use, based on FAO (2014) in order to get the food energy loss of land use in each country (MJ / m^2yr).

From here, the food loss model developed by Motoshita et al. (2014) was applied to account for the local and trade-related effects of food production loss in each country. This model reports local as well as global protein-energy caused malnutrition and is linked to DALY based on health damages occurring from malnutrition in each country leading to the effect factor for each country ($EF_{country}$) relating DALY to loss of food production (DALY/MJ).

The final characterization factor for each grid cell *i* (CF_i) in country *j* is calculated as follows:

$$CF_{LU,\ malnutrition,\ i} = LPI_i / LPI_j * CSI_j * FLF_j * EF_j \qquad \text{Eq. 1}$$

In order to account for the domestic health impacts we applied the EF for domestic malnutrition by Motoshita et al. (2014) on country level ($EF_{dom,j}$). The domestic CF ($CF_{LU,\ malnutrition,\ dom,\ i}$) is calculated as:

$$CF_{LU,\ malnutrition,\ dom,\ i} = LPI_i / LPI_j * CSI_j * FLF_j * EF_{dom,j} \qquad \text{Eq. 2}$$

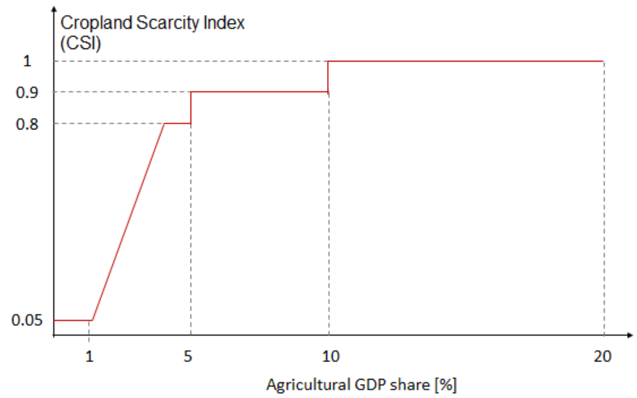

Figure 2. Cropland Scarcity Index (CSI) as a function of national GDP share of agriculture

2.2. Comparison of human health impacts caused by freshwater consumption and land use

In order to compare human health impacts from freshwater consumption and land use directly, we calculated water consumption damage equivalents for land use (WC_{eq}), which is indicating how much water consumption would cause equal damage as land use (m^3 / m^2yr). For assessment on high level of detail, the water consumption impacts on human health from Pfister et al. (2009) for each watershed *k* ($CF_{WC,\ malnutrition,\ k}$) were normalized to grid cell domestic land use impacts ($CF_{LU,\ malnutrition,\ dom,\ i}$) for each 5 arc minute grid cell ($LU_{eq.,i}$):

$$WC_{eq.,i} = CF_{LU,\ malnutrition,\ i} / CF_{WC,\ malnutrition,\ k} \qquad \text{Eq. 3}$$

The water consumption related impacts only account for domestic effects and therefore they are compared to domestic land use effects only. Furthermore, the cause-effect model by Pfister et al. (2009) leads to lower results per lack of food than other models (Boulay et al. 2014) and therefore we applied also the upper level of the 95% interval ($CF_{WC,\ malnutrition,\ 97.5\%,\ k}$, as provided by Pfister and Hellweg 2010) for comparison that accounts for sensitivity:

$$WC_{eq.,\ 97.5\%,\ i} = CF_{LU,\ malnutrition,\ i} / CF_{WC,\ malnutrition,\ 97.5\%,\ k} \qquad \text{Eq. 4}$$

2.3. Cotton case

We applied the developed factors to assess human health impacts caused by land use in cotton production based on the land use data calculated by Pfister et al. (2011) on high spatial resolution (5 arc minutes). We compared the impacts of land use to those of water use by multiplying the water consumption data of Pfister et al. (2011) with $CF_{WC,\ malnutrition,\ k}$.

3. Results

The newly developed model reports land use induced health impacts for each 5 arc minute grid cell as presented in Figure 3A. Figure 3B shows the domestic effects and reflects that industrialized countries and some emerging economies are modeled to have few or no impacts within the country but export impacts through variation in trade with other regions.

Figure 4 presents the comparison of land use and water consumption impacts on malnutrition. The damage equivalents for water consumption in terms of land use show no impacts for land use but impacts for water use in many emerging economies, which is due to the different model of health impacts in Pfister et al. (2009) compared to our approach. In many regions impacts of more than 100 m^3 correspond to 1 m^2 yr, which is a very high ratio considering that on global average 1 m^3 of rainfall occurs on 1 m^2 yr (1000mm rainfall per year). This is especially the case when comparing with the expected water consumption impacts. The upper level of the 95% interval for water consumption changes the picture quite a lot as e.g. in the case of the Indian sub-continent. This comparison already allows to estimate the relevance of water consumption and land use in agriculture. Most tropical regions (mainly except India) have relatively high volumes of water as land use equivalents and most probably land use is the higher problem. The case of India shows no robust trend in terms of priority of land or water use (compare Figure 4A and B).

The cotton case study reveals damage on human health due to land use and water consumption per tonne of harvested seed cotton (Figure 5). Cotton production causes especially high impacts in tropical regions due to land use (Figure 5A) and some significant impact due to water consumption (based on the expected value) in arid regions such as India, Egypt and the Aral Sea region (Figure 5B). To evaluate the impact of land use compared to water consumption in the cotton case, land use impacts are divided by water consumption impacts at the upper confidence level (Figure 6). In emerging economies (where domestic land use impacts are set to zero) and in arid regions water consumption impacts are higher. In India the impacts are at the same level, while in other tropical regions land use impacts are higher in most cases.

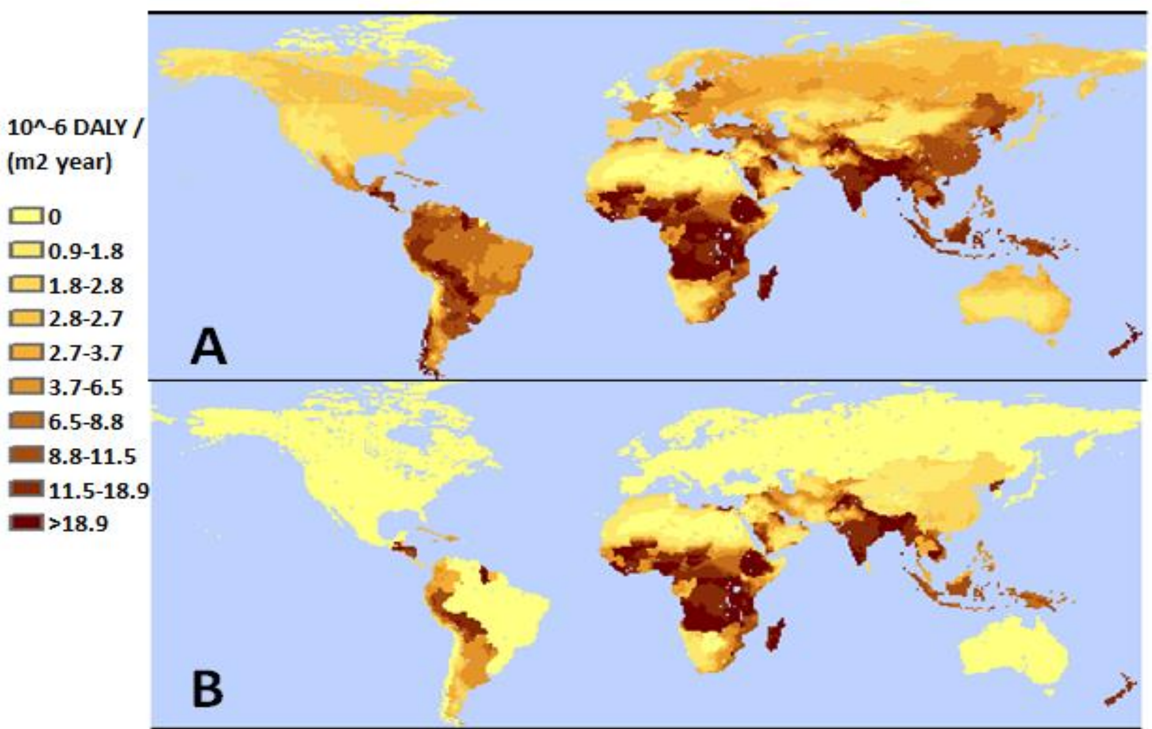

Figure 3. Characterization factors quantifying DALY from malnutrition per m^2 year of land use on 5 arc minutes spatial resolution. (A) shows total impacts including trade effects ($CF_{LU,\ malnutrition,\ i}$) and (B) only domestic impacts ($CF_{LU,\ malnutrition,\ dom,\ i}$).

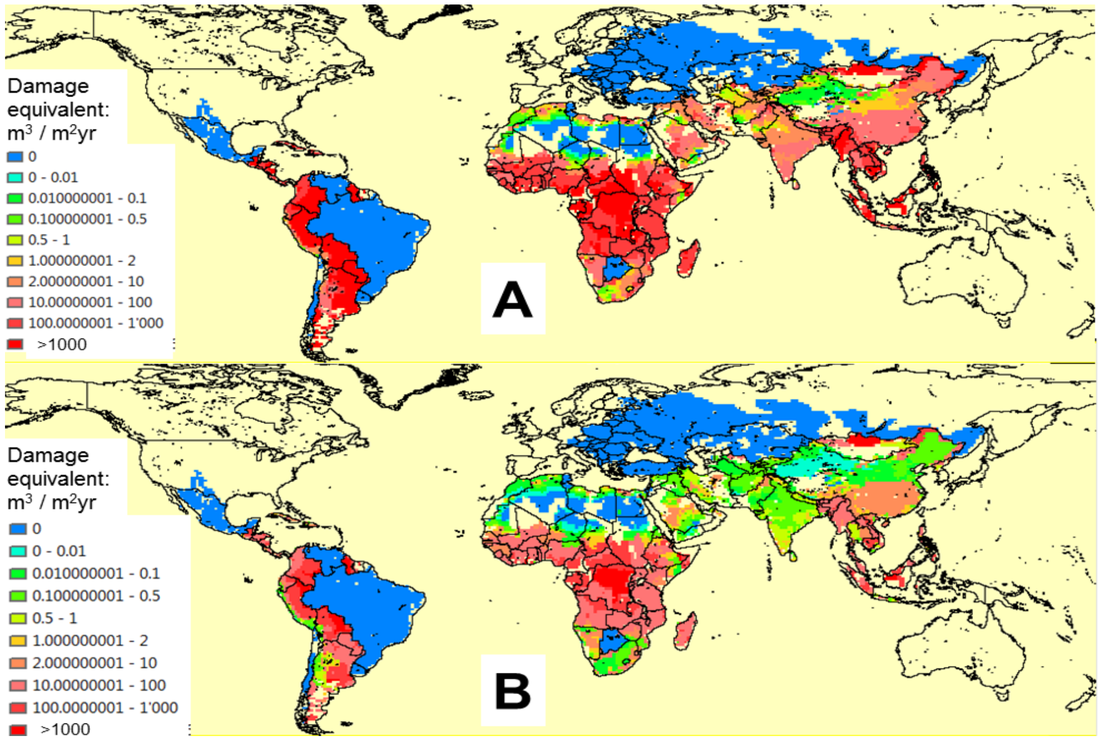

Figure 4. Comparison of human health impacts (domestic impacts only, trade-related impacts excluded) related to land use and water use. (A) Based on expected water consumption impact ($WC_{eq., i}$) and (B) based on 97.5% percentile estimate of water consumption impact ($WC_{eq ,97.5\%,,i}$)

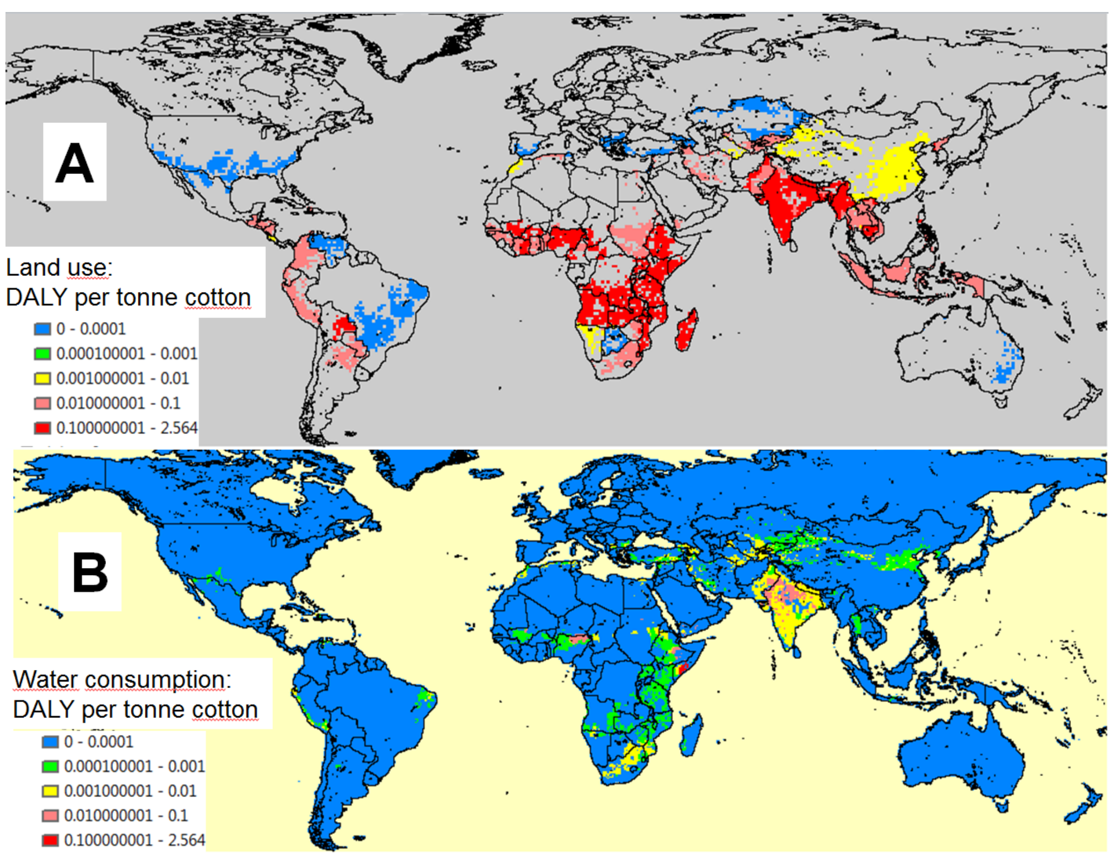

Figure 5. Cotton case study results comparing potential human health impacts from (A) land use (based on $CF_{LU, malnutrition, dom, i}$) and (B) water consumption (expected value, based on $CF_{WC, malnutrition, k}$)

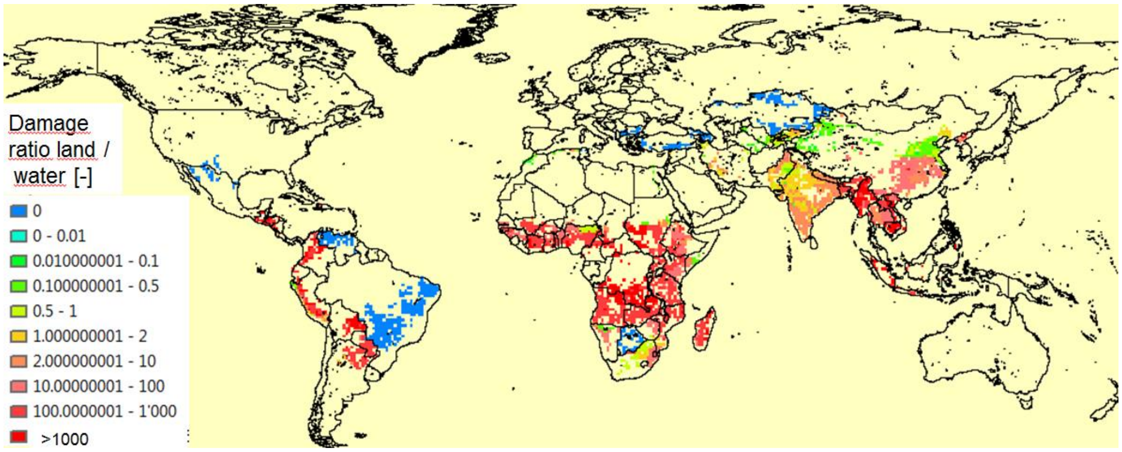

Figure 6. Ratio of impacts between land use and water consumption for cotton production. For water consumption the upper level of the 95% confidence interval (based on $CF_{WC,\ malnutrition,97.5\%,\ k}$) is used.

4. Discussion

Through the agency of trade, the local consumption of goods and services can impose pressure on land resources throughout the world. It is estimated that 197 million ha (or 33%) of the land supporting US consumption is located in other countries (Yu et al. 2013). For the EU and Japan, the figures are 50 and 92% respectively (Yu et al. 2013). Assessment of the environmental impacts of land use from a life cycle perspective is therefore critical. High levels of consumption in developed countries can be contributing to land scarcity in countries where land and water resources are already insufficient to meet the needs of local communities and access to food is limited by low incomes (Fader et al. 2013; Weinzettel et al. 2013). In addition, activities which are intended to have a positive environmental impact, such as land conservation and the cultivation of bio-fuel and energy crops to avoid the combustion of fossil fuels, could also have unintended negative consequences. Although a complete suite of LCA impact assessment models for land use addressing all Areas of Protection remains a future aspiration, the modeling presented in this paper is a first step toward filling the gap in relation to land use and human health. We also envisage this new model contributing to a land footprint indicator which goes beyond ecosystem impacts.

It might seem counterintuitive that the model can potentially be used to report land use impacts in relation to malnutrition for production systems where land is used for food production. However, in LCA environmental impacts are quantified in relation to the life cycle of a functional unit and not the direct benefit of the functional unit itself. As such, the model can be used to compare alternative food production systems and the potential impacts associated with using arable land for purposes such as textile and bio-energy production. In any case, we do not make assumptions about the way crop products are utilized: direct consumption, utilization for livestock, bio-fuel or other industrial production, waste, or contribution to excessive food consumption beyond a healthy diet, since this is part of the functional unit in LCA and not impact assessment.

The impact assessment model presented in this paper has three main components: land productivity assessment, land scarcity assessment and the food production-trade-DALY model. The current model is operational, as demonstrated by the case study presented, however we regard it as preliminary and subject to ongoing refinement, especially in relation to the first two model components. There is potential for refinement of the Land Productivity Index in terms of the relationship to NPP_0, by the inclusion of other factors which influence suitability for cropping, as well as the local level of technological advancement in agriculture. The land scarcity assessment seeks to describe the extent to which land occupation in a country constrains the agricultural sector. This assessment is based on the % GDP from agriculture at the country level. In other words, land use is deemed to have a greater impact on food production in countries where the agricultural sector is a large proportion of GDP. However, the relationship is not considered straightforward, depending in part on the potential for additional land conversion to agriculture as well as local preference for employment in the agricultural sector and numerous other factors. An improvement of the Cropland Scarcity Index could be achieved by integrating assessment of available and used land for agriculture, analysis of past trends in agricultural land use, as well as productivity of different land use types and related competition among sectors. It is important to note that in calculating potential food production deficits, care has been taken to avoid double counting due to irrigation water scarcity which is separately accounted in water use impact assessment models (as shown in the cotton case study).

Due to the high complexity of the cause effect chain and data limitation the characterization factors seem to have a very high uncertainty and might be in a similar range as those provided for water consumption (Pfister and Hellweg 2010). Quantification of uncertainties needs to be done as a future step along with improving the model components as described above.

The cotton case study shows that land use impacts on human health might cause one DALY per tonne of seed cotton in an extreme case and more than one DALY per 10 tonnes in other cases (e.g. India and Africa). In the case of India, these results would suggest around 10% of national malnutrition-related DALYs are attributable to cotton production, which occupies around 8% of arable land area. That said, the uncertainty of these numbers is even higher than the uncertainty of the CFs since the global model of land use in cotton production also has high uncertainties (Pfister et al. 2011). However, the range of the values shows relevance when compared to overall impacts of cotton production on human health, which is in the order of 0.01 DALY per tonne based on ecoinvent v2.01 data (Ecoinvent Centre 2008) and the eco-indicator 99 method (Goedkoop et al. 2001) without land and water related health impacts.

5. Conclusion

Addressing potential human health impacts caused by land use has shown to be relevant and possible. In particular, our method strengthens the ability to assess trade-offs between GHG emissions, land and water use (Pfister et al., 2011; Ridoutt et al., 2013) which are central to concerns about sustainable food production and sustainable diets. The method will also be vital to exploring the impact of land use systems that compete with food production (e.g. bio-fuels) as well as the role of livestock products in a sustainable global food system since livestock systems vary enormously in feed supply (and therefore productive land requirements) and have the capacity to both add to or subtract from the global food system (Foley et al., 2011).

ABSTRACT

A case study comparing extensive, low-yielding smallholder maize production with an intensified, high-yielding production system ('sustainable intensification') is used to illustrate potential trade-offs between agricultural product carbon footprints (PCFs) and land use (LU). In the comparative analysis the extensive systems had lower PCFs so the conclusion may be that these systems should be encouraged as a climate mitigation strategy. However, if LU and the potential for land use change as a consequence of the extensive systems' low yields are also considered, then the conclusion changes in favour of the intensified, high-yielding system. Our conclusion is that an assessment of the success of sustainable intensification with regard to climate mitigation needs to also include indirect effects at a larger spatial scale than individual farms in order to avoid misinterpreting PCF results.

Keywords: sustainable intensification, maize, greenhouse gas emissions, extensive farming, land use change

1. Introduction

The agricultural sector is key for addressing various interconnected challenges, including food security, land use and climate change. Significant yield reductions are predicted over the next decades in many regions of the world as a result of climate change (IPCC 2007). At the same time, agricultural activities contribute to global warming by releasing greenhouse gases (GHGs) at all stages of agricultural value chains. The application of sustainable practices along entire food supply chains is essential for reducing GHG emissions, ensuring continued agricultural production, increasing global food security and feeding the growing world population (Beddington et al. 2012). The concept of sustainable intensification, i.e. the production of more food from the same area of land while reducing associated environmental impacts, is of particular importance in this respect (Beddington et al. 2012).

Product carbon footprints (PCFs) estimate the amount of GHGs emitted during the life cycle of goods and services. They are reported per unit of product and aim at maximising input-output ratios, where high input-high output systems can have low PCFs, i.e. low levels of GHG emissions per unit of output. Despite the importance of GHG accounting per unit of product for assessing efficiencies and potential leakage effects, such analyzes are lacking for many agricultural production systems and agroecological and socio-economic contexts (Smith and Wollenberg 2012).

Our case study on the PCF of maize cultivation in smallholder production systems in Tanzania is part of a project investigating sustainable intensification practices. So far, little information has been reported on the GHG emissions from smallholder production as previous analyzes have focused on large export oriented farms (e.g. Edwards-Jones et al. 2009). Our analysis includes extensive, low-yielding farming systems as practiced widely in the region, and an improved, more intensive management system which aims at increasing yields by applying more targeted inputs. The PCF of these two systems are compared and their respective climate impacts discussed. The hypothesis is that raising yields by applying more targeted inputs under the concept of sustainable intensification can reduce the climate impact from maize production.

2. Methods

2.1. PCF calculation

For the calculation of farm gate PCFs we used data on smallholder maize production in Tanzania generated as part of a larger public-private partnership project implemented by the Norwegian University of Life Sciences, Sokoine University of Agriculture in Tanzania, Syngenta and Yara International. Field trials were conducted on five smallholder farms located in the Njombe and Morogoro regions of Tanzania. At each site, paired treatments were established where the farmers continue with their traditional management ('farmer practice', FP treatment) on one plot. On a second plot more targeted farm inputs are applied, following a protocol devised by the project partners ('YSS treatment'). At all sites soil samples were taken at the beginning of the trials in order to develop a balanced and crop-specific nutrition program.

The system boundary of the PCF analysis included the production and transport of farm inputs and all relevant on-farm processes up to the farm gate for one project year. Primary data on the amounts of fertilizers, agrochemicals, yields and crop residues were available for each treatment. Direct N_2O emissions from soils as a result of nitrogen inputs (mineral fertilizers, crop residues) were estimated using the IPCC (2006) Tier 1 method. Indirect N_2O emissions were calculated using the Bouwman et al. (2002) model for ammonia volatilisation and a nitrogen balance approach to identify potential nitrate leaching losses. Mineral NPK fertilizers used in the YSS treatment were produced in Norway and transported to Dar es Salaam by container ship. Mineral fertilizers applied on FP plots were assumed to be produced in China and Morocco and shipped by bulk. Emission factors for the production of inputs were obtained from Yara International, Brentrup and Pallière (2008), IFA (2009), Saling and Kölsch (2008) and PE International's GaBi 4 database.

2.2. Description of the case study farms

All field operations on the case study farms were carried out manually. The YSS treatments received 138 kg N ha^{-1} $year^{-1}$, 57 kg P_2O_5 ha^{-1} $year^{-1}$, 34 kg K_2O ha^{-1} $year^{-1}$ and micronutrient applications. On two of the FP plots, no fertilizer was applied at all whereas some nitrogen (11-79 kg N ha^{-1} $year^{-1}$) and phosphorus (28-57 kg P_2O_5 ha^{-1} $year^{-1}$) was applied on the other three FP plots. Weed control was mainly done manually on the FP plots whereas plant protection agents were applied on the YSS plots as and when necessary. Grain yields achieved on the YSS plots ranged between 2.1 and 6.3 t ha^{-1}. Grain yields on FP plots were considerably lower (1.8-4.0 t ha^{-1}). Stover yields were 1-5 times greater on most YSS plots, leading to a greater return of organic residues to the soil.

2.3. Land use (LU)

A second indicator, land use (LU), was calculated to compare the paired treatments and highlight trade-offs between PCFs and LU. We define LU as the area of land required to produce a unit of output (Tuomisto et al. 2012), i.e. as the inverse of the yield.

2.4. Potential land use change (pLUC)

If low-yielding maize production systems as in our FP treatment are expanded to meet growing demands for Tanzania's rapidly increasing population (UN 2010), this will cause GHG emissions outside of the farms studied due to land use change (LUC). Therefore, it is not direct LUC (dLUC) taking place on the farms analyzed. Although it is an indirect effect of the extensive farming system outside of the PCF system boundary, we suggest not to calculate these indirect impacts using established methods for estimating indirect LUC (iLUC) emissions. Such iLUC occurs outside of the product system being assessed as a result of the conversion of land due to changes in agricultural land use elsewhere in the world. Modelling iLUC impacts is complex and based on assumptions about economics, market factors, pre-conversion land use types and other factors (Prins et al. 2010). In our case study region, in contrast, it is likely that LUC will be induced by an expansion of extensive farming to increase production under a business-as-usual scenario (FAO 2012). This LUC occurs nearby in order to meet growing demands for the same crop in the same region. We call this form of land use change 'potential LUC' (pLUC) and estimate associated GHG emissions based on the available land use type in the region for an extended FP system, FP_{ext} (Brentrup and Pallière 2008). First, we calculate the amount of land that needs to be converted to produce the same amount of maize harvested in YSS under the current FP management. This additional area of land is then assumed to be subject to LUC, leading to the emission of 12.4 t CO_2e ha^{-1} and year (IPCC 2006, Tier 1) if emissions are allocated evenly across 20 years (BSI 2011). In the case study area tropical shrubland is potentially available to support this expansion. These emissions, scaled by the yield on each FP plot, are added to the FP PCF for the amount of land that needs to be converted to match the YSS yield.

3. Results

3.1. Farm gate PCF

The farm gate PCF of maize varied greatly between 102 and 963 kg CO_2e t^{-1} grain. A comparison of the results for the paired YSS and FP systems reveals that in most cases the FP systems had lower PCFs (Fig. 1a). The main emissions sources on all farms were related to fertilization and crop residues. On the YSS plots, the production and transport of mineral fertilizers to the farm, direct N_2O emissions from soils, and N_2O emissions from crop residue management were the main emissions sources. On the FP sites, N_2O from crop residues was the main source of emissions with the exception of Farms A and B, where the production and transport of mineral N fertilizer was the greatest contributor, closely followed by direct N_2O emissions from soils. On the two FP plots that did not receive any mineral fertilization (Farms D and E), the only sources of emissions were N_2O from crop residue management and the production of seeds.

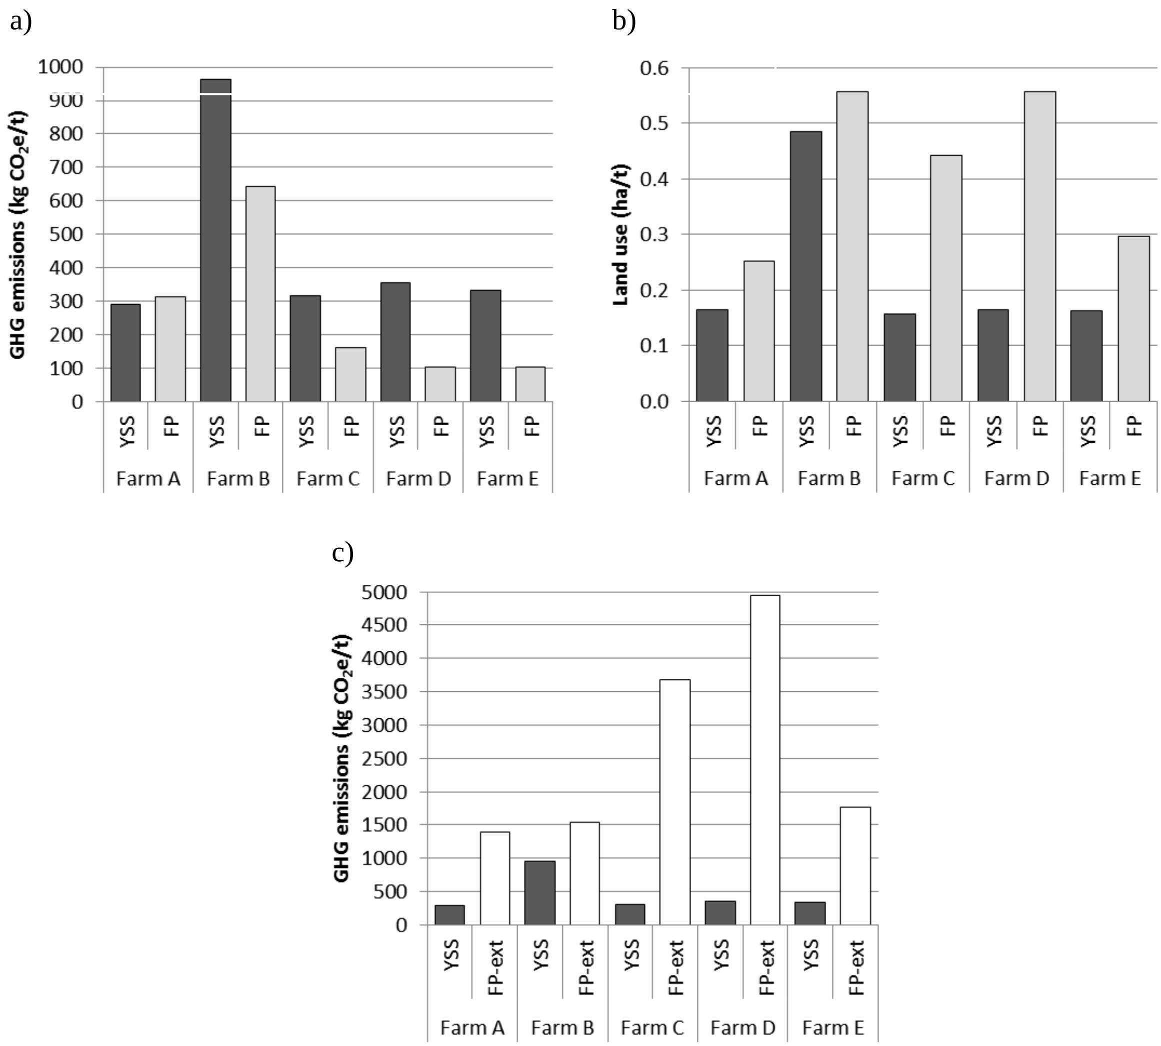

Figure 1. Results for maize production at five sites of paired management treatments: a) Product carbon footprint (PCF) up to the farm gate; b) Land use; and c) PCF including potential land use change. The black bars denote the intensified YSS management system, the grey bars the widespread farmer practice (FP) and the white bars the expanded FP system that matches YSS yields, including potential land use change on the additional land needed to produce this yield (FP_{ext}).

3.2. Land use

The LU of the case study farms ranged between 0.16 ha t^{-1} and 0.56 ha t^{-1} (Fig. 1b). Contrary to the PCF results where the YSS farms generally were associated with greater GHG emissions per t of maize than the FP farms with their extensive management, the LU indicator shows the exactly opposite pattern: for all pairs of YSS vs. FP management LU is lower and therefore more favourable for the YSS systems. The transition from FP to YSS thus indicates a move towards a lower LU and a more efficient use of land. In order to produce one ton of maize, the FP plots needed between 1.1 and 3.8 times more land than the paired YSS plots.

3.3. Indirect impacts from land use change

If GHG emissions arising from FP_{ext} from an area large enough to match the paired YSS yields (including pLUC for the additional area) are considered, the conclusions drawn from considering the farm gate PCF only change dramatically (Fig. 1c), with GHG emissions related to FP_{ext} between 2.4 and 48 times greater than the FP PCFs up to the farm gate.

4. Discussion

4.1. Smallholder maize production

The present study demonstrates the significant potential for achieving yield increases in smallholder systems by addressing limitations to productivity and applying targeted inputs of fertilizers and agro-chemicals. The wide range in PCFs between farms and within paired treatments also shows the impact of individual farm management decisions and location specific conditions such as soil pH or soil nutrient supply. Nutrient deficits and soil degradation which limited yields on smallholder farms were identified and improved, leading to significantly increased yields in the YSS system. For most FP systems, nutrient mining was observed which explains their low yields but also shows that these systems are not sustainable in the long run without increasing the input of plant nutrients in the form of organic or mineral fertilizers.

4.2. Trade-offs between PCFs and land use

If LU is considered, the conclusions differ from those based on the farm gate PCF where the extensive FP systems which use very little inputs might be taken for more environmentally friendly. When looking at the land area needed to produce a ton of maize, the FP plots clearly exert a much greater pressure on land resources than the intensified systems, which is likely to lead to land use change in the region to satisfy growing demands. This trade-off can lead to significant indirect impacts beyond the farm gate which are important to consider before concluding on the respective climate friendliness of the contrasted systems. LU can draw attention to this trade-off and should be considered whenever systems with great yield differences are compared. Out of two farms or production systems with similar PCFs but a high LU for one and a low LU for the other, the latter should be preferred.

The UK Royal Society (2009) defined sustainable intensification as “the production of more food on a sustainable basis with minimal use of additional land”, clearly recognising the need to reduce LUC and the continuing expansion of agricultural areas while meeting the challenge of increasing global food production. Our study illustrates the potential climate change impact of expanding the present low-yielding maize systems. The results emphasize the need for meeting increasing food demands without further LUC by carefully intensifying current production systems. The analysis of pLUC also highlights the need for more integrated assessments and policies, e.g. on land use and climate change, and a wider landscape scale approach to assessing the environmental impacts of farming systems and comparing the climate impact of different production systems. This is particularly important in regions where low-yielding systems dominate and increasing demands are likely to be met by converting land locally (pLUC).

5. Conclusion

The present case study highlights the risks associated with the interpretation of single issue indicators such as PCFs. In contrast, in a full LCA, trade-offs within the same system boundary become evident (e.g. Tuomisto et al. 2012). Our results show that raising the productivity and long-term sustainability of the systems analyzed by applying more targeted inputs and addressing nutrient limitations can result in a greater climate impact than the current low-yielding systems within the system boundary of a farm gate PCF. However, the benefits of sustainable intensification should be assessed at a greater spatial scale. In order to achieve food security for current and future populations, large increases in food production are necessary. Against this background, an assessment of the climate impact of extensive vs. intensive agricultural systems with significant differences in yield levels should consider trade-offs between PCFs, yields and LU. In such cases it is important to consider indirect impacts that may occur beyond the farm gate before concluding on the climate friendliness of one or the other system. A comparison of the LU indicators of the different systems can highlight the risk of LUC and help interpret PCF results. If this is not done, there is a risk that PCF results may be misinterpreted and agricultural systems that have low PCFs but exert a large pressure on land resources may be encouraged, unintentionally causing significant carbon emissions due to land conversion to agriculture.

In conclusion, the success and benefits of sustainable intensification on existing agricultural land should not be assessed based on direct impacts only. There is a need to also consider indirect impacts and larger spatial scales and to develop appropriate policy responses to ensure positive results (Garnett et al. 2013). In our analysis of the climate mitigation potential of two agricultural systems a consideration of indirect land use effects can help resolve potential conflicts between climate impacts on farm and in the wider landscape, with the benefit of sustainable intensification becoming obvious at a larger spatial scale.

ABSTRACT

Conventional disposable cups, made of fossil-based plastic or paper with inner lining of fossil-based plastic, are typically associated with an unnecessary use of scarce resources and a superfluous production of waste. An alternative has become available in disposable cups from bio-based and biodegradable materials, so-called biocups, made from bioplastic or paper with inner lining of bioplastic. Many stakeholders consider disposable biocups as more environmental friendly than fossil-based disposable cups, though other stakeholders prefer reusable cups over disposable cups. Existing LCA studies show inconsistent and sometimes conflicting results, due to differences in used data and modeling choices, for LCA studies comparing different disposable cups and/or comparing disposable with reusable cups. This paper summarizes an LCA deliberately applying multiple inventory data sets and crediting principles for recycling in comparing disposable PolyStyrene (PS) cups with (1) disposable biocups of PolyLactic Acid (PLA) and paper lined with bioplastic, (2) handwashed and dishwashed reusable cups.

Keywords: Facility arrangements & food safety, Environmental LCA, Disposable and reusable cups, Multiple inventory data sets and modeling choices, Scenarios

1. Introduction

Public provision of drinking water was in the start of the previous century usually facilitated with a “common drinking cup” (as they were referred to in that time). Such “common drinking cup” could be found near water vessels and fontains in public places as parks, trains and railroad stations, department stores, schools, theatres and offices. Even hospitals made use of the “common drinking cup”, despite public awareness and scientific evidence about their role in distributing contagious diseases. Alvin Davison, professor of biology in Lafayette College (Easton, Pennsylvania, United States of America), published in 1908 an influential study “Death in school drinking cups”. This study documents the human cells and pathogens on a cup having been used nine days in row on a school, and contributed to the introduction of a disposable paper cup to curb pathogens growth and spread by the “common drinking cup”. Kansas was in 1909 the first American state to abolish by law the “common drinking cup”, and was eventually followed by all other American states putting into force similar laws (Anonymous 1995; Davidson 1991; Montreal Gazette 1908; Reading Eagle 1909).

A “common drinking cup” has meanwhile become an antiquity, and the use of disposable cups penetrated all sectors in society. Official numbers are not publicly available, but Wikiversity (2014) claims a worldwide use of 300 billion disposable cups per year (i.e. 300E9 disposable cups/year). Many restaurants and kiosks sell beverages in disposable cups for on-the-go consumption (e.g. by commuters, shopping public, or beach visitors). Disposable cups are also typically employed where absence of cleaning facilities and large numbers of customers in short time intervals make reusable cup service practically impossible. This is not only at stake for large public events like festivals and manifestations, but as well in medium and large organizations as schools and universities with peak-consumption during breaks. Disposable cups are also increasingly used in office-type organizations, typically in combination with vending-machines, to save time and money and to streamline their hot beverage facilities. Conventional disposable cup are made from fossil-based plastic (e.g. polystyrene, polypropylene, polyethylene terephthalate), or from paper with an inner lining of fossil-based plastic (e.g. polyethylene) or wax.

Whereas disposable cups were in the first half of the last century praised for their contribution to public health, the first commercial ones were even named ‘health cups’, they became in the second half of previous century increasingly associated with an unnecessary use of scarce resources and a superfluous production of waste (Butijn et al. 2014; Reinink et al. 1991). The debate about disposable cups already goes on for decennia, though the proposed solutions have slightly shifted over the years, also given changing facility arrangements for providing beverages. Reusable cups were often put forward as the obvious alternative for disposable cups in the nearby past when organizations typically had restaurant facilities or a room-to-room-service by a ‘coffee-lady’

(Reinink et al. 1991). Restaurant facilities and 'coffee-ladies' will not be easily found anymore, however, as many organizations nowadays make use of vending machines for providing hot and cold beverages. Reusable cups are also not practical, or simply infeasible, in situations where many customers need to be served in a short time. An alternative for the conventional disposable cups, however, has recently become available with the introduction of the so-called biocups. Disposable biocups are made from materials that are renewable and have the compostability label (EN 13432). The most common disposable bioplastic cups are made from PolyLactic Acid (PLA), typically produced from corn. Disposable biopaper cups are obviously from paper, but lined with a bioplastic instead of a fossil-based plastic.

The renewable and compostable characteristics make biocups in the eyes of many stakeholders more environmental friendly than the conventional disposable cups from fossil-based plastic or paper lined with fossil-based plastic (Jager 2008). Many restaurant facilities and catering services, or organizations buying these facilities or services, therefore consider a transition from conventional disposable cups to disposable biocups. Wageningen University & Research (Wageningen UR) already (partly) made this transition by replacing conventional disposable cups by disposable biopaper cups in their office-buildings having vending machines for hot beverages without automatic cup supply. The education buildings of Wageningen UR have hot beverage vending machines with automatic cup supply. Disposable biopaper cups tend to disrupt the vending machines with automatic cup supply (Butijn et al. 2014). Technology has just become available for producing disposable bioplastic cups for hot beverages, i.e. from thermo-resistant PLA, but these thermo-resistant disposable cups are not yet taken into commercial production. Cup producers wait for a sufficient large market demand, whereas potential customers wait for an actual market supply (a clumsy impasse; Potting 2013). Disposable PLA cups for cold beverages are already longer on the market.

The transition to disposable biopaper cups for vending machines with hot beverages in their office-buildings was first decided by Wageningen UR after careful consideration of the pros and cons of the earlier used disposable PS cup in comparison with disposable biocups from PLA and from biopaper (i.e. paper lined with bioplastic). The pros and cons of the three disposable cups were investigated by research employees and students of Wageningen UR in a comprehensive internal research project looking into environmental, economic as well as social aspects. It goes too far to describe the whole research project here (see therefore Potting 2013; in Dutch), but the in-depth comparative LCA study for the three disposable cups is summarized in this paper (see for details Van der Harst and Potting 2013; Van der Harst and Potting 2014; Van der Harst et al. 2014). A survey under employees and students of Wageningen UR turned out that over half of the office-building inhabitants for environmental reasons is using an own reusable cup (Butijn et al. 2014). The LCA results for the disposable PS cup were therefore also compared with the results of an additional (screening) LCA study for reusable cups washed by hand and washed in an energy-efficient dishwasher. The comparisons are summarized in this paper and their results are discussed in relation to environmental beneficial facility arrangements.

2. Methods and means

Existing LCA studies show inconsistent, sometimes conflicting results for comparisons of different disposable cups (Van der Harst and Potting 2013), and also for comparisons between disposable and reusable cups. This can be traced back to differences across LCA studies in data used, and modeling choices made. Van der Harst and Potting (2014) and Van der Harst et al. (2014) therefore deliberately applied multiple inventory data sets and crediting principles for recycling, i.e. a modeling choice, in an LCA study comparing disposable fossil-based PS cups with disposable biocups from the bioplastic PLA and from biopaper (i.e. paper lined with bioplastic). The additional LCA study comparing the disposable PS cup with handwashed and dishwashed reusable cups, in Potting (2013), refrained from using multiple inventory data sets and modeling choices for the reusable cup LCAs. The LCAs for the handwashed and dishwashed reusable cups took a screening approach. Both comparative LCA studies thus followed on this point different methodological approaches in their inventory phase, that therefore are separately described in more detail (i.e. Section 2.1 and 2.2). Both LCA studies basically took a similar methodological approach in the other LCA phases than the inventory phase (Potting 2013; Van der Harst and Potting 2014; Van der Harst et al. 2104):

Functional unit: Both LCA studies used the same functional unit of facilitating the serving of one hot beverage from a vending machine as frequently used in the Netherlands in big organizations. This functional unit puts constraints on the disposable cups, as most hot beverage vending machines with automatic cup supply in the

Netherlands use disposable cups with a volume of 180 ml (see 2.1 and 2.2 for details about the cups weights used in our LCA comparisons).

Impact assessment: Results from the inventory phase were translated into environmental impact by means of the CML Baseline 2001 methodology (Guinée et al. 2002), supplemented with the Cumulated Energy Demand (CED) from Frischknecht et al. (2003). Both comparisons therewith covered all together eleven environmental impact categories (see Table 2). Impact results were not normalized and neither weighted. ISO 14044 (2006) rejects normalization and weighting in comparative LCAs which results are to be disclosed to the public.

Interpretation: The results for the in-depth LCA study of the disposable cups were carefully evaluated against the background of the methodological approach used, quality of data obtained, and relevance of the results in the context of Dutch environmental policies. The screening LCAs of the handwashed and dishwashed reusable cups provided indicative impact results that were compared with average impact results of the in-depth LCA for the disposable PS cup. The results of both comparative LCA studies were evaluated with regard to their relevance for environmental beneficial management options.

Software: All LCAs for the disposable and reusable cups were performed in SimaPro 7.3, but impact results for the disposable cups were imported in Microsoft Excel 2010 for calculating average impact results and spread related to the applied multiple inventory data sets and crediting principles for recycling in the cup life cycles. Microsoft Excel 2010 was used in both comparative LCA studies for making the appropriate graphical representations of results.

2.1. Comparison of disposable PS cups and disposable biocups from PLA and biopaper

Van der Harst and Potting (2013) recently made a critical comparison of ten existing LCA studies comparing disposable beverage cups. These ten LCA studies only shared climate change as a common impact category. The variation in climate change results across LCA studies for each disposable cup material was quantitatively explored by Van der Harst and Potting (2013). They calculated the ratio between the highest and lowest climate change value, and found a ratio of 1.7 for PLA cups, 3.4 for petro-plastic cups, and 20 for paper cups. Since there was also no consistency among the LCAs about the cup with the smallest climate change impact, Van der Harst and Potting (2013) next qualitatively compared the data used and methodological approach followed in each of the selected ten LCA studies. Identified possible sources for the variation in outcomes were differences in the properties of the disposable cups (e.g., material choice and weight), differences in the data used, and different choices made in modeling production processes, energy production (e.g., fossil or renewable sources), and waste treatment (e.g. different allocation/crediting principles and waste treatment processes applied).

The critical comparison of the ten LCA studies was the basis for a new in-depth comparative LCA study of disposable cups. Van der Harst and Potting (2014) and Van der Harst et al. (2014) deliberately applied multiple inventory data sets and crediting principles for recycling, a modeling choice, in their LCA study comparing disposable fossil-based PS cups with disposable biobased cups from PLA and biopaper (i.e. paper lined with bioplastic). Their use of multiple inventory data sets and crediting principles for recycling involved two LCA iterations according to the following procedure (Van der Harst and Potting 2014; Van der Harst et al. 2014):

1. Initial LCAs with one inventory data set for each process in the life cycle of the disposable cups from the three selected materials (these initial LCAs used incineration as waste treatment process)
2. Contribution and sensitivity analysis to identify processes with major influence on the initial LCA results
3. Collecting additional multiple inventory data sets for all processes with an influential contribution
4. Applying multiple data sets, multiple modelling choices:
    - Applying the collected multiple inventory data sets in next LCAs,
    - Combined with one waste treatment processes (i.e. incineration, recycling, composting, or anaerobic digestion), and with
    - Applying multiple crediting principles for the disposable cup life cycles with recycling (e.g. multiple crediting principles for recycled material)
5. Calculating and presenting average impact results and their spread (highest and lowest value) for each life cycle process based on the multiple inventory data sets and crediting principles for recycling
6. Calculating and presenting average impact results and their spread (highest and lowest value) for each of ten disposable cup life cycles

Steps 1 to 6 were gone through for each of ten disposable cup life cycles. These ten disposable cup life cycles resulted from three disposable materials (i.e. fossil-based PS, biobased PLA, and paper lined with PLA), and four waste treatment processes (i.e. incineration, recycling, composting and anaerobic digestion; the latter two not being relevant for PS). This led to ten disposable cup life cycles for which multiple inventory data sets were collected, whereof three disposable cup life cycles with recycling for which multiple crediting principles were applied (see Table 1). The applied multiple inventory data sets and crediting principles for recycling are related to disposable cups as commonly used in hot beverage vending machines in the Netherlands (i.e. not necessarily for similar disposable cups used abroad). These disposable cups typically have a volume of 180 ml. Representative cup weights related to this volume were used in the analysis (see Table 1).

Table 1. Overview of the disposable cup materials, cup-weight for each material, life cycle processes and number of inventory data sets and crediting principles included in the in-depth LCA study comparing disposable cups. The LCA study covers altogether ten disposable cup life cycles, indicated by the grey-shaded cells, resulting from three disposable cup materials and four waste treatment processes (composting and anaerobic digesting are not relevant for PS). The dark grey-shaded cells indicate the three initial LCAs, each having incineration as waste treatment process and covering the rest of the life cycle for only one disposable cup material. All processes for which only one inventory data set was used, showed to be of minor importance in the contribution and sensitivity analysis.

Life cycle processes	**PS** 4.2 gram	**PLA** 4.2 gram	**Biopaper** 5.6 gram
Cradle to disposable cup material production	**3**	**5**	**5**
Transport of disposable cup material to cup manufacturer	1	3	1
Disposable cup manufacturing	**5**	**5**	**3**
Cradle to grave for the packaging of disposable cups	1	1	1
Transport of disposable cup to customer	1	1	1
Transport of used disposable cups to waste treatment	1	1	1
Waste treatment:			
- Incineration	**4**	**4**	**5**
- Recycling (recycling process/crediting principle)	**5/4**	**5/4**	**3**
- Composting		**4**	**4**
- Anaerobic digestion		**3**	**4**

2.2. Comparison of disposable PS cups with handwashed and dishwashed reusable cups (Potting et al. 2013; Van der Harst and Potting 2014; Van der Harst 2014)

The average impact results for the disposable PS cup life cycle with incineration from the in-depth LCA study was used for comparison with two reusable cup life cycles, one with handwashing and one with dishwashing of the reusable cup after use. The comparison took a one-time use of the disposable cup before disposing it, but looked into an increasing number of reuses of the reusable cup before dishwashing or handwashing. Screening LCAs were performed, i.e. screening inventory data were used, to calculate the impact results for the two reusable cup life cycles. The weight of the reusable cup was in both LCAs taken to be 370 grams, based on a random sample of reusable cups used in the Netherlands. The composition of the reusable cup was taken from Bramberg et al. (2011). The reusable cup was assumed to endure on average 1750 consumptions before breaking, and just like the disposable PS cup to go to the incinerator as waste (Hoeboer 2012).

Dishwashing: The composition of the dishwasher was taken from Kok et al. (1996), the energy use for assembling the dishwasher from Boustani et al. (2010), who also gave basis to the assumption of 2150 dishwashing-turns before disposing the dishwasher. Waste treatment for the dishwasher was ignored, which is a worst case approach as large parts of the dishwasher are probably recycled (leading to lower impact results for the dishwasher sub-life cycle). Based on currently common dishwashers from AEG and Bosch (Hoeboer 212), the dishwasher was taken to use 9.25 liters of water, 1 kWh electricity, and 1 gram of salt per washing turn. The composition and use of soap, 9.8 grams per washing-turn, was based on Bramberg et al. (2011).

Handwashing: Handwashing of the cups was assumed to be a single item-washing (as common for people using an own reusable instead of disposable cup). The use of hot water for handwashing was set on 1 liter, and the energy use for heating the water was set at 0.222MJ (heat from natural gas) as based on Eclectsite (2013). A use of 1 gram of soap per handwashing was assumed. The soap composition is based on data from the Dutch association of detergent manufacturers (2012). We assumed the use of two towels for drying one cleaned cup (Tork 2006, Jacobs 2006).

All cradle to product and electricity data in both reusable cup life cycles were taken from EcoInvent Centre (2010).

3. Results and discussion

The two LCA studies provided a wealth of information that is summarized in a number of subsections below. Detailed results and discussions can be found in the earlier publications for both LCA studies. The LCA study comparing disposable cups is addressed in Potting (2013), Van der Harst and Potting (2014), and Van der Harst et al. (2014). The LCA study comparing the PS disposable cup with dishwashed and handwashed reusable cups can be found in Potting (2013).

3.1. Disposable PS cups not better or worse than biocups from PLA and biopaper (Potting 2013; Van der Harst and Potting 2014; Van der Harst et al. 2014)

Table 2 summarizes the comparison of, i.e. the ratio between, the average impact results for all ten disposable cup life cycles with the average impact results for the disposable PS cup life cycle with incineration. The other nine disposable cup life cycles consist of one for PS with recycling, and eight for the two biocup materials (i.e. PLA and biopaper (i.e. paper lined with bioplastic) with one of the four waste treatment processes (i.e. incineration, recycling, composting and anaerobic digestion). The comparison in Table 2 may mistakenly lead to the wrong conclusion that the disposable PS cup life cycle with incineration tends to perform better than the other nine disposable cup life cycles, i.e. for PS with recycling and the two biocup materials regardless their waste treatment process. The table does not indicate, however, the considerable and overlapping spread around the average impact result for all ten cup life cycles in most impact categories as caused by applying multiple inventory data sets (and crediting principles for recycling). This large and overlapping spread in impact results prevents any conclusion about a preferable disposable cup material. The disposable PS cup life cycles do thus not perform better, but also not worse than the disposable biocup life cycles for PLA and biopaper (i.e. paper lined with bioplastic).

The large spread in our results were already presaged by the inconsistent and sometimes even conflicting results of the ten LCA studies in Van der Harst and Potting (2013). Each of these ten LCA studies always differed on more than one inventory data set and/or modeling choice with each of the other LCA studies. The influence and therewith importance of potential individual sources for spread in LCA results were therefore impossible to trace. Applying multiple inventory data sets for all major life cycle processes and multiple crediting principles for recycling allowed systematic quantification of their influence on the impact results for each of the ten cup life cycles. That is a major achievement of applying multiple inventory data sets and crediting principles for recycling, which in this LCA study generated a wealth of additional valuable scientific insights that are summarized here:

- The large spread in impact results, i.e. from applying multiple inventory data sets and crediting principles for recycling, hampers drawing decisive conclusions about the preferred disposable cup material. Such outcome in based on more robust impact results, however, than for those from LCAs based on single inventory data sets per life cycle process
- Despite their large spread, impact results consistently point to the same dominant processes in the life cycles for each disposable cup material. These dominant processes turned out to be the same as identified in the contribution analysis (i.e. none of the used inventory data sets made a given process into a minor contributor in the impact results for the cup life cycles)
- Particularly cradle to PLA production dominated the impact results for the four PLA cup life cycles. It should also be noted that PLA production was based on ‘cold’ PLA, since thermo-resistant PLA is not yet commercially produced
- The crediting of recycled material also considerably influenced the impact results for the recycling life cycles across all three disposable cup materials
- Across disposable cup materials, spread in impact results for energy related impact categories tend to be clearly smaller than in non-energy related impact categories (in the toxicity categories particularly)

- Average impact results for Abiotic Depletion and Global Warming are (obviously) better for the disposable biocups than PS cups, because PLA and paper are renewable materials and PS is not
- Production of all three disposable cup materials can environmentally improve, but this potential is probably largest for the relative new material PLA (presently produced from economically valuable sugar and starch instead of from lignocellulose in arable crops)
- Correlations between inventory data within one data set, e.g. between energy use and carbon dioxide emissions, are maintained by calculating spread on the basis of impact result. Mainstream LCA studies first calculate spread in inventory data, before performing impact assessment, which often violates existing correlations between inventory data within one data set

Table 2. Summary of the potentially misleading comparison of the average impact results for the disposable PS cup life cycle with incineration to the average impact results for the disposable PS cup life cycle with the recycling, and for the eight disposable biocup life cycles (i.e. PLA or biopaper in combination with one the four waste treatment processes; incineration = I, recycling = R, composting = C, anaerobic digestion = D). The results are potentially misleading because the spread around the average results is large and overlapping across all three materials in all impact categories. This is not reflected in the below indication whether average impact results for each of the other nine life cycles are higher than (>, darker grey shading), lower than (< , lighter grey shading) or similar as (1, similar grey shading) the average results of the disposable PS cups that is incinerated after use.

Impact category indicators	**PS**		**PLA**				**Biopaper**			
	I	**R**	**I**	**R**	**C**	**D**	**I**	**R**	**C**	**D**

ground-level PhotoChemical Oxidation Potential (PCOP)	1	<	>	>	>	>	<	1	<	<
Human Toxicity Potential (HTP)	1	>	>	>	>	>	>	>	>	>
Terrestrial EcoToxicity Potenital (TETP)	1	>	>	>	>	>	>	>	>	>
Fresh-water Aquatic EcoToxicity Potential (FAETP)	1	>	>	>	>	>	>	>	>	>
Marine aquatic EcoToxicity Potential (MAETP)	1	>	>	>	>	>	>	>	>	>

3.2. Recycling slightly preferable over incinerating disposable cups
(Potting 2013; Van der Harst and Potting 2014; Van der Harst et al. 2014)

Table 3 shows the ranking of cup life cycles, within on disposable cup material, according to the average impact results for the used waste treatment process. Within one disposable cup material, the spread in impact results is identical from cradle to waste treatment entrance-gate, which allows focusing on the waste treatment processes only. There is also a large, but only partly overlapping spread in average impact results for the waste treatment processes within each cup material. Some cautious preferences are therefore possible to express on the basis of average results for the waste treatment process (i.e. not necessarily supported by the range in impact results for these processes.

Composting of the biocups is less good than the other three waste treatment processes as result of the absence of useful products derived from composting (e.g. both biocups do not contain nutrients). Composting therefore does not get credits, in contrast to the other three waste treatment processes, for the avoided production of products they replace. For the PLA cup, anaerobic digestion performs on average on almost all impact categories better than incineration for the PLA cup (i.e. avoided impact by energy production from biogas is larger than from incineration with energy recovery). There is no similar trend for the biopaper cup. The average impact results suggest a slight preference of recycling over incineration for the PLA cup and biopaper cup, i.e. the avoided impact of recycling is larger than for incineration, but not for the PS cups which average impact results are better in five and worse in six impact categories for recycling as compared to incineration. The comparison of recycling and incineration, however, revealed an interesting drawback of crediting processes with avoided production caused by their co-products.

The cup life cycles with incineration as waste treatment process got relative large credits for avoided electricity production from energy recovery by incineration, and these credits for incineration became more dominant when inventory data for improved disposable cup material production were used (i.e. credits for recycling became less). This may mistakenly suggests incineration to become preferable when disposable cup material production improves, whereas the appropriate policy recommendation would be to improve the relatively “dirty” Dutch electricity production. Dutch policies aim to improve the environmental performance of Dutch energy supply, amongst others by increasing the share of renewables (Government of the Netherlands 2014). Compared to other countries, Dutch electricity production uses little renewable sources, and predominantly relies on fossil fuels (CBS 2012; European Commission 2012; Eurostat 2012). A sensitivity analysis with hydro-dominated Norwegian instead of Dutch electricity production showed better impact results for recycling than for incineration of disposable PS cups in most impact categories.

The relatively large credits for avoided Dutch electricity production affected the comparison of cup life cycles with incineration and recycling as waste treatment process for all three disposable cup materials, but this particularly shows for the disposable PS cup in Table 3. Against this background, there is a slight preference for recycling over incinerating disposable cups. Other reflections worth to be mentioned here (Potting 2013):

- Pilot experiments suggest that efficiency and contamination of separate collection of disposable cups depends on the way of collecting (e.g. in stacks or loose in bins or containers). Contamination of the collected disposable cups was roughly 40%, 20% of beverage-remainders, and 20% others (e.g. plastic stirrer, plastic bread bags, metal staples, clock houses etc.)
- PLA is not compostable in a back-garden compost-heap, but disposable PLA and biopaper cups both composts well in (semi-) industrial compost facilities as a composting experiments showed (‘cold’ instead of thermo-resistant disposable cups were used in these experiments). Incomplete composted PLA cups remains visible as white traces, however, which makes the compost unfit for commercial sales
- Disposable biocups are in practice not composted in Dutch commercial composting facilities as biodegradable and non-degradable cups are difficult to distinguish, and also because incomplete composting of PLA cups leave white traces in the compost

Table 3. Ranking according to average impact results of waste treatment processes within disposable cup materials. Lowest impact results are indicated by 1, highest impact results are indicated by 4 (incineration = I, recycling = R, composting = C, anaerobic digestion = D).

Impact categories	PS		PLA				Biopaper			
	I	R	I	R	C	D	I	R	C	D
Abiotic Depletion Potential (ADP)	2	1	3	1	4	1	1	3	4	2
Cumulative Energy Demand (CED)	2	1	3	1	4	2	2	1	4	2
Global Warming Potential (GDP	2	1	3	1	4	2	1	3	4	1
stratospheric Ozone Depletion Potential (ODP)	1	2	1	3	4	2	1	2	4	3
Acidification Potential (AP)	2	1	3	1	4	2	2	1	4	3
Eutrophication Potential (EP)	1	2	3	1	4	2	3	1	4	2
ground-level PhotoChemical Oxidation Potential (PCOP)	2	1	3	1	4	2	2	1	4	3
Human Toxicity Potential (HTP)	1	2	3	2	4	1	3	1	4	2
Terrestrial EcoToxicity Potenital (TETP)	1	2	2	1	4	2	1	2	4	3
Fresh-water Aquatic EcoToxicity Potential (FAEP)	1	2	3	1	4	2	3	2	4	1
Marine aquatic EcoToxicity Potential (MAEP)	1	2	3	2	4	1	3	2	3	1

3.3. Dishwashing not convincing better than handwashing for reusable cups (Potting 2013)

Figure 1 shows the impact results of the screening LCAs of the reusable cup life cycles. The impact results are expressed as ratio with the average impact results for the disposable PS cup life cycle with incineration (for which the number of hot beverage consumptions is kept at a one). The reusable cup life cycle with dishwashing performs slightly better than the reusable cup life cycle with handwashing. The impact results for handwashing are strongly influenced, however, by the user-dependent amount of hot water, soap and paper towels applied in the screening LCA. These amounts were set on reasonable worst case amounts, but may in practice be considerably higher as well as lower. It is thus difficult to express a preference for either dishwashing or handwashing of reusable cups on the basis of these results.

As also can be seen from Figure 1, the impact results for both reusable cups roughly halves with two hot beverage consumptions before washing. The environmental gain declines with every next consumption before washing, however, and more than two or three consumptions does hardly lead anymore to a decrease of impact results. The disposable cups can of course also used for more than one consumption, and then a similar decline is at stake with every next consumption before disposing.

3.4. Reusable cups not better or worse than disposable PS (Potting 2013)

The impact results for the reusable cup life cycles from the screening LCA have been compared with the average impact results for the disposable PS cup life cycle with incineration from the in-depth LCA (for which the number of hot beverage consumptions is kept at one time). Similarly as reusable cups, disposable cups can also be used for more consumptions before disposing them. A fair comparison therefore should be based on using reusable and disposable cups for the same number of consumptions. This number of consumptions can be any, as long as it is similar between reusable and disposable cups. This comparison put the number on one consumption, however, since Figure 1 expresses the impact result for the reusable cups as ratio with the impact results for one consumption. Based one consumption for both reusable and disposable cup, the impact results for the reusable cup life cycle with dishwashing are better in some and worse in other impact categories, whereas the impact results for the reusable cup life cycle with handwashing are worse in all impact categories than the impact results for the disposable PS cup life with incineration. As already mentioned in Section 3.3, however, the impact results for the reusable cup life cycle with handwashing are strongly influenced by the user-dependent amounts of hot water, soap and paper towels applied in the screening LCA (which represent reasonable worst case amounts).

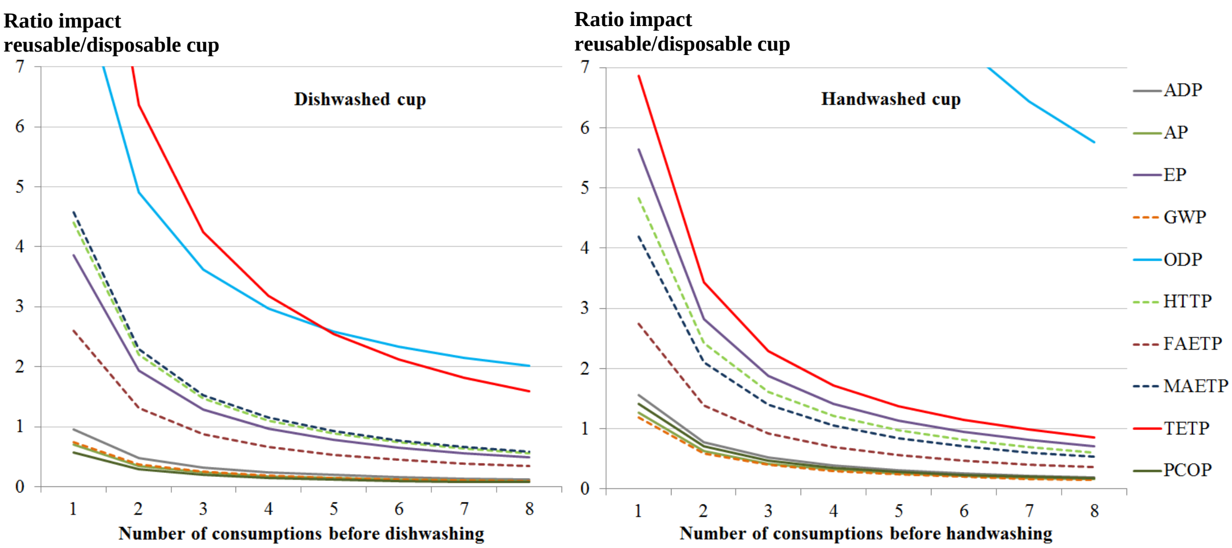

Figure 1. Impact results for the reusable cup life cycles, with dishwashing on the left and with handwashing on the right, expressed as ratio of the average impact results for the disposable PS cup life cycle with incineration as waste treatment (for which the number of hot beverage consumptions is kept one time)

3.5. Facility arrangements improving the environmental performance of all cups

While the overall comparison does not allow any preference for one of the three disposable cup materials, and neither for disposable versus reusable cups, Figure 1 does indicate for the reusable cups a considerable environmental gain from a second and possibly third hot beverage consumption with the reusable cups before washing it. This environmental gain obviously also exist for increasing the number of consumptions of the disposable cup before throwing it away. A second or third consumption is roughly the number of hot beverages that a consumer takes during one morning or one afternoon. Since pathogens probably not multiply so fast, and consumers usually do not share cups, there seems no real public health issue here. Facility arrangements can encourage a second or third serving with the same cup by financial incentives (e.g. paying for a new disposable cup), only putting on the dishwasher around noon and after working time, and/or consumer awareness activities. Consumer awareness activities should also point to the fact that more than two to three servings with the same cup hardly add environmental gain.

4. Conclusion

The overall results do not allow any preference for one of the three disposable cup materials (large and overlapping spread in impact results), and neither for disposable versus reusable cups (impact results for the latter too uncertain and too close to those for the disposable cups). All cups can be used more than once before getting rid of a disposable cup or washing a reusable cup. This gives a considerable environmental gain for the second and third hot beverage consumption with the reusable as well as disposable cups. Facility arrangements can encourage a second or third serving with the same cup by financial incentives (e.g. paying for a new disposable cup), only putting on the dishwasher around noon and after working time, and/or consumer awareness activities. Consumer awareness activities should also point to the fact that more than two to three servings with the same cup hardly add environmental gain.

It was not possible to indicate a preference for one of the three disposable cups, but comparison of waste treatment processes for each cup material gave some basis to express some preferences on the basis of average impact results. Composting is the least preferred waste treatment for both biocups. Anaerobic digestion performs better than incineration for the disposable PLA cup in most impact categories, though this trend does not apply for the biopaper cup. The average impact results suggest a slight preference of recycling over incineration for the PLA cup and biopaper cup, i.e. the impact of recycling is smaller than for incineration, but not for the PS cups which average impact results are better in five and worse in six impact categories for recycling as compared to incineration. The comparison of recycling and incineration, however, is biased by the relative large credits for avoided “dirty” Dutch electricity production. Against this background, there is a slight preference for recycling for all three disposable cup materials.

The in-depth LCA study comparing the disposable cups deliberately applied multiple inventory data sets for the processes contributing most to the impact results, as well as multiple crediting principles for recycling. This led to a large spread in impact results, though for energy related impact categories smaller than for the others. The large spread in impact results may be less easy to interpret, but they represent more robust results.

ABSTRACT

Changes of soil organic carbon (SOC) content can have a substantial effect on greenhouse gas emissions, but are rarely included in crop production LCAs. SOC content strongly influences soil fertility and therefore crop yields, but is declining in many European soils. The present study investigated if integration of 1-2 years of grass-clover crops in a cereal-dominated crop rotation can increase the SOC pool and how this would impact food production. Results show that when grass-clover crops are integrated, the potential SOC content at steady state will be 41 to 52% higher than in the conventional cereal-dominated crop rotation. The net increase of wheat yields based on SOC improvements indicate that for a crop rotation with one year of grass-clover crops, the initial loss of food production can be counterbalanced due to the impact on fertility of the SOC increase.

Keywords: soil organic carbon, grass-clover crops, food crop production, crop yield, soil carbon model

1. Introduction

Energy crop production is often claimed to negatively impact food and feed production, i.e. by competition for arable land and by reducing soil quality. On the other hand, current intensively managed agricultural food and feed production systems are often not sustainable: Loss of soil organic carbon (SOC), erosion and compaction are the main processes threatening soil fertility throughout the EU (EC 2002; Soilservice 2012). Intensively cultivated clay soils have in Swedish studies been shown to give up to 20% decreasing food crop harvest yields due to soil compaction and reduced soil organic matter content (Arvidsson and Håkansson 1991).

The build-up or degradation of SOC is a process with dual and important impact on sustainability in crop production. Firstly, SOC content strongly influences soil fertility and crop yields, but due to e.g. unsustainable management practices and crop rotations it is declining in many European soils (Soilservice 2012). Secondly, agricultural soils can act either as carbon sinks, or, if SOC is declining, as contributors to greenhouse gas emissions. Changes in SOC can contribute substantially to greenhouse gas emissions of crop production, but are rarely included in LCA (Brandão et al. 2011).

SOC content is positively influenced by addition of organic materials such as intermediate crops, crop residues and manure or other organic fertilizers. The main negative impacts on SOC are the outflow caused by mineralization processes of the soil organic matter, the degree of which is related to e.g. climatic conditions and the severity of soil management practices. By changing crops in the crop rotation SOC can be influenced actively. However, addition of organic material is often small in comparison to the amount of carbon already stored in the soil. Therefore long-term changes of SOC are often quantified using models that are calibrated with long-term experimental data.

The present study investigated if integration of 1-2 years of grass-clover crops in a cereal-dominated food crop rotation on intensively managed heavy clay soils can increase the SOC pool. The work is presented in two parts, where the present paper, Part I, shows the impacts on the SOC pool and discusses the potential impact on fertility and crop yields. Part II shows the LCA and effects on greenhouse gas emissions of grass-clover crop introduction to the crop rotation (Björnsson and Prade 2014). In areas with little animal husbandry there is no or a very limited market for grass-clover crops as animal feed and limited availability of organic fertilizers such as manure. Therefore, the approach in this study was to integrate grass-clover crops in the crop rotation for use as biogas feedstock. The biogas plant then takes on the role of the absent ruminants, creates a market for the grass-clover as energy crop, and produces biogas and a digestate (the liquid residue of the biogas production), which is used as biofertilizer.

The study was performed as a farm based case study, where the case farm is representative for a large agricultural region in which the low input of carbon in the cereal based crop rotation has been identified as problematic with regards to the high clay content in the soil. The hypotheses of this study were that (a) an increased SOC content can be obtained by introduction of e.g. grass-clover crops as well as by fertilization with biogas digestate; and (b) that the increased SOC content may increase food crop yields enough to compensate the initial food production losses when the crop rotation is changed.

2. Materials and methods

2.1. The case farm

The farm based case study investigates the effects of different crop rotation and biomass utilization scenarios. As a basis for this case study, a farm with mainly clay rich soils in North West Scania (56°6'N 12°58'E) was chosen. This farm, Wrams Gunnarstorp, is located close to the site of long-term SOC content field experiments in Ekebo, performed by the Swedish University of Agricultural Sciences (SLU) (Kirchmann et al. 1999).

This study concentrated on 650 ha of medium to heavy clay soils with soil clay content up to 65%. The soils are rather cold, and crop establishment is often carried out very shortly in the autumn after harvest of the previous crop. Crop establishment is rather slow, and the risk for the plants to be too big for overwintering is little. This leaves no opening for the introduction of after-sown intermediate crops. In this study, introduction of clover-grass crops extending the crop rotation was chosen as a measure to increase SOC content.

The latest analysis of soil carbon content expressed as humus on the Wrams Gunnarstorp farm dated from 1984. That year, the soils had an average SOC content of ~2% and consisted of very heavy clay soils, heavy clay soils and medium clay soils. The fairly high content of humus in the Wrams Gunnarstorp soils at this time was probably a result of the consequent use of cow manure as biofertilizer until 1960.

2.2. Crop Rotation

On the major part of the farm, a 4-year crop rotation typical for the region is used, Table 1. This present crop-rotation was used in the reference scenario. In the investigated alternative scenarios, grass-clover crops were introduced one year in a five year crop rotation (scenario GC1) and two years in a six-year crop rotation (scenario GC2).

Table 1. Typical sowing and harvest dates on the Wrams Gunnarstorp farm for the reference crop rotation (years 1-4) and extension with grass-clover crops.

Year	Crop	Sowing date	Harvest date
1	Winter oilseed rape	1-10 August	20 July
2	Winter wheat	1-20 September	10 August
3	Winter wheat	1-20 September	10 August
4	Oats	1-20 April	20 August
Scenario GC1 years 1-4 plus			
5	Grass-clover crops	1-20 April[a]	Cut 1: 1 June; cut 2: 1 August
Scenario GC2 years 1-4 plus			
5	Grass-clover crops	1-20 April[a]	Cut 1: 20 June; cut 2´: 20 August
6	Grass-clover crops	-	Cut 1: 1 June; cut 2: 1 August

[a] Undersown in oats in the previous year

2.3. Crop production

Average crop yields were estimated based on annual measurements on the Wrams Gunnarstorp farm. For cereal grains and oilseed rape average production yields were calculated, Table 2. Yields for grass-clover crops were estimated from hand-harvested samples and corresponding machinery field losses (20%) within an ongoing research project at SLU, evaluating grass-clover crop yields on the Wrams Gunnarstorp farm (funded by Stiftelsen Lantbruksforskning, SLF). A grass-clover crop system with two harvests per year was assumed.

Grass-clover crops were assumed to be undersown with the preceding crop, oats. After the oats have been harvested, the grass-clover crops grow up. In the year of establishment, grass-clover crops are assumed to be harvested once in the late autumn. Oats are assumed to be harvested 20th of August and grass-clover crops harvested 30th of September are assumed to result in a biomass yield of 1.5 t ha^{-1} of DM. Winter wheat is assumed to be harvested 10th of August. Breaking of the grass-clover crop is assumed to be carried out 1st of August in order to allow establishment of winter oilseed rape (WOSR). In this year, the grass-clover crop is assumed to yield 9.0 t ha^{-1} instead of 12 t ha^{-1} DM in a full production year. A full production year is only possible the first year of a two-year grass-clover crop.

Details on inputs in crop production (machinery, materials, diesel, fertilizer) are based on typical cultivation input and fertilization levels at the model farm and are presented in Part II of the study, where greenhouse gas emissions for the different scenarios are calculated.

2.4. Amounts of crop residues

Crop yields play a central role in this study, since many analysis parameters are directly or indirectly connected to biomass and/or grain yields. Higher crop yields often result in larger amounts of crop residues, e.g. straw, stubble, roots and extra root biomass, which will impact SOC input. Most models for calculation of crop residues assume a linear connection between harvestable biomass (i.e. grains, seeds, beets, above-ground biomass) and remaining residues above- and belowground in the form of fixed mass ratios for the different plant parts. This is the case for the calculation model for amounts of crop residues suggested by IPCC (2006).

Swedish long term field experiments support models that result in high biomass respective carbon inputs from root and extra root material, higher than what is suggested in the IPCC model (Björnsson et al. 2013). This is especially valid for grass-clover crops, where a large number of plant species of grasses and legumes can be mixed in endless combinations. While grasses contribute much harvestable biomass, legumes contribute nitrogen fixation and root biomass. Another aspect of grass-clover crops is the time factor. High production systems may utilize grass-clover crop blends for 1-3 years, while more long-term or permanent grass-clover crop systems exist as well.

Swedish studies fitting long-term soil carbon measurements to a soil carbon model suggest a constant amount root biomass, 6 t ha^{-1} of DM (Bertilsson 2006). However, in this study, a proportional root biomass development was assumed in the base case, limited with a ceiling value of 6 t ha^{-1} of DM. Another issue is that straw yields suggested in the IPCC calculation model are unrealistically high compared to actual straw yields in cereal cultivation in under Nordic conditions (Nilsson and Bernesson 2009).

In the base case calculations of SOC, model parameters from regional studies (called Nordic) are used for the calculation of amounts of crop residues as described above (Table 2) (Björnsson et al. 2013). For comparison the calculations were repeated with the IPCC methodology for crop residue calculation (Table 2).

Table 2. Dry matter (DM) yield data of harvested crop parts (grains, seeds, grass-clover cuttings) and coefficients used in the systems analysis and for calculation of crop residues and SOC. (1 t = 10^6 g; 1 ha=10.000 m^2).

Crop	DM yield	Nordic		IPCC (IPCC 2006)			Humification coefficients[c]	
	[t ha^{-1}]	Slope	B/A ratio[a]	Slope	Intercept[b]	B/A ratio[a]	Above-ground	Below-ground
Winter oilseed rape	2.5	0.92	0.20	1.09	0.88	0.22	0.15	0.35
Winter wheat	6.5	0.57	0.33	1.61	0.40	0.23	0.15	0.35
Oats	4.0	0.50	0.47	0.91	0.89	0.25	0.15	0.35
Grass-clover, 0 year after oats	1.5	0.25	0.58[d]	0.30	0.00	0.00[d]	0.12	0.35
Grass-clover, 1st of one year	9.0	0.25	0.88	0.30	0.00	0.80	0.12	0.35
Grass-clover, 1st of two years	12.0	0.25	0.26[d]	0.30	0.00	0.00[d]	0.12	0.35
Grass-clover, 2nd of two years	9.0	0.25	0.88	0.30	0.00	0.80	0.12	0.35

[a] Belowground residues/aboveground biomass ratio: aboveground includes stubble and harvested biomass; belowground in Nordic includes extra-root material.

[b] DM in [t ha^{-1}]

[c] (Kätterer et al. 2011); Digestate: 0.41

[d] Only extra-root biomass is accounted for.

Another carbon input with relevance for the SOC calculations in the GC1 and GC2 scenarios is the added biofertilizer, the digestate, which is the residue from the harvested above ground part of the grass-clover crops after biogas production. The details of biogas production are presented in Björnsson and Prade (2014). The data used in the SOC calculation in the present part of the study are presented in Table 3.

Table 3. Harvested grass-clover crop biomass for use as biogas feedstock and resulting digestate for the grass-clover scenarios.

Parameter	Unit	Scenario GC1		Scenario GC2	
		Biogas feedstock[a]	Digestate[b]	Biogas feedstock[a]	Digestate[b]
Dry matter	[kg ha^{-1} a^{-1}]	1995	867	3563	1543
Carbon	[kg ha^{-1} a^{-1}]	904	430	1614	766

[a] Feedstock indicates the average amount of grass-clover removed in the crop rotation after field drying to 35% DM and ensiling.
[b] Digestate indicates what is returned to the field as biofertilizer in average for the whole crop rotation after biogas production and losses during digestate storage.

2.5. SOC model

In order to calculate changes in the SOC content as influenced by the choice of crop rotation, Introductory Soil Carbon Balance Model (ICBM) was used (Andrén and Kätterer 1997; Kätterer and Andrén 2001). The model was applied to calculate the SOC content according to carbon inputs and mineralization rates. The model was modified to account for different input types with specific humification factors (Figure 1).

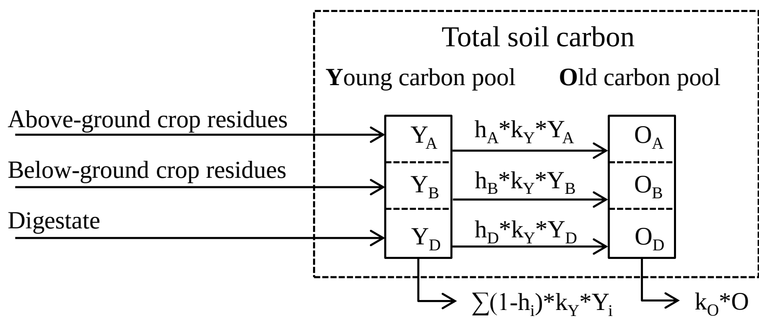

Figure 1. Introductory Soil Carbon Balance Model (ICBM)

All carbon from aboveground residues (A), belowground residues (B) and digestate additions (D) enters the young carbon pool (Y). From this pool, easily degradable carbon is released as CO_2 by mineralization according to a degradation function, while only a material-specific fraction is humified, i.e. stored in the humus part of soil carbon, or, in this model, the old carbon pool. Y has an outflow of carbon with a relatively high reaction coefficient of k_Y=0.8, i.e. within one year 1-exp(-0.8)=55% of the carbon leaves the young carbon pool again (Andrén and Kätterer 1997). The output from the old carbon pool follows a much lower reaction coefficient (k_O) than the young carbon. Carbon content of crop dry matter was assumed to be 45% (Kätterer et al. 2011). A starting value of 2% SOC content was assumed. In the base case, annual SOC content changes were calculated as average values over a time span of 40 years.

2.6. Model calibration

In order to adapt the ICBM to Nordic conditions, the model was calibrated against data derived from the long-term soil carbon field experiment in Ekebo, Sweden (Kirchmann et al. 1999). The Ekebo soil carbon field experiment includes two different crop rotations. One was designed as a crop rotation for an animal production farm, with all cereal straw and sugar beet tops removed. The other crop rotation was designed for a pure plant production farm, with all straw and sugar beet tops left in the field. For each rotation 16 different fertilization regimes (all combinations of 4 nitrogen and 4 phosphorous/potassium fertilization levels) were tested. The experiment started 1957 and is ongoing with regular soil carbon content analyses.

Calibration was done using the reaction coefficient of the old carbon pool (k_O) as a variable to fit model soil carbon predictions to the measured soil carbon data. This was done using crop residue data as computed by (a) the IPCC calculation and (b) by the Nordic calculation for comparison. The prediction power of the model was computed by maximizing the coefficient of determination (R^2) of the measured and predicted data.

2.7. Yield impact

Food crop grain and seed yields have been shown to increase corresponding to the SOC content (Lal 2004; Soilservice 2012). Yield changes due to SOC increases have been calculated for wheat grain yields assuming a DM yield increase of around 0.4-0.8 t ha^{-1} $\%_{SOC}^{-1}$ (Lal 2004). For the SOC content of the case farm soils, each percent of SOC corresponds to approx. 20 t ha^{-1} carbon.

2.8. Sensitivity analysis

In the base case, calculations follow the Nordic methodology, while in the sensitivity analysis IPCC methodology was applied (Table 4).

Table 4. Parameters use in the base and the alternative case.

Parameter	Nordic – base case	IPCC – alternative case
Aboveground crop residues	Only slope	Slope and intercept
Belowground crop residues	Limited to 6 t ha^{-1} of DM; extra root residues correspond to 65% of root residues[a]	Unlimited
Time span for calculation of average annual carbon changes	40 years	20 years

[a] (Bolinder et al. 2007)

3. Results

3.1. SOC changes

The soil carbon content develops positively for all scenarios, but with largely different long-term results, Figure 2. The reference scenario has the conventional cereal based 4-year crop rotation, where all of the straw is left in the field. In this scenario, the steady state of SOC content was reached at 2.9% after approx. 145 years. In the GC-scenarios, grass-clover is introduced in the crop rotation, and the amount of digestate produced from grass-clover digestion is large enough to cover substantial shares of the fertilizer need at the farm, i.e. 15 and 24% of nitrogen, 23 and 34% of phosphorous and 42 and 50% of potassium for scenarios GC1 and GC2, respectively (Björnsson and Prade 2014). The GC-scenarios contribute to a much higher increase in SOC content with steady states at 4.1 and 4.4% after approx. 125 years for scenarios GC1 and GC2, respectively.

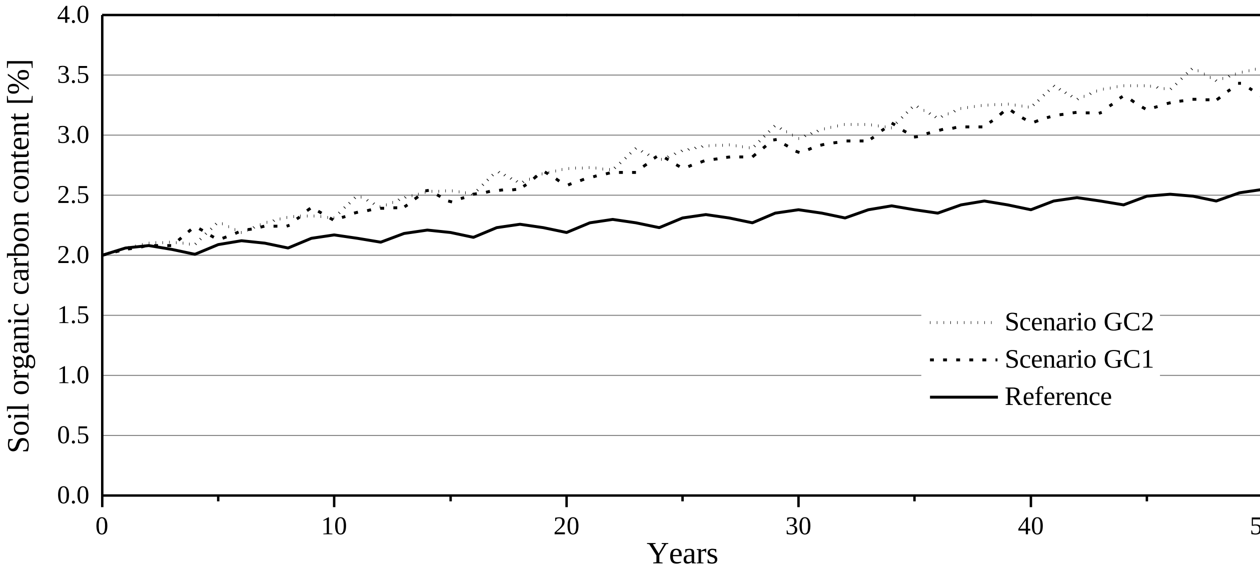

Figure 2. Change in soil carbon content in the investigated scenarios over a 50-year period according to base case calculations.

Figure 3 shows the average annual SOC changes for the crops and the crop rotations studied calculated both with the Nordic and the IPCC methodology. For oilseed rape, oats and grass clover crops, the Nordic methodology results in lower annual SOC additions than the corresponding IPCC methodology, but with relatively small differences. For wheat, using the IPCC methodology results in 168% higher crop residue inputs.

These differences are reflected in the average annual SOC changes calculated for the complete crop rotations. Using the IPCC methodology resulting annual SOC changes are 170%, 47% and 18% higher for the reference scenario, GC1 and GC2 respectively than using the Nordic methodology.

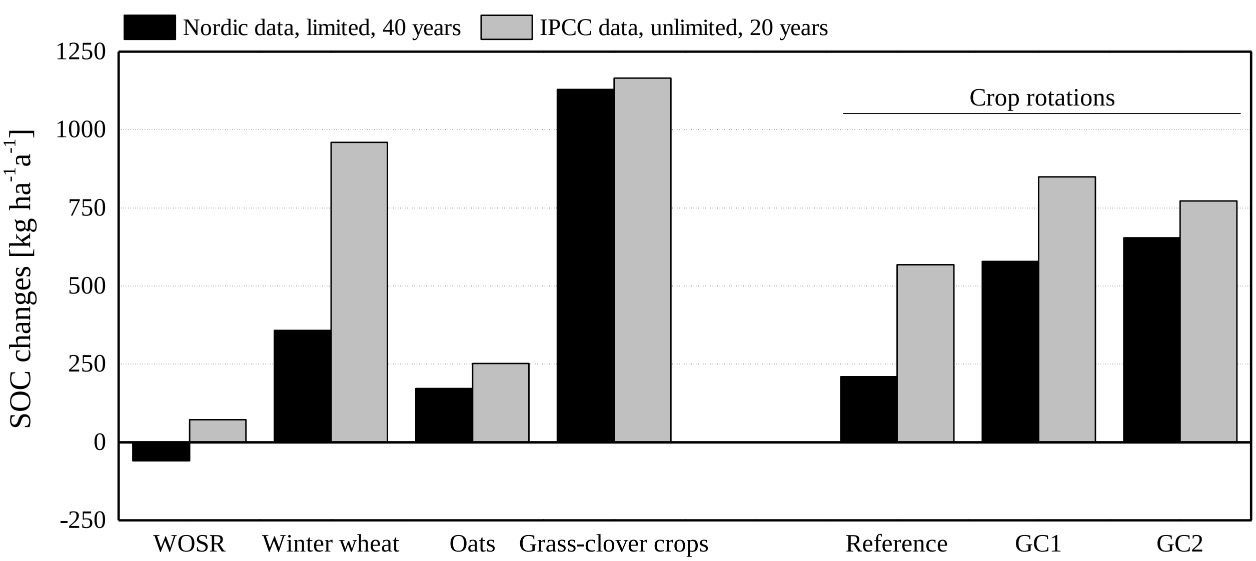

Figure 3. Annual SOC changes of crops and crop rotations according to Nordic and IPCC methodology. For crops, continuous cultivation was assumed. Data for crop rotations represent average annual SOC changes from crop residues and digestate application. 'Limited' and 'Unlimited' refer to root SOC contribution for grass-clover crops. Years given refer to the time span used for the calculation of the average annual SOC changes. WOSR=winter oilseed rape.

The SOC content after 50 years and at steady state (SS) calculated both with Nordic and IPCC methodology are shown in Figure 4. With the rapid and large SOC increase in the GC1 and GC2 scenarios (Figure 2), SOC after

50 years will be more than 0.6-0.8% higher (GC1) to 0.5-1.0% higher (GC2) than in the reference scenario.

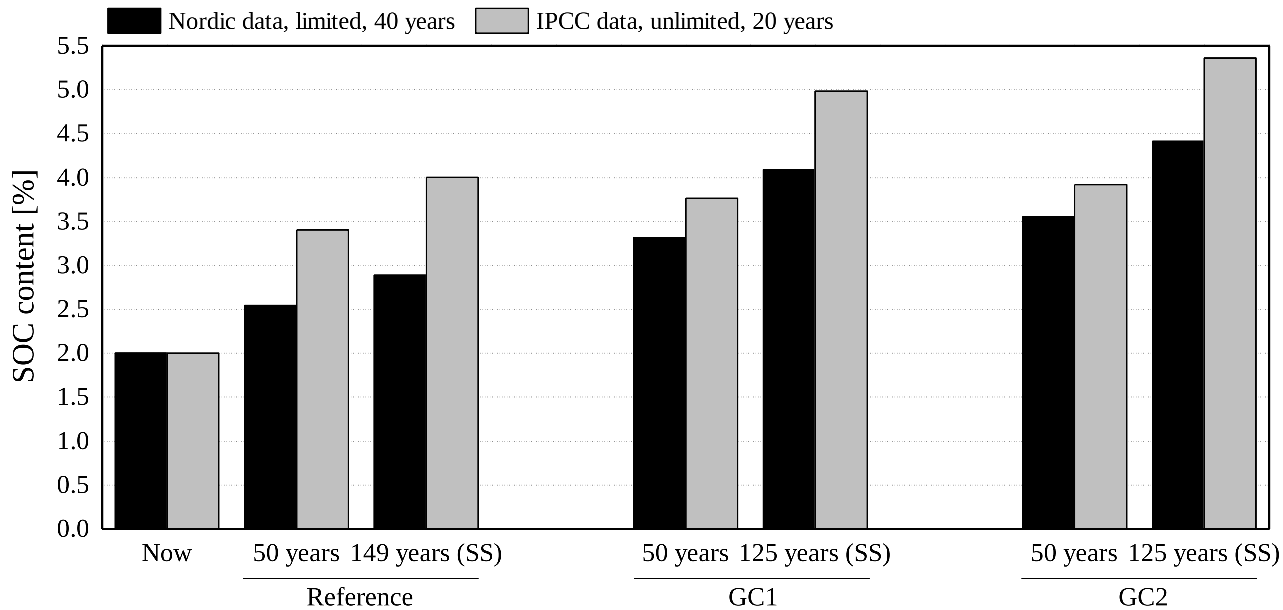

Figure 4. Predicted SOC content at the case farm after 50 years and at steady state (SS) for to the different scenarios according to the Nordic and IPCC calculation methodologies.

3.2. Yield changes

The SOC values after 50 year (Figure 4) would mean 5-10% and 6-12% net increase in yield of wheat grain for scenarios GC1 and GC2, respectively compared to yields in the reference scenario (Figure 5). At steady state, the decrease in food crop production of 20 % - which is the consequence of introducing one year of grass-clover crops in the crop rotation (scenario GC1) - could be offset to a major extent by the yield increase. In scenario GC2, the yield increase at steady state would correspond to around half of the initial food production losses for Nordic and IPCC approach.

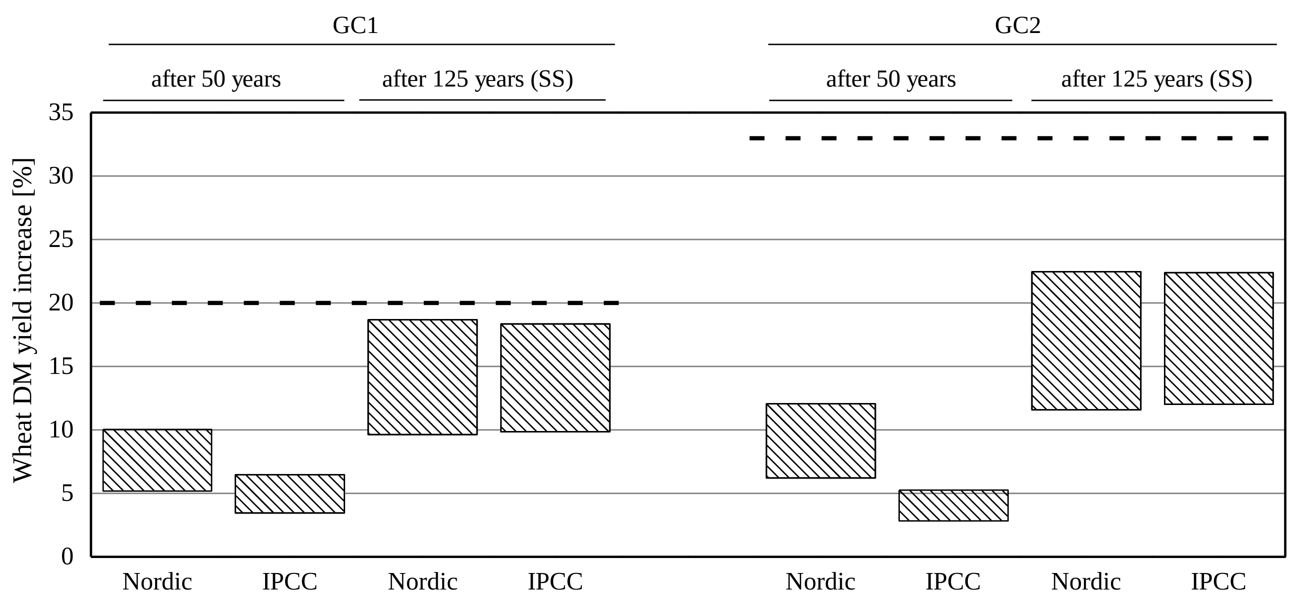

Figure 5. Predicted wheat yield increase relative to the reference scenario at the case farm after 50 years and at steady state (SS). Dashed lines correspond to the initial food production losses caused by the crop rotation changes in the scenarios.

4. Discussion

4.1. SOC changes

SOC content is a parameter that connects soil fertility, crop yields and greenhouse gas issues and therefore is a crucial factor for the environmental performance of a cropping system. Processes leading to changes in carbon soil content are often slow; therefore the time perspective becomes important for life-cycle assessment of agricultural production systems.

This study has shown that extension of a cereal-dominated crop rotation with one or two years of grass-clover crops can improve SOC content in a heavy clay soil substantially, given that the change is a medium to long-term commitment. In fact, the case farm currently operates a second crop rotation on a smaller fraction of the farm, including three years of meadow fescue for seed production in order to decrease problems associated with heavy clay soils and to improve soil fertility. However, the area on which this improved crop rotation is used is limited by the marketing possibilities for meadow fescue seeds. A biogas plant in a region characterized by crop production and lack of organic fertilizers could help create a potential market for grass-clover crops and in return deliver digestate, the liquid effluent from the biogas process, for utilization as organic fertilizer. The results further indicate that improvements of SOC content by including one year of grass-clover crops can potentially offset the initial food production losses caused by the crop rotation change.

Soil carbon content affects many cultivation factors such as nutrient availability, water retention capacity, soil density, soil temperature etc. An increase of soil carbon content may lead to, but is no guaranty for, increased soil productivity, i.e. increased crop yields. But also decreased requirements for fertilization can be a positive result of soil carbon increase. Other, more short-term effects may contribute positively to food production in the system, e.g. the pre-crop effect of grass-clover crops.

Another strategy for improving SOC content would be to implement grass-clover crops in order to boost SOC content to the steady state of the reference scenario in only 29 and 26 years for scenarios GC1 and GC2, respectively, e.g. if return to the crop rotation in the reference scenario is desired.

4.2. Yield increases

The estimates of food crop yield increases in the present study are rather conservative, since calculations neglect two effects. First, in the short term, soil structure improvements by grass-clover crop cultivation could help decrease yield losses due to soil compaction and standing water. Secondly, these short-term yield increases and SOC-related yield increases have a positive impact on crop residue input. Therefore, these calculations underestimate potential yield increases. Therefore, the next step for a follow-up project is to implement yield impacts, accumulated food production losses and impacts on fertilization requirements in the SOC model.

4.3. Calculation methodology

While changes in a crop rotation have a small short-term effect, the long-term effects may lead to significant changes in soil fertility, crop yields and greenhouse gas emissions of a cultivation system. It is therefore important to investigate potential long-term effects of carbon input on the soil carbon content. IPCC suggests a period of 20 years to be used for this purpose. In theory, changing from one established cropping system to another with a change in the average carbon input may result in a change of soil carbon content. How quickly the change will take place and the time required to reach a new steady state depends on many factors. However, the soil carbon content will change along an asymptotic curve, with the highest absolute changes in the beginning. With time, these differences will become smaller and smaller until a new steady state is reached. Therefore, the shorter period for calculating the average annual carbon change as suggested by IPCC will result in higher changes compared to a longer calculation period and may therefore potentially overestimate the effect of crop residue additions.

Another issue with the IPCC calculation methodology is the overestimation of wheat crop residues, at least compared to Nordic conditions. The straw yields suggested in the IPCC calculation model are unrealistically high compared to actual straw yields in cereal cultivation in Sweden (Nilsson and Bernesson 2009). IPCC data gives thus higher SOC accumulation for all the investigated scenarios, but with larger impact on the reference scenario with 75% cereals in the crop rotation.

5. Conclusions

The investigated change from an agricultural food production system only producing food crops to a system with integrated production of food and energy crops was shown to be a potentially important tool to improve SOC content considerably. Securing future food production will require sustained or even increased SOC content. While extending food crop rotations with grass-clover crops results in a direct decline in food production, the long-term effect of SOC increase may increase food yields, both due to improved soil fertility and structure.

Extending cereal-crop dominated crop rotations with grass-clover crops could help integrate biofuel and food production. Plant nutrients in the biogas digestate can be recycled, including SOC building carbon. This diversification of crop rotation is especially interesting in regions with no demand for cattle feed.

Finally, carbon sequestration by increasing SOC content and greenhouse gas mitigation by biogas production from grass-clover crop biomass may improve the carbon balance of food production considerably, which is further discussed in Part II of this study (Björnsson and Prade 2014). This study demonstrated the importance of SOC changes in agricultural production systems and such changes should be accounted for in future LCA studies.

ABSTRACT

Besides biofuels from microalgae, an emerging interest in using macroalgae as feedstock for biofuel production is observable. Macroalgae have the advantage that they are much easier to harvest than microalgae so that the problem of low feedstock concentration does not arise. The environmental performance of bioethanol from onshore grown green algae is assessed using literature data and initial laboratory scale data. The optimized system model allows for producing an environmentally efficient biofuel in comparison to fossil fuel and bioethanol from sugar cane. Handling the co-product by substitution instead of energy allocation significantly reduced the environmental impacts of the system and resulted in environmental bonuses in several impact categories. Thus, the management of the co-product in the LCA model (energy allocation vs. substitution) is a key step in the LCA, as it highly influences the impact assessment results.

Keywords: Bioethanol, macroalgae, *Ulva*, eco-design, allocation, substitution

1. Introduction

Algae (microalgae and macroalgae) have recently been identified as an attractive, alternative renewable source for biofuel production compared to biomass from food or cellulosic materials (John et al. 2011; Wei et al. 2013). Marine algae production does not compete with food production, as algae do not need fresh water or arable land, but may use land depending on the culture system selected. Algae can use CO_2 from industrial emissions as carbon source. In addition, the biomass yield per unit area is higher than that for terrestrial biomass (Gao and McKinley 1994). While the production of biofuels from microalgae is intensively studied since a couple of years, the interest of using macroalgae as feedstock for biofuel production just emerges. Macroalgae have the advantage that they are much easier to harvest than microalgae so that the problem of low feedstock concentration does not arise.

To our knowledge, only a few Life Cycle Assessment (LCA) studies have been carried out so far with respect to biofuel production from macroalgae. Pilicka et al. (2011) evaluated the environmental impact of biogas production from onshore cultivated macroalgae. Langlois et al. (2012) studied environmental effects of biogas production from offshore grown seaweed. Alvarado-Morales et al. (2013) conducted an LCA study of biofuels from offshore grown brown algae in Nordic conditions, focusing on biogas production, and both bioethanol and biogas production. Aitken et al. (2014) assessed environmental burdens of biofuel production from offshore grown macroalgae, focusing on different offshore cultivation methods and the production of biogas and biogas + bioethanol.

This study assesses the environmental performance of bioethanol from onshore cultivated green macroalgae (sea lettuce). The evaluation was based on literature data and initial laboratory scale data, as industrial scale facilities for bioethanol production from macroalgae do not exist. Limits of this approach were discussed with a focus on the co-product management in the LCA model.

2. Methods

2.1. Goal and scope, and functional unit

The goal of the study is to evaluate the environmental performance of bioethanol production from onshore grown macroalgae (*Ulva* sp.) using the Life Cycle Assessment (LCA) methodology. A reference scenario (Figure 1) is assessed to determine the main contributors to the environmental impact of the system. Based on this contribution analysis, an optimized system is proposed with eco-design improvements. The functional unit of the system is the production of 1 MJ by combustion in a passenger car in order to compare the environmental impact of the combustion of bioethanol from *Ulva* with that of other fuels. Environmental impacts are assessed at midpoint level using the ILCD 2011 impact assessment method (European Commission - Joint Research Centre - Institute for Environment and Sustainability 2011).

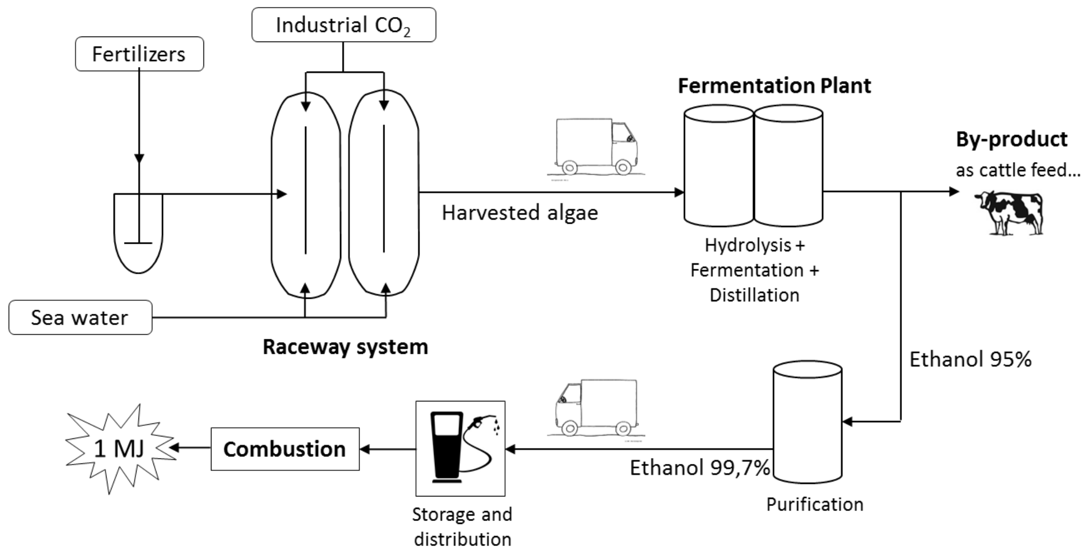

Figure 1. Schematic representation of the process chain for bioethanol production from onshore grown macroalgae.

2.2. Life cycle inventory

The life cycle inventory is based on literature data and initial laboratory scale data, as industrial scale facilities for bioethanol production from macroalgae do not exist.

2.2.1. Seaweed production

Algae (*Ulva* sp.) are cultivated in open raceways, and are stressed by nitrogen starvation to obtain high starch contents (up to 40% of the dry matter). In total, 8 raceways, each with a surface area of 500 m^2 and a water volume of 250 m^3, are used for seaweed production. Four raceways are used for growing *Ulva* at high nitrogen concentrations (high biomass yields), while the other four raceways are used for nitrogen starvation of *Ulva*. The excavated raceways are lined with an EPDM liner of 1 mm thickness and are mixed by paddle wheels. The productivity of *Ulva* is estimated to be 20 g dry weight (DW)/m^2/day with an initial algae density of 3 kg fresh weight (FW)/m^2. Assuming that the *Ulva* production site is located in Brittany, France, the *Ulva* production season has a length of seven months, ranging from April to the end of October. A season of 28 weeks is assumed, resulting in an *Ulva* production of 3.92 kg DW/m^2/season (39.2 t DW/ha/season). The seawater in the raceways is exchanged once a week with fresh seawater, filtered by a drum filter. Nutrients are supplied once a week to the first raceway system by dosing a modified f/2 culture medium (without vitamin and silicium solutions) at recommended quantities (Andersen 2005). The nutrient solutions are stored in three stainless steel tanks with an effective volume of 1 m^3 each. The tanks are mixed during the night (12 hours) to ensure homogenization of the nutrient solutions. Compressed and liquefied CO_2 is injected into the raceways through PVC pipes. Seaweed is harvested using perforated conveyor belts.

2.2.2. Bioethanol production

The harvested seaweed is transported over 60 km from its production site to the bioethanol production plant. Ethanol is produced by hydrolyzing and fermenting starch, followed by a distillation. The ethanol production process is based on ethanol production processes inventoried in the EcoInvent v2.2 database and described in detail in Jungbluth et al. (2007). Data for input of chemicals and other materials, energy consumption (electricity and heat), needed equipment, and emissions to the environment are determined as dry weight-based averages from EcoInvent inventories for bioethanol production from other starch-rich biomasses (potatoes, rye, and corn). The bioethanol yield of *Ulva* is estimated to be 0.13 g bioethanol/g DW *Ulva*.

2.2.3. Bioethanol purification, storage, distribution, and combustion

Purification, storage, distribution to service stations, and combustion of bioethanol in a passenger car are based on processes inventoried in the EcoInvent v2.2 database for bioethanol from other feedstocks.

2.2.4. Valorization of by-products and allocation

The residue of the fermentation step (named Distiller's dried grains with solubles (DDGS) by analogy) is assumed to be valorized as animal feedstock, as it is done in EcoInvent v2.2 for fermentation residues issued from other starch-rich biomasses (potatoes, corn, rye) (Jungbluth et al. 2007). The production of 1 kg ethanol from *Ulva* generates 5.74 kg (dry weight) of a DDGS equivalent. The co-product is handled by energy allocation as recommended by the European Commission for biofuels (European Commission 2009). A lower heating value (LHV) of 28.1MJ/kg is assumed for ethanol (Jungbluth et al. 2007). For the by-product, a LHV of 13.5 MJ/kg is estimated based on the LHVs of its components. This results in an environmental burden of 26.6% for the produced bioethanol and 73.4% for the by-product.

3. Results

The contribution analysis for producing 1 kg bioethanol with the reference system showed that the main contributors to the environmental impact of the system were the electricity consumption (French electricity mix: 78.1% nuclear, 10.8% hydroelectric, 4.4% coal, 3.2% natural gas, 1.5% other fossil fuels, 2.0% other), the infrastructure of the macroalgae production system (scale-up effect), and the origin of the nutrients for macroalgae production. Based on these results, an optimized system was defined, which had a modified algae production infrastructure (raceway dimensions and choice of materials) resulting in reduced electricity consumption and used fish farm wastewater as nutrient source for macroalgae.

The improved system model significantly reduced the environmental impacts of bioethanol production from onshore grown macroalgae (Figure 2). While the reference system had the highest environmental impacts on 12 of the 16 impact categories, the optimized system did not have the highest impact on any impact category. With the optimized system, bioethanol from macroalgae can be produced at lower environmental burdens than from sugar cane. The large impact of bioethanol from macroalgae on ionizing radiation resulted from the consumption of French electricity for macroalgae production. Using electricity from offshore wind power plants drastically reduced the impact on ionizing radiation to a level similar for petrol or bioethanol from sugar cane (data not shown). Macroalgae based biofuel combustion (optimized scenario) reduced greenhouse gas emissions by 57% and ozone depletion by 67% compared to fossil fuel combustion. In general, the optimized system model allows for producing an environmentally efficient biofuel in comparison to fossil fuel and bioethanol from sugar cane.

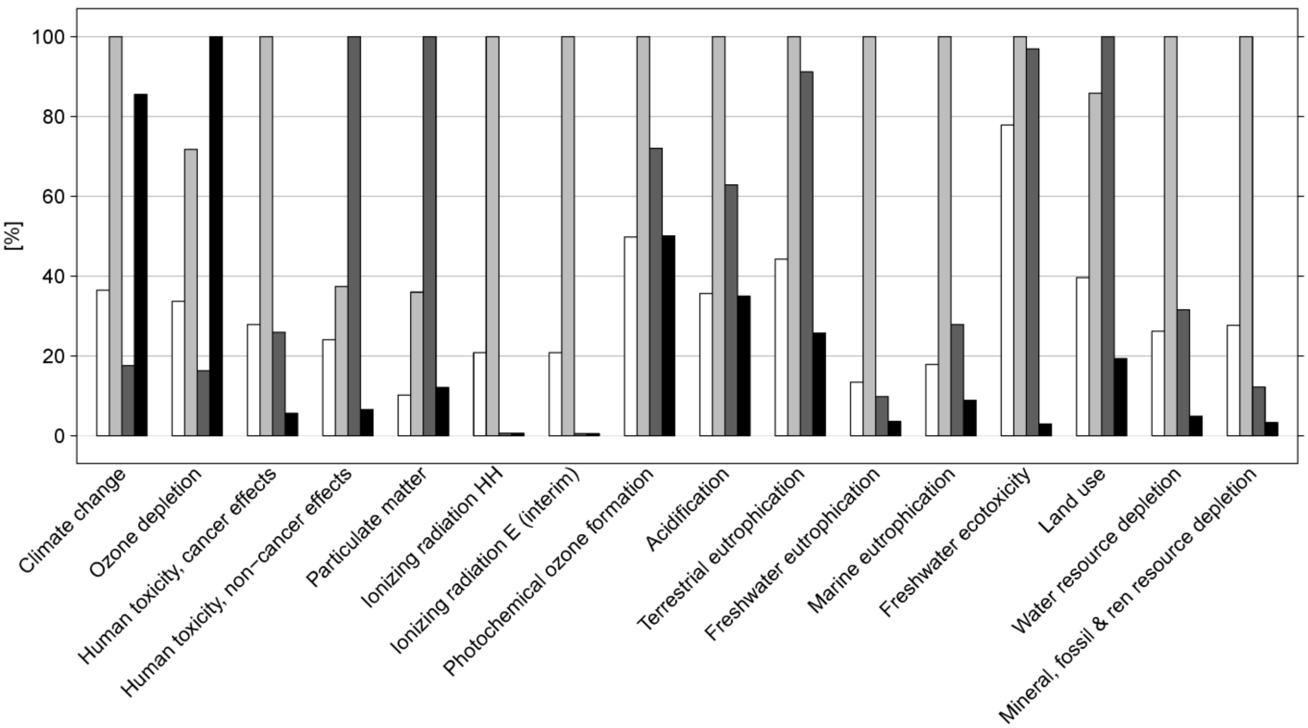

Figure 2. Life cycle impact assessment of 1 MJ obtained by combustion of petrol (black) and bioethanol from sugar cane (dark gray), from algae with the reference scenario (gray), and from algae with the optimized scenario (white).

4. Discussion

Co-product handling is a reiterated topic in LCA. We handled the obtained co-product, which was valorized as animal feedstock as for fermentation residues issued from other starch-rich biomasses (potatoes, corn, rye) (Jungbluth et al. 2007), by energy allocation as recommended by the European Commission for biofuels (European Commission 2009). As a consequence, only a quarter of the environmental burdens of the system were attributed to the produced bioethanol. Following ISO 14044 (2006), allocation should, however, be avoided wherever possible by dividing the unit process to be allocated or by expanding the product system. In order to avoid allocation, we extended the product system by substituting the produced co-product (DDGS equivalent, valorized as animal feedstock) for animal feedstocks, such as DDGS from rye, or grass silage (from intensive farming). Substitution of animal feeds is based on the dry weight of the feedstocks and their neutral detergent fiber (NDF) content, as NDF is the most common measure of fiber used for animal feed analysis. The composition of DDGS from rye was taken from the animal feed resources information system Feedipedia (www.feedipedia.com) and the one of grass silage from Yan and Agnew (2004). For the production of 1 kg ethanol from *Ulva*, 6.24 kg DDGS equivalent from *Ulva* (fresh weight) replace 5.85 kg of DDGS from rye or 10.11 kg grass silage. Whether a DDGS equivalent co-product from *Ulva* grown on intensive fish farming effluents is suitable as animal feed, due to (1) potential contamination with pharmaceuticals and other pollutants from the fish farm absorbed by the macroalgae and (2) possible aversion of animals to DDGS equivalent feed, remains, however, to be studied and discussed. The goal of comparing the different co-product handlings was to evaluate the impact of the choice of co-product handling on LCA results.

Handling the co-product by substitution instead of energy allocation significantly reduced the environmental impacts of the system and resulted in environmental bonuses in several impact categories for both replaced animal feedstocks (Figure 3). Thus, the management of the co-product in the LCA model (energy allocation vs. substitution) highly influenced the impact assessment results.

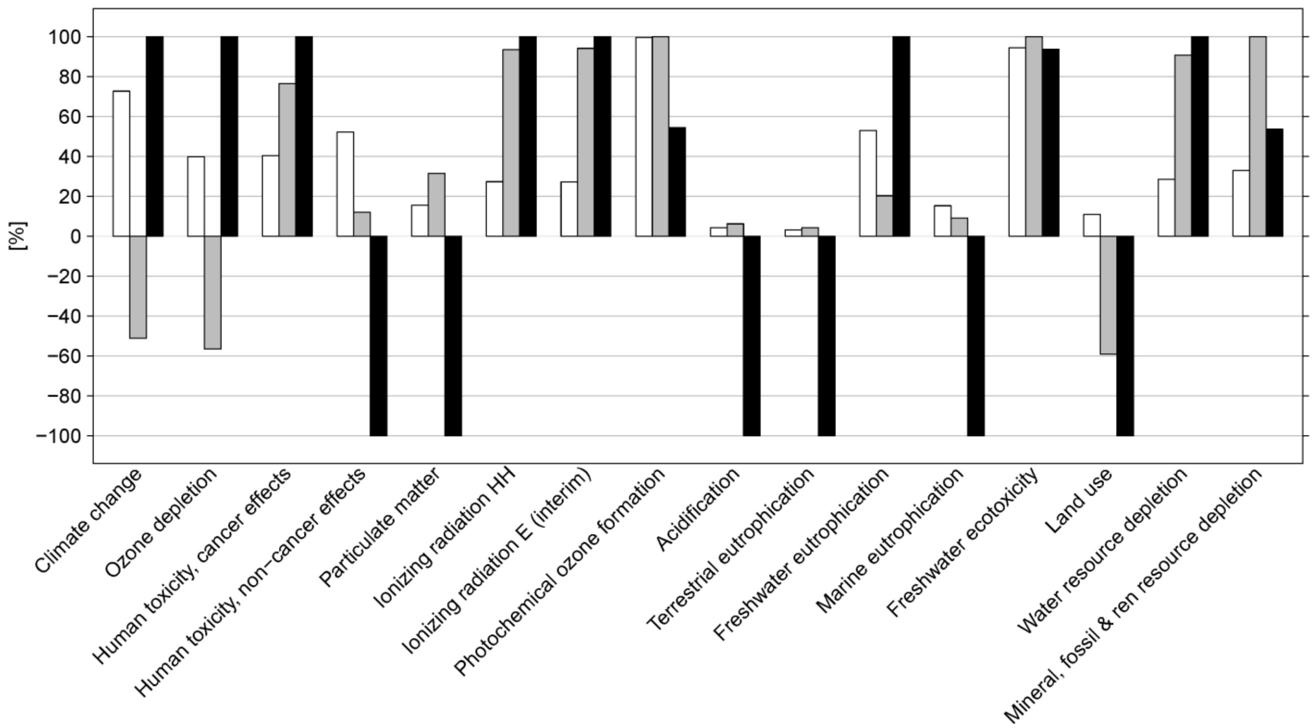

Figure 3. Life cycle impact assessment of one mega joule (MJ) obtained by combustion of bioethanol from algae with the optimized scenario applying energetic allocation (white), substitution for DDGS from rye (gray), and substitution for grass silage (black).

5. Conclusion

Based on literature data and preliminary studies, this work assesses environmental burdens of bioethanol from onshore grown macroalgae. The study revealed that an optimized system model allows for producing an environmentally efficient biofuel in comparison to fossil fuel and bioethanol from sugar cane. LCA results were highly dependent on the type of co-product management selected, as changing the co-product management from energy allocation to substitution significantly reduced the environmental burdens of the studied system.

ABSTRACT

A concept for communication of climate impacts of lunches was developed in Finland. The criteria for a Climate Choice Lunch concept were created in a stakeholder dialogue and three restaurant operators piloted the concept in 25 restaurants in spring 2014. The pilot was based on simplified carbon footprint assessment of 105 ordinary lunches, consisting of around 200 different ingredients. Quantitative assessment was made to understand variability and reasons of plate level climate impacts and to set up quantitative criteria, maximum limit, for a Climate Choice Lunch. Other sustainability criteria were also included in the concept. The pilot confirmed that to promote climate-friendly eating a long-term concept, instead of a short campaign, is needed. There is interest among consumers and restaurants for climate impact information on food. Lunch is regarded as a good opportunity for consumers to learn about climate-friendly eating. The main challenge is to produce sufficient reliable background data.

Keywords: carbon footprint, communication, consumer, eco-design, stakeholder dialogue

1. Introduction

A quarter of climate impacts of consumption come from food production and its consumption (Seppälä et al., 2011), yet consumers do not have enough information or sufficient understanding to make climate-friendly choices about food (Hartikainen et al. 2014). The most significant reductions in greenhouse gas emissions for food consumption can be made at the diet level. Reducing consumption of meat, eating seasonal foods and eating according to energy needs are key issues. Not all the responsibility can be placed on consumers, but they could play a significant role by making informed choices that are good for the environment and their health.

Consumer communication of climate impacts of foods should be made very simple, but challenges are substantial and consumers do not perceive food consumption as being a significant source of environmental impacts, particularly regarding contribution to greenhouse gas emissions (Hartikainen et al. 2014). Therefore, the Climate Lunch project (2013-2014) was established with two specific aims: to raise consumer awareness of climate impacts of food and to concretize the features of climate-friendly food portions and ingredients. The project aimed to decrease the climate impact of Finnish lunches significantly by offering a climate friendly lunch alternative to Finnish consumers, and indirectly by educating them about climate friendly food choices in general.

During the project, a concept of a Climate Choice Lunch was developed and tested in co-operation with pilot restaurants. The project defined, in close co-operation with stakeholders in the Finnish food sector, a set of criteria for the Climate Choice Lunch based on reliable and unbiased scientific information that are sufficiently ambitious enough in terms of reducing climate impact. This concept is significantly different to other campaigns on climate friendly eating in that the maximum limit of climate impact for Climate Choice and Better Climate Choice were defined and also other sustainability and nutritional criteria were considered. Efforts were also made to make sure that all the criteria would be acceptable to all stakeholders in the Finnish food sector.

Additionally, the concept of the Climate Choice Lunch aimed to be simple enough to be easily integrated into the current production systems of Finnish restaurants and cause minimum extra work to the restaurant staff. Developing the concept balancing between scientific precision, simple consumer communication and practicality for service providers has been crucial.

2. Defining criteria for Climate Choice Lunches in a stakeholder dialogue

The planning started with a review of initiatives, campaigns and concepts related to climate impacts of ready meals and lunches. Nothing similar to the planned concept was found, but different types of campaigns were found, including ‘Meatless Mondays’. In particular, no information was found on the successfulness or lessons learned from different initiatives. Closest to the planned concept was a project in Finland, in which one of the restaurants that participated in the Climate Lunch project had also participated a few years ago and in which a one-week climate friendly lunch campaign was staged. The recipes were not evaluated and the climate friendliness was only assumed by offering seasonal vegetables and vegetarian and fish meals.

A second review was made of methods to evaluate additional sustainability aspects of food. It was noted that no meal should be promoted that could be considered a non-sustainable choice in another impact category. Therefore, nutritional and other sustainability criteria were reviewed. Mainly issues of social responsibility, such as animal welfare, working conditions, product safety, and environmental impacts (eutrophication and acidification) were looked at, but we did not find enough information to make justified exclusions of specific ingredients. It was also noted that there are insufficient easily-available, science-based criteria for animal welfare, working conditions etc. It was also seen that animal welfare could conflict with climate impact. Product safety in Finland is already well developed and was not necessary to include as a criterion. It was also considered if fair trade products should be recommended, but it was not seen as a relevant criterion for climate friendly concept. Regarding other environmental impacts, such as eutrophication and acidification, there are not enough data in the literature to estimate them qualitatively.

Through a stakeholder dialogue with restaurants, government, health organizations, environmental organizations etc., consensus for inclusion of criteria for climate-friendly lunches other than for climate and carbon footprint maximum limit were set. First, results of the review were presented to the project's steering group. Afterwards a stakeholder workshop was held for 23 participants to comment on and accept the steering group's choices on criteria other than for climate and to define target maximum limit for climate impact of climate-friendly lunches. A simplified carbon footprint assessment formed the basis for the stakeholder discussions on the quantitative climate impact maximum limit of the Climate Choice Lunch concept. Voting on the target maximum CO_2-eq. limit, different stakeholders exhibited differing preferences on the ambitiousness. The restaurants and food industry were much more careful in setting the reduction target than were NGOs, which were more courageous. Ultimately, the project steering group suggested two levels for labeling, (standard) Climate Choice and Better Climate Choice. Two levels of labeling were seen as being more complex for consumers, but were acknowledged as being crucial to the concept, being both credible and ambitious enough in the eyes of environmentally aware persons while, being of general interest (for people who want to eat at least some meat). Milk and bread were always fixed in a meal according to national public mass catering guidelines and restaurants have only few possibilities to affect their climate impact. Therefore, the limits for the lunches were defined for the meal components for which restaurants can make significant changes to recipes and thus to climate impacts: main course, possible side dish (pasta, rice, potatoes etc.) and side salad.

Final decisions were made in the steering group after the workshop. The limit for the Climate Choice Lunch was defined as 15% less emissions than an average lunch, which means it can still include at least some meat, and for the Better Climate Choice Lunch at 30% less emissions than average. This means that the maximum climate impact of a Climate Choice Lunch is 0.65 kg CO_2-eq./main course and side salad, and for a Better Climate Choice 0.8 kg CO_2-eq./main course and side salad, based on the quantitative assessment of climate impact of lunches presented in chapter 3. Thus, the Better Climate Choice Lunches were almost all vegetarian, expect for some herring, pollock and salmon dishes. Climate Choice Lunches were also mainly vegetarian, with some fish dishes and a few pork or broiler dishes. Generally speaking meat dishes needed to have a side salad with a lower climate impact than average salad and relatively less meat and more vegetables to have a climate impact below the threshold.

Finally, WWF's sustainable fish list and national public catering nutritional recommendations applied as minimum criteria for the concept. The public recommendations define a nutritious meal and they include a glass of milk or sour milk with the meal. Because of the relatively high climate impact of animal products, the inclusion of milk was greatly discussed, but in the end a glass of milk was included in the concept in line with the recommendations.

3. Quantitative assessment of climate impacts of lunches

In the planning process of the concept it was already clear that greenhouse gas emissions for all ingredients from different production systems and countries, as used by the restaurants involved, could not be estimated in detail. Therefore, a simplified carbon footprint assessment was conducted based on MTT's previous Life-Cycle-Assessment (LCA) studies and literature reviews, and new scientific literature.

There was no intention to study the precise greenhouse gas emissions of a specific lunch meal based on particular LCA guidelines, but the order of magnitude of different types of lunches and the contribution of different ingredients to total climate impacts of meals was sought. The estimation would serve at this point only to enable development of the Climate Choice Lunch concept, its criteria and incentives, and piloting of the concept for one week.

The main criterion of the concept being climate impact, it was crucial that it be based on as reliable background information as possible. However, it is clear that the comparability of climate impact results from different studies and different products are not directly comparable. The lack of comparability and harmonization creates challenges and limitations for communicating initiatives such as this concept. The best available and applicable data from previous carbon footprinting projects were used, a few data gaps were filled and where regarded as important, a few production systems and average regional and or seasonally adopted estimates were created (such as for tomato, cucumber and salad production in south, central and northern Europe in winter).

Impacts of 105 lunches from three types of lunch restaurants were estimated, comprising around 200 different ingredients. The emissions were estimated for each restaurant's one-week menu and mainly for the raw-material production of ingredients in the recipes. They could be unprocessed raw materials, such as uncooked and unpeeled potatoes, or readily processed and cooked ingredients, such as fish fingers.

As the major share of a meal's climate impact comes from its primary production and due to limited resources of the project, mainly emission figures readily available in LCA literature, such as those from agricultural stage and input production (energy, fertilizers etc.), were included in the assessment.

As figures for processing, transport and storage were not always included in the studies available, they were not systematically included. In the case of processed ingredients, the original recipes were assessed so as to assess the actual amount of raw materials used (wheat, sugar, vegetable oil etc.). Generally, no emissions from the processing stage were included. Production losses were not taken into consideration systematically, even though they can have significant influence. Yet, because of its significance, values for the yield of processing stage of meat were included, and thus boneless meat was considered in recipes. Production losses when cooking meat (water loss) were also considered when restaurants used cooked ingredients in their recipes. In addition, it was known that emissions from processing and cooking in restaurants would be significant, but the restaurant sector does not currently record enough information on the corresponding energy consumption, which would have been allocated differently for different lunch meals.

The estimation was not made according to real consumption data of consumers in different restaurants, but to allow comparisons of different meals from different restaurants, estimations were in line with the standardized meal composition as defined in the Finnish public catering nutritional recommendations (Ministry of Social Affairs and Heath 2010). Therefore, a meal included a main course (400g of soup, 300g of casserole, 150 g of meal sauce or 120 g of meatballs or fish or equivalent + 30 g of sauce), with a side dish (100 g rice, 150 g potatoes or 120 g pasta, all weights as boiled), 200 g of side salad, 30 g slice of bread (or two if main course was soup), 5 g of margarine per slice of bread and 170 g of milk. The recommendations also defined minimum fiber and vegetable intake per meal, and maximum total and saturated fat and salt intake per meal.

The climate impacts of complete meals ranged between 0.6-2.8 kg CO2-eq. per meal, the average being 1.21 kg CO2-eq. per meal or 0.95 kg CO2-eq. per main course and side salad (some examples are given in Figure 1). According to the results, the climate impacts of main courses and side salads varied greatly. The largest impact of a main course was almost 20-fold compared with the smallest. The largest burden of a side salad was fourfold in comparison with the salad with the smallest burden. On average, a main course caused 45% of the impact of a meal, a side salad almost 30%, milk 20% and bread less than 10%. According to the results, differences in different lunch plates were large. By composing a meal differently, or even only changing the recipe of the main dish or side salad, climate impact could be decreased significantly without compromising nutrition.

Vegetarian meals usually had significantly lower emissions than the average meal. However, the climate impact of some meals that included a lot of cheese, cream or northern European vegetables grown in greenhouses during winter, were above the average. Fish main courses generally had low impacts, except for a few salmon dishes. Whether a fish meal was below or over the average depended greatly on the impacts of the side salad. The emissions of meat dishes were at or above the average. Moderate meat consumption as a part of well composed meal can keep the burden to the average level. For example, a pork stew with a side salad, which has low climate impact, can be below the average. Also the burden of pasta with mincemeat sauce can be average or very high depending on the type and amount of meat.

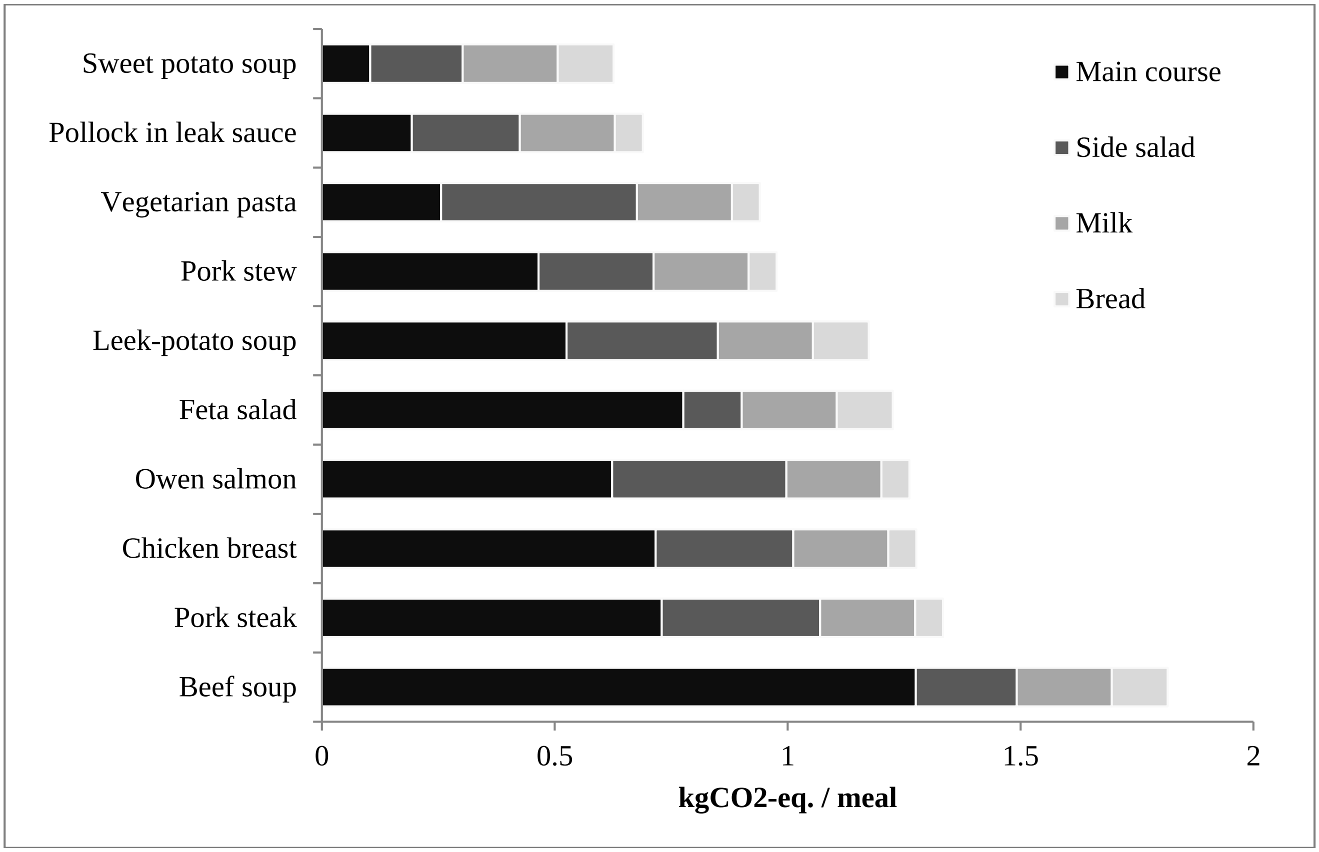

Figure 1. Examples of climate impacts of lunches.

4. Piloting the Climate Choice Lunch concept

To ensure practicability and to pilot the developed concept, three types of restaurants were included in the process. All restaurants offered a buffet lunch with 3-6 options per day, including at least one vegetarian option. Two of the 25 restaurants were office canteens, on the premises of an industrial company and one a canteen of an environmental institute. One restaurant was a public canteen for mainly office workers and students and this was the only one outside the main metropolitan area of Helsinki. The three were part of the leading Nordic catering company. One restaurant was a high quality but small restaurant of a catering school already committed to the Nordic Swan environmental label. The remaining 21 restaurants belonged to the same chain of canteens for students and offered government subsidized lunches.

The restaurants offered the project lunch recipes over a typical week. Based on the initial assessment, most of the restaurants needed to make changes in their recipes to lower climate impacts of their meals and to have Climate Choice and Better Climate Choice lunches available on their menus every day. Restaurants planned their own communications (both on-site and on the Internet) of the pilot weeks based on a common layout, logo (see Figure 2) and slogan developed in the project. After the pilot stage, restaurant staff gave valuable feedback on the practicality of the concept.

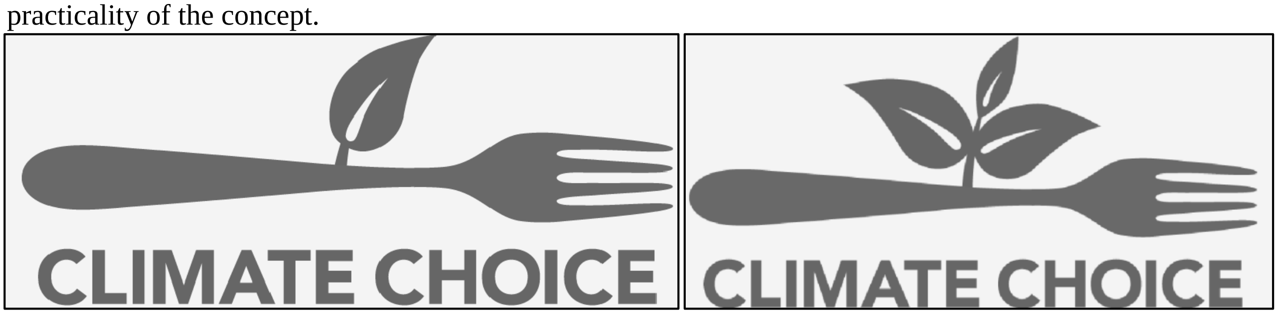

Figure 2. Logos for Climate Choice (one leaf) and Better Climate Choice (three leaves) lunches.

The starting point of the project was that most consumers do not have sufficient understanding to make informed climate-friendly decisions, which has been discovered in the earlier projects of MTT. Therefore, simple, label-based communication was considered the best way to communicate the issue to most consumers. Most of the restaurants differentiated Climate Choice meals from other meals by labeling them in the buffet. Only one restaurant marked Climate Choice Lunches solely on the menu available at the buffet. In addition, some restaurants informed about the Climate Choice Lunch week on tables where clients ate and in posters around the restaurant. Some restaurants also labeled their menus on the Internet.

The aim of the consumer studies was to have information on consumers' first impressions of the concept: if they liked the idea or not, why they chose Climate Choice Lunch if they did and whether they would choose it again. Consumer studies were conducted in two simple ways. A one page paper survey was available to be filled in voluntarily in restaurants on Thursdays or Fridays, after four or five days of the pilot phase. In total 307 paper responses were received. In addition, on Wednesdays and Thursdays of the pilot week, 33 interviews were carried out in 4 different restaurants. A short electronic survey was conducted also among restaurant staff about their experiences on the concept and the pilot week.

The concept was tested in 25 restaurants in spring 2014. The motivation of restaurant staff to ensure survey responses from consumers was very important, and in this project it was successful in some restaurants but not all. Therefore, not as many responses were received as hoped for.

Based on the 33 interviews, only around 50% of customers seemed to notice the pilot of Climate Choice Lunch. Information given on the tables where people were eating seemed to be the most efficient means of communication and that information was registered best when put on tables two weeks before the pilot week. A few consumers actually stated they were too hungry and busy when they are queuing to notice information at that stage. Labels that were placed on the buffet, where people choose their main course and which was thought to be the most noticeable and important site for communication, were actually noticed the least. Some people noticed the labels on the menus before the buffet. Very few customers noticed that there were two levels of Climate Choices. Customers also automatically thought that all vegetarian meals would be climate friendly: many people that had chosen the vegetarian meal thought that they would have opted for the Climate Choice, even if that was not true.

It seemed that during a short campaign as represented by this pilot phase, people who reacted quickly to communication (here the label) and chose the climate-friendly lunch, did so because they already thought about the environment when making decisions on consumption. Few customers acknowledged that the idea of thinking about climate impacts during lunch was new to them, even though they might have thought about it when grocery shopping. Consumers who had noticed the campaign, and were probably more environmentally aware, wanted more information on why specific lunches were Climate Choices. Even if the sales of Climate Choice meals did not increase compared with a reference week, consumers felt positive towards the concept, and thought it gave them information in a very simple way and which they could use to make better choices.

The 307 paper responses indicated that the most important criteria for choosing a meal in general were the attractiveness and expected taste of the dish. It was clear that consumers, who chose a Climate Choice Lunch, chose it because of expected healthiness of the meal more often than for environmental reasons. Even though the criteria of Climate Choice Lunches included health criteria, it should not be expected that consumers had learned that in a one-week period. 40% of the 307 respondents in the paper survey stated that they would choose a Climate Choice Lunch at least often, if not always. 54% stated they would choose it at least every now and then.

Restaurant staff seemed to feel very positive about the new concept. Extra work is needed mainly from the staff that plan the new recipes, but others did not seem to mind the little extra work as most were interested in and felt engaged with the concept.

4. Discussion

Even though an approximate climate impact assessment of ingredients was made, it is apparent that more detailed and comprehensive carbon footprint databases are needed for restaurants to evaluate and design lunches. Creating a reliable and harmonized database for a credible concept remains a challenge.

Some secondary data can be collected with rather limited resources from the literature and databases but validating, harmonizing, filling the data gaps and reporting data requires multiple efforts. 50% of the lunches varied between 0.94 and 1.37 kg CO2-eq./meal. The range shows that the definition for whether a lunch is climate-friendly or not is very sensitive to even small changes in the amounts of ingredients or changes in the ingredients themselves. Therefore, it is crucial that a credible future concept relies on good quality carbon footprint data based on scientific and objective research.

Not only harmonization of methodologies used in different studies, such as allocation and consideration of local production circumstances, including soil types, but also system boundaries and practical calculation procedures (e.g. energy consumption of field machinery) need to be harmonized. Also more life cycle stages, such as processing and freezing and in particular raw material losses, should be added. Uncertainties and variability should be assessed to make reliable differentiations between climate-friendly and other lunches. In addition, data have to be transparently reported provided to any stakeholder who wishes to verify them. Only then a future low-carbon meal concept can be reliable. This kind of research should be conducted objectively, but with a focus on the largest contributions and the most uncertain estimates so as not to be too overwhelming.

Recipes and menus change often and in the future databases for climate impacts of ingredients and processing should be integrated with restaurants' recipe software. Such software already assesses, for example, nutritional values and it would be most practical for restaurants that the same program would assess climate impacts. Hence, restaurants could use such a program as an eco-design tool for meals and could verify their communication with it.

It would be good to include energy consumption for cooking and losses during processing in a concept like this because it could provide relatively interesting information for consumers when choosing their lunch restaurant or for differentiating between differently cooked meals. It would however require that more information on energy consumption and losses from food processing would be available to enable fair comparisons to be made among restaurants using different shares of raw materials (such as vegetables) and processed ingredients (vegetable steaks), which consume energy and create waste streams during different stages. According to one small Finnish study including very few restaurants, the energy and heat consumption of different restaurants can vary between 0.5-2.3 kWh/meal. Using average Finnish electricity and heat production emission factors, the greenhouse gas emissions would vary between 0.2-0.6 kg CO_2-eq. per meal. The largest energy consumption was measured for an à la carte restaurant, and the smallest one in a school canteen. For an average public restaurant adopting the Climate Choice Lunch concept we could estimate the value to be around the average. As losses can be significant and directly cause direct increases in emissions during raw material production, it appears that the impacts of both energy consumption and losses are significant at the meal level and should be taken into consideration in the future in developing such concepts, but for the time being it is not feasible for restaurants to collect the necessary data nor to differentiate among meals.

The consumer study results should be considered in the light of this kind of concept being unlikely to succeed as a short campaign, but perhaps being much more successful as a permanent feature of a restaurant. Therefore, the learning aspect would increase slowly and people would come to understand more about the information provided. Currently the two levels of Climate Choice Lunches were not recognized as wanted. Moreover, some of the customers who showed interest in the concept regarded the simple information as deficient, and they would have preferred more detailed information.

It is hard to communicate climate impacts of lunches to consumers when most consumers do not consider food and agriculture as being significant sources of environmental impacts, not to speak of climate impact. Even when environmentally aware consumers think about environmental impacts of foods, they might think about them when they are grocery shopping for home cooking, but not when eating lunch in a restaurant. It is necessary to emphasize to the consumers that lunch choices can be a good and simple way to influence the climate through a concept like this. It is understandable that this kind of concept would take a longer period than a week to become noticed and increase understanding significantly, and subsequently affect consumer behavior.

It is obvious that most of those who would choose a Climate Choice Lunch currently would do it either for health reasons or because they are already vegetarians and would anyway choose a vegetarian meal for animal rights concerns. Therefore, emission reductions could also be achieved by educating restaurants in provision of climate-friendly vegetarian meals. Climate friendliness and healthiness could then go hand in hand, e.g. reducing the amount of cheese and cream consumed and increasing the amount of beans and lentils. However, to make vegetarian dishes more attractive to others than vegetarians, and to show them that vegetarian meals can be tasty, cream and cheese are often used. To be able to develop a concept where some animal-based products can be used and dishes made attractive to all, climate impacts need to be estimated with good reliability rather than be based on a simple list of high and low impact ingredients, which would lead to vegetarian meals being the sole climate-friendly options.

As some consumers said, information on climate impacts of meals can have an impact on the buying decision when two alternatives are otherwise equal. Therefore, climate-friendly lunches have to be made attractive, in particular, if they do not contain meat.

5. Conclusion

Consumers need to be given simple ways to affect the climate burden of their consumption. Small changes, like choosing one of the two Climate Choice Lunches a couple of times a week, can directly decrease climate impacts of food consumption significantly. In addition, consumers can start to learn slowly what climate-friendly eating actually means. The pilot project confirmed the idea that promoting climate-friendly eating in a campaign is not enough, a long-term concept is needed.

Lunch represents a challenge, but if successful could represent a very successful opportunity to communicate climate impacts of foods to consumers. It is hard to make people notice communications in a restaurant when they come there hungry and busy, but as so many people eat lunch in a canteen every day, it could represent a very efficient way to inform consumers as they are likely to be open for new information in canteens. The first step would still be to make ordinary consumers think and talk about climate change and to bring the subject closer to consumers.

ABSTRACT

Climate change is mainly linked to greenhouse gas (GHG) emissions in which the agricultural sector occupies 14% of total emissions. In this paper, the questionnaires were implemented to investigate the effects of green bean quality including eco-burden factor and price on consumer buying decision. Also, on the estimation of eco-burden, LCA methodology was considered, and the carbon footprint of green bean in the supply chain process in Indonesia was expressed. The results showed that the total emissions (CFP) of green bean were between 4.92 and 7.38 kg-CO_2eq/kg green bean by varying farmers, and they became larger than that of Japan case (1.11 kg-CO_2eq/kg green bean). In addition, through our questionnaires on basis of the quality and price of green bean, we confirmed that the factor of quality is more significant for consumer buying decision.

Keywords: LCI, green bean, supply chain, carbon footprint of product, quality change

1. Introduction

Food sustainability is unquestionably a major issue for the years to come (Catherine et al., 2013). Nevertheless, the food industry is one of the world's largest industrial sectors and a large user of energy. Food production, preservation and distribution consume a considerable amount of energy, which contributes to total CO_2 emission. Andersson et al. (1994) stated, there is an increasing awareness that the environmentally conscious consumers of the future will consider ecological and ethical criteria in selecting food products. In addition, Boer (2002) reported, consumers in developed countries demand safe food of high quality that has been produced with minimal adverse impacts on the environment. It is thus essential to evaluate the environmental impact and the utilization of resources in food production and distribution systems for sustainable consumption (Poritosh et al., 2009).

Based on NASA-Goddard Institute for Space Studies (2012), the climate changes are mainly linked to GHG emissions in which the processes of farming, land use change and transport contribute 14%, 18% and 14% of total emissions. Thus, the reduction of GHG emissions for agriculture and food systems would be required (Catherine et al., 2013). For instance, the improvement of food supply chain would be brought by the higher efficiency of energy usage, and that would contribute to the reduction of GHG emissions.

By mapping all ingredients and components contained in the product, it will be able to assess the environmental impact (Alan et al., 2010). The application of supply chain management techniques has proven to dramatically improve efficiencies in a variety of industries (Haarteveit et al., 2004). As a more systematic and integrated strategy, the green supply chain management has emerged as an important new innovation. This fact helps farmers to develop strategies so as to earn profit and market share by lowering their environmental risks and impacts, while raising their ecological efficiencies (Qinghua et al., 2007). For that reason, our purpose is to evaluate carbon footprint of fresh and rejected green bean along its supply chain in Indonesia. Also, we argued the effect of CO_2 emissions are reflected to the product quality.

In previous studies, it was confirmed that eco-labeling was a way to encourage consumers to prefer the products whose characteristics are more environmentally friendly (Ralph et al., 2007). In the consumer research carried out in recent years, it was shown that consumers would be affected by not only the demand change of reliable products, but also by the corporate social responsibility (i.e. environmental consciousness) to some extent (Turan, 2007). Also, in general, since vegetables are perishable, the growth of these agricultural products is affected by the capability and/or availability of supply chain so as to be quickly delivered to consumer with fresh condition (Madeleine and Zhaohui, 2012). Thus, since the quality of product is an important factor, we should consider the quality change during the handling process. As a first step, we focus on the comparatively popular agricultural product, and estimate the carbon footprint of product of it on basis of LCA methodology. We attempt to verify the relationship between the quality including eco-burden element and price for consumer buying decision. Here, the reason why we select the Indonesia area as a case study is as follows: the cold chain is not enough constructing, the economic loss with quality worse due to the proper climatic condition is caused and the residential people has a great concern on eco-friendliness. Moreover, based on our preliminary research, it shows that 75% of citizen in Indonesia often eat green bean within a week which means that it is one of the popular vegetable in Indonesia.

2. Methods

2.1. Basic supply chain of vegetable

Chien-Jung et al. (2013) pointed out that all supply chains cover the processes from the raw material supply to the added value providing, including the sale to customers. In this study, we focused on the Indonesia market. For the supply chain of vegetable in Indonesia, as illustrated in Figure 1, some processes of nursery, planting, growing and harvesting are done by farmers. Until the agricultural products are harvested, some of them are not harvested and are consciously left in the field for new seed production. Once vegetables are harvested, they are transported in use of small trucks from the field to the warehouse managed by farmer union. If the transportation distance to the warehouse is less than 500 meters, they will be carried by man power. Otherwise, the truck is used and the harvested products are sorted and graded. The purpose for sorting and grading the products in the warehouse is to discriminate each product for whether it is suitable for export, modern or traditional market. After they are packed, these products are delivered directly to a distributor, by whom they are sold to consumer or just stored in their warehouse.

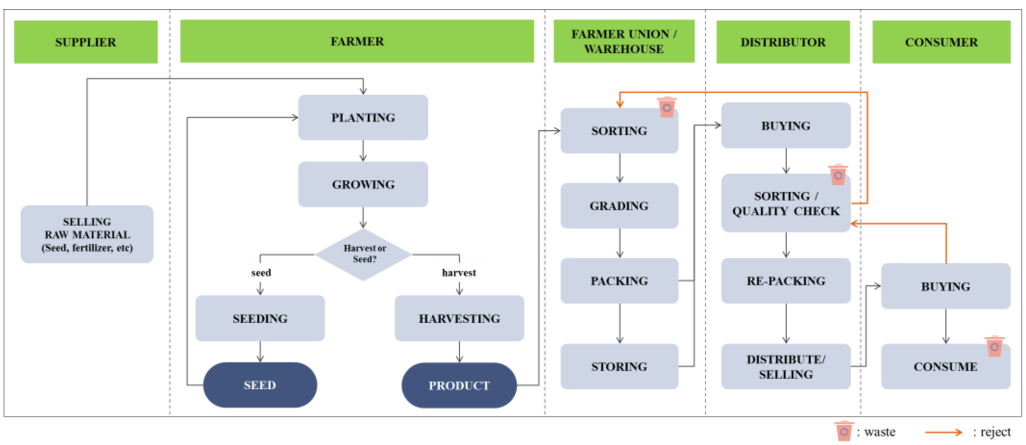

Figure 1. Basic supply chain of vegetable in Indonesia

Next, in a distributor, the agricultural products such as vegetables will be re-sorted on basis of quality requirement. This process is needed because the physical quality of them usually changes due to the influence of transportation process. As a result, all products are determined whether they have commercial value or not. The unfit products mean irregular and/or rotten ones. Those worse products would be caused due to their inappropriate cultivation or physical damages. Thus, both of them would be returned to the farmer, and the irregular product will be re-delivered to another consumer. While, the rotten ones will be no longer possible to be consumed. As Diana (2009) described about the related facts, if growers do not satisfy with the pre-harvest food safety standards, their crops would become waste as significant losses. Also, from the same viewpoint of Lundqvist et al. (2008), they defined that the food waste is the deliberately discarded food. It is no longer possible to eat for human consumption, even if its state would still be eatable. Recently, the requirements of end-consumers have been increasingly requested with regard to the better qualities of food products, assortment and package features, and the presented way of food products at a food store (Jon and Taras, 2009). Simultaneously, the loss percentage of agricultural products of vegetables is approximately 25% to 30% in the following processes of packing, transportation and storage (Dan, 2012). However, this percentage is very small for that of total waste due to its quality loss. Note that the terminology of "loss percentage" does not mean the amount with lost quality but the amount which accidentally fall off in the delivering process.

On the other hand, from the viewpoint of environmental impact, the impact for the lost amount in supply chain becomes smaller than that of the waste disposal, because the total lost amount in supply chain is less than 5% than the percentage of disposal amount including the factors of quality loss. If we describe about the carbon footprint of products and other environmental indexes for agricultural products, we have to discuss about not the material balance in the supply chain but the quality change of target product. Accordingly, in this paper, we focused on the agricultural product of green bean whose quality would be changed in some processes including the delivery process to more extent and whose supplied amount would be affected by its quality loss.

2.2. LCA methodology

LCA methodology is required for evaluating the carbon footprint of product in the supply chain process. Almudena et al. (2010) assessed the environmental impacts of products and services in use of LCA, which has been applied to many industrial sectors including food and agriculture. Guido et al. (2000) emphasize that the use of LCA in agricultural sector can cover all environmental impacts and that the result can provide us a significant potential for supporting the environmental improvement and innovation of the proposed agribusiness by Rene (Rene, 2002). This methodology is used to compare the primary energy requirement (Michael, 2005) and to analyze environmental impacts that can occur at all steps of the product chain (Gaudreault et al., 2009) by quantifying and evaluating the consumed resources and/or the emissions at all stages of its life cycle from the extraction of resources, through the production of materials and products parts, and the use of the product including its reuse and/or the recycle of final disposal (Hayo, 2004). In this respect, LCA approach is used to evaluate the impacts from the view point of consumers, which might be able to be reduced significantly on their food purchases (Niels et al., 2000).

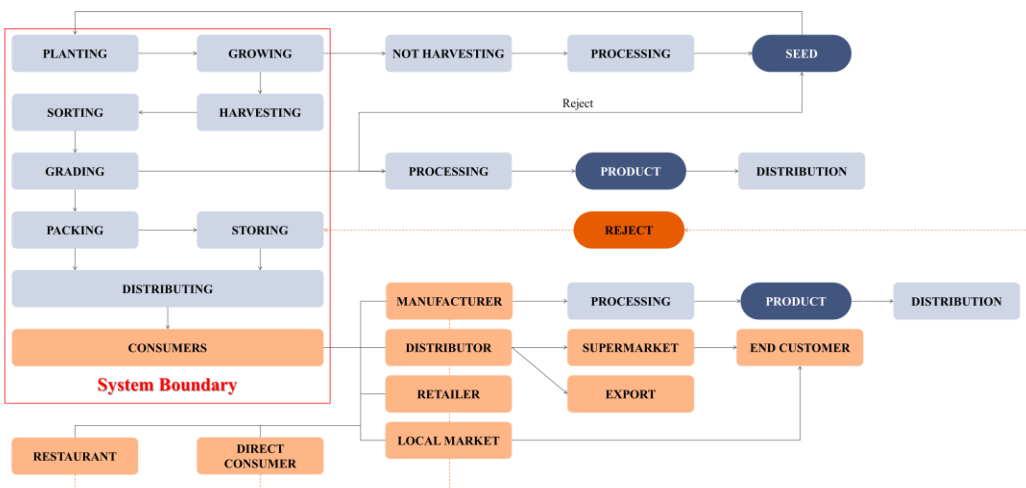

Figure 2. System boundary

In this study, as a first step, we estimated the LCI of green bean which harvested by the three different farmers. Actually, the production capacity would be varied by the cultivation area and/or farmers. Thus, considering these uncertainties, we analyzed the impacts. Also, we prepared the following two cases: (1) the LCI of fresh green bean and (2) that of rejected one. Here, the rejected green bean is defined as an irregular and/or a rotten product which are less commercial value. Note that the rate of rejected amount is from 13 to 20 % against the total harvesting product due to the difference of farmer (see Figure 3). The functional unit of LCI in this study is kg-CO_2eq/kg-green bean. Since the specific CO_2 emission of LCI includes other global warming gasses, that is evaluated as equivalent CO_2 emission. Also, assuming that the total equivalent CO_2 emission of i-th farmer for the final products, that for the fresh ones and that for the rejected ones are $LCI_{total,i}$, $LCI_{fresh,i}$ and $LCI_{rejected,i}$, respectively, $LCI_{total,i}$ is,

$$LCI_{total,i} = (1-\alpha)\, LCI_{fresh,i} + \alpha\, LCI_{rejected,i} \quad \text{Eq. 1.}$$

Where, α is the rate of rejected amount.

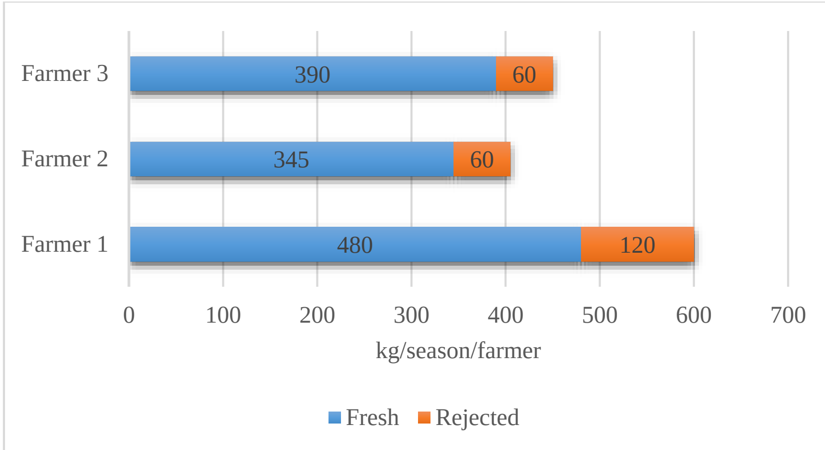

Figure 3. Comparison between fresh green bean and rejected one

Next, as shown in Figure 2, the system boundary of this study encompasses production (planting, growing and harvesting), transportation from field to warehouse, warehouse handling (sorting, grading, packing and storing), and transportation from warehouse to consumers. Based on these conditions, we estimated the LCI of green bean in consideration of the farmer difference and the harvested product difference due to the quality loss.

Here, Table 1 shows material inputs for each case of LCI calculation. For each case, we simulated that in use of LCA calculation software MiLCA (The Japan Environmental Management Association for Industry (JEMAI)). However, the loading ratio of truck long transport was assumed to be 62% of 15 ton truck due to the transportation condition of Japan since there is no data of that in the target area. The estimation of fuel consumption was based on the guideline of fuel consumption of truck (Ministry of Economy, Trade and Industry and Ministry of Land, Infrastructure, Transport and Tourism). Here, the fuel consumption of diesel truck is as follows:

$$LnF=2.71-0.812Ln(R/100)-0.656LnM \qquad \text{Eq. 2}$$

Where, F, R and M are the fuel consumption per t-km [L/tkm], the loading ratio [%] and maximum capacity [kg], respectively. Also, Ln means logarithm natural.

Table 1. Material inputs

Case	**Process**	**Material input**	**Farmer 1**	**Farmer 2**	**Farmer 3**
				Amount	
Fresh and Rejected	Production	Fertilizers	0.041 kg/kg	0.062 kg/kg	0.03 kg/kg
		Pesticide	0.063 kg/kg	0.095 kg/kg	0.1 kg/kg
		Herbicide	0.033 kg/kg	0.05 kg/kg	0.03 kg/kg
		Gasoline	1.54 L/kg	2.31 L/kg	2.1 L/kg
	Transportation from field to warehouse	-	1.5 ton truck	Man power	1.5 ton truck
		-	loading ratio 40%		loading ratio 30%
		-	distance 5 km	distance 0.5 km	distance 4 km
		Diesel	2.17 mL/kg	-	2.93 mL/kg
	Warehouse handling	Electricity	0.018 kWh/kg	0.027 kWh/kg	0.024 kWh/kg
	Transportation from warehouse to distributor	-	15 ton truck	15 ton truck	15 ton truck
		-	loading ratio 62%	loading ratio 62%	loading ratio 62%
		-	distance 32 km	distance 32 km	distance 40 km
		Diesel	0.14 mL/kg	0.14 mL/kg	0.17 mL/kg
Rejected	Transportation from distributor to warehouse	-	15 ton truck	15 ton truck	15 ton truck
		-	loading ratio 62%	loading ratio 62%	loading ratio 62%
		-	distance 32 km	distance 32 km	distance 40 km
		Diesel	0.14 mL/kg	0.14 mL/kg	0.17 mL/kg
	Warehouse handling	Electricity	0.092 kWh/kg	0.183 kWh/kg	0.183 kWh/kg

2.3. Consumer behavior analysis

Next, we argued about the following hypothesis: "Consumer buying decision on green bean would be influenced by variable quality and price". In the quality, the environmental factor is included, too. We perceived the relation between both variables at the time when consumer bought green bean on basis of a multiple regression analysis. This analysis is a statistical technique which can be used to analyze the linear relationship of $Y_1 = X_1 + X_2 + \ldots + X_n$. The objective of multiple regression analysis is to use the independent variables by which the selected single dependent value is predicted (Joseph et al., 2010). The dependent variable in this study is consumer buying decision (Y) and independent variables are quality (X_1) and price (X_2) of green bean. Also, we focused on consumer's behavior analysis so as to discover the importance of quality of green bean when the consumer buys it. For instance, according to the data of Ministry of Agriculture Indonesia, the average consumption weight of green bean in 2009 and 2010 were 832 g/capita and increased to 884 g/capita. Also, FAO reported the average times of eating green bean in Indonesia was 5 days per week with the total consumption of 3 g/capita/day. Thus, from the viewpoint of food LCA concept, on the often eaten food, to analyze the LCI and investigate the number of eating the product are significantly important. Note that the LCI would be affected by the qualities which are the factors of size, color, texture, flavor and nutrition content, and that the inventory result has to be based on the dynamic aspect. This time, we only referred to the LCI of green bean in consideration of the material balance.

In this study, the questionnaires were executed for a month between Jan 1 and 27, 2014 through the online system, and we collected 174 valid respondents. The investigated areas were Jakarta, Surabaya and Bandung in Indonesia. The questionnaire consists of the following 3 sections: (1) the respondent demographics profile, (2) the consumers' awareness on the environment and their health conditions, and (3) the measurement on important factors for consumers.

3. Results

3.1. Carbon footprint of product (CFP)

We used two sources to evaluate the carbon footprint of fresh or rejected green bean in consideration of material balance in the supply chain. These data were collected by the field investigation including the interview with farmers, and the other was based on the reference papers. As we mentioned above, we evaluated the specific CO_2 emissions of fresh green bean and rejected product. The initial green bean is categorized as follows: size of 8-12 cm, weight of 3-5 g, color of green, firm texture and unbruised bean. Here, both of fresh and rejected green beans are assumed to be transported to the distributor warehouse. Then, the rejected one is returned to the farmer.

Using the software of MiLCA in which approximately 3,000 inventories of materials, energy use and transportation were bundled (Haruhiro et al., 2013), we estimated the specific CO_2 emission on basis of Eq. 1. In each case, we obtained the CFP between 4.92 and 7.38 kg-CO_2eq/kg green bean. The influences of rejected green bean were from 0.94 to 1.15 kg-CO_2eq/kg green bean (see Figure 4). Compared to the CFP in the Japan case, there seems to be enough potential to reduce them of Indonesia to more extent. That is, according to Ajinomoto Group Environmental Report 2006, that of same product was 1.11 kg-CO_2eq/kg green bean, and that was equivalent to about 6 times against the CFP in this study.

Table 2. CFP of green bean supply chain in Indonesia (kg-CO_2eq/kg green bean)

	Total Global Warming	Production	Transportation	Warehouse handling
Farmer 1	4.92	4.88	0.02	0.02
Farmer 2	7.38	7.33	0.01	0.04
Farmer 3	6.86	6.80	0.02	0.04

According to Figure 4, the CO_2 emission of rejected product became larger in comparison to the fresh, since that has longer processes in the supply chain process. As illustrated in Figure 2, the rejected product is returned to the warehouse, and then, that is re-delivered to another consumer. That is, the added process requires more fossil fuel for the transportation and electricity in storage of product. The largest CO_2 emission in the production process was emitted in comparison to other ones in the green bean supply chain. This reason is due to the machineries utilization which is fueled by much gasoline.

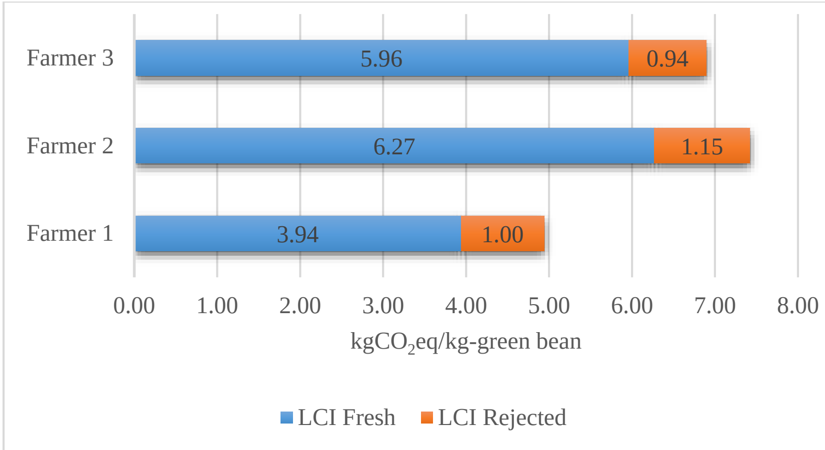

Figure 4. Comparison of emissions produced by fresh and rejected green bean

3.2. Consumer's behavior

This paper also has aim to analyze the relationship between quality and price at the time of purchase. As the result on basis of questionnaire, from first section of questionnaire a respondents profile was obtained. Table 3 shows the demographics profile of the respondents.

Table 3. Respondents' demographics profile

Category		Frequency	Percentage
City	Jakarta	92	52.87
	Surabaya	33	18.97
	Bandung	49	28.16
Gender	Male	78	44.83
	Female	96	55.17
Marital	Single	69	39.66
	Married	105	60.34
Education	Secondary	12	6.90
	Diploma	9	5.17
	Bachelor	105	60.34
	Postgraduate	48	27.59
Monthly income	Below USD 85	10	5.75
	USD 85 – USD 339	52	29.89
	USD 340 – USD 595	35	20.11
	USD 596 – USD 850	27	15.52
	Over USD 850	50	28.74

Also, we asked the respondents about their consciousness on environment and their health. More than half of respondents (66.67%) always dispose their garbage in the appropriate place, the 29.89% of them often do that, and the rest of them (3.45%) seldom do that in the appropriate place. That is, they have seems to have highly environmental awareness.

Table 4. Consumer's behavior

Questions	Never		Seldom		Often		Always	
	Total	%	Total	%	Total	%	Total	%
How often do you throw away your garbage in the appropriate place?	0	0.00	6	3.45	52	29.89	116	66.67
How often do you pay attention on your food consumption?	1	0.57	32	18.39	97	55.75	44	25.29
How often do you consume organic vegetables or fruits?	7	4.02	98	56.32	59	33.91	10	5.75
How many times do you shop for vegetables in one week?	17	9.77	47	27.01	73	41.95	37	21.26
How often do you consume vegetables in one week?	0	0.00	31	17.82	91	52.30	52	29.89

Next, in order to discover consumer's behavior in consuming vegetable, we asked the respondents about the importance of their food consumption. The majority people have an attention to the products (55.75%), the 25.29% always worry about the qualities. Although there are respondents who seldom do it (18.39%) or have no attention to it (0.57%), most consumers concern with their health conditions which reflected by their behavior in consuming of vegetables. On the other hand, on their consumptions status of both organic vegetable and fruit, almost respondents hesitate to consume them (56.32%). That is, it is shown that the organic products are unpopular for Indonesian.

On the behavior of purchases of vegetables, the 41.95% of respondents go shopping of them by a few times for a week. However, there are also respondents who seldom do it (27.01%) or do not go shopping (9.77%).

Finally, according to the personal habit of vegetables eating, the 52.30% of respondents often eat them per a week, or the 17.82% seldom do it. However, there is no people who do not eat them. That is, this results indicate that they are likely to eat vegetables for their health condition.

Using the questionnaire results, we analyzed them due to Likert-scale (i.e. 1=strongly disagree, 5=strongly agree) for estimating the statistical perception.

A multiple regression analysis was used to analyze the data. A validity test was conducted to evaluate the questionnaire. A questionnaire can be stated as valid if its questions were able to reveal something that will be measured by it. Using the correlation coefficient of Pearson, the results are clearly valid, because R-value is larger than sample correlation coefficient r table (0.148) and P-value is smaller than 0.05. Also, the t-values of quality (X_1) and price (X_2) are 8.15 and 2.10, respectively (See Table 5).

$$Y = 6.28 + 0.39 X_1 + 0.26 X_2 \quad \text{Eq. 3}$$

Based on this equation, the regression coefficient of quality was 0.39. This means that the quality would have a positive effect on consumer buying decision. For instance, if the quality of green bean is good, the consumers' awareness for buying that would increase. On the other hand, the variable of price was 0.26. That is, the consumers have awareness of the price to some extent, but, they have stronger interest in the condition of green bean at their purchases.

Table 5. Results of multiple regression analysis

Model Summary[b]

Case	Model	R	R square	Adjusted R square	Std. Error of the estimate
Green bean	1	0.61	0.37	0.36	2.17

a Predictors: (Constant), Quality, Price b Dependent Variable: Consumer decision

ANOVA[b]

Case	Model		Sum of squares	df	Mean square	F	Sig.
Green bean	1	Regression	477.16	2	238.58	50.55	0.000 (a)
		Residual	807.14	171	4.72		
		Total	1,284.30	173			

a Predictors: (Constant), Quality, Price b Dependent Variable: Consumer decision

Coefficients[a]

Case	Model		Unstandardized coefficients		Standardized coefficients	t
			B	Std. Error	Beta	
Green bean	1	(Constant)	6.28	0.93		6.76
		Quality	0.39	0.05		8.15
		Price	0.26	0.12		2.10

a Dependent Variable: Consumer decision

Coefficient of Correlations[a]

Case	Model			Quality	Price	Consumer' decision
Green bean	1	Correlations	Quality	14.16		
			Price	2.23	2.16	
			Consumer decision	6.10	1.43	7.38

4. Discussion

Based on our results, it was shown that the total emission of fresh green bean was smaller than that of the rejected. This implies the following matters: if the farmer who cultivates green bean does not pay attention to the handling of product, the rejected amount, that is, the waste amount would be increased. Likewise, in Indonesia where the annual consumption of green bean is large, the CO_2 emission for the target product might be attributed to the large amount of emission. Also, as we referred to the section of 3.1, the specific CO_2 emission of green bean was about 6 times larger than that of product of Japan. We have to think what kind of good countermeasure for reducing that we can propose. For instance, the Photovoltaic (PV) technology would be able to be promoted in the agricultural product. In the previous study by Eidelweijs et al. (2012), it was shown that the promotion of PV system on paprika distribution process in Indonesia can decrease CO_2 emission by 1.947 g-CO_2/paprika, that is, the 11.9% of cultivation process, the 30% of packaging, and the 30% of cold storage in comparison to the conventional case, respectively. As the same as the study by Fukumoto et al. (2011), the advanced paprika cultivation system in consideration of the energy supply of low carbon emission fuel such as a bio-fuel was proposed. Based on the biomass gasification process of Blue-Tower (BT) technology, they showed that the promotion of new technology can reduce the CO_2 emission on LCA concept. The BT co-generation (BT-CGS) was able to decrease by 104.6 gCO_2/paprika, that is, the CO_2 abatement was 82.0% in comparison to the conventional system.

According to Douadia and Pierre (2009), the shopping choices can contribute to the global warming protection. All over the world, the use of eco-labelling as a market-driven environmental policy tool is increasing. A number of articles have dealt with eliciting consumer's preferences and willingness to pay (WTP) for eco-friendly food products. Also, in the previous study about consumers' awareness in Jakarta, Indonesia, we understood that the consumers have a high awareness on global warming issues. Simultaneously, we knew that CO_2 emission factor is the most important factor and that their decision on purchase of paprika is affected by the communication index of eco-label. In other words, there would be somewhat potential market for paprika with eco-label in Indonesia. In that case, the WTP of consumers was corresponding to the 15% or more against the average existing price of paprika (Eidelweijs et al., 2012).

Furthermore, it was shown that the carbon footprint of product (CFP) for agriculture products of vegetable is unique, since the quality is attributed to many of the changes which would be produced in its life cycle. That is, the quality is an important factor of vegetable because it will change inevitably by passage of time. From the point of view of consumer, the good commercial product is defined as an attractive physical appearance and/or its good taste. In this study, the main reason why green bean was rejected is due to the lack of consumer satisfaction on quality. That is, that was the following causes: the size of green bean was too large or small, the color was bruised, and the green bean itself was rotten. If we can reduce the rotten amount, there would be an improvement on the total emission to some extent. In our future plan, we will investigate the effects of cold chain, the buying decision for the eco-friendly vegetable and the promotion of low emission agricultural product system.

5. Conclusion

Due to the quality change of green bean, the total CO_2 emission of product would be different. For this difference, the consumers' behaviors would be changed, and the worse environmental effect would be brought. Hence, in the future work, we will propose a dynamic LCA based on quality change on vegetable.

As described by Annie et al. (2010), a dynamic LCA is proposed to improve the accuracy of LCA by addressing the inconsistency of temporal assessment. For instance, the utilities by which consumers' behaviors would be influenced need to obtain the basic data through the experimental measurement and/or the process investigation. Also, the multi-indexes might be necessary for clarifying the product status, since there are many physical parameters of size, weight, color, edible portion, and nutrients such as sugar, acidity, vitamin and protein content. Based on this study, at the next stage, we will analyze the dynamic life cycle inventory data set of green bean.

ABSTRACT

SENSE project aims to deliver a harmonized evaluation system for the environmental impact assessment of food & drink products. The project evaluates existing relevant environmental impact assessment methodologies, and considers socio-economical, quality and safety aspects, to deliver a new integral system for the environmental and social assessment of agrifood and aquaculture products. The system integrates: (a) (regionalized) data gathering system; (b) matrix of key environmental performance indicators and a (c) methodology for simplified environmental impact assessment. The web-based SENSE tool has been validated in the juice, meat & dairy and aquaculture chains; however, the methodology and its associated software will be modular allowing its implementation in any food product.

The tool is based on the sustainability information collected along the production cycle of any food or drink products. The obtained results are reflected into an Environmental Identification Document (EID). Main results of SENSE will be: (i) Standard key environmental performance indicators (KEPI); (ii) harmonized methodology for environmental impact assessment; (iii) SENSE-tool for environmental data collection; (iv) EID; (v) Certification Scheme Concept (CSC) for sustainability; (vi) Roadmap for policy and governance implementation. SENSE consortium is formed by a multidisciplinary team involving 23 partners from 13 countries made up by a combination of complementary profiles: research organizations, food and drink SMEs, environmental and LCA experts, SMEs for dissemination and communication and European food Associations.

Keywords: Food SME, Online LCA tool, Impact communication, Benchmarking, SENSE Project

1. Introduction

Food production and consumption cause significant strain on the environment as it is estimated that 29% of global emissions of greenhouse gases (GHG) are from agriculture and food production. In the EU, food consumption accounts for 20–30% of various environmental impacts and, in the case of eutrophication, more than 50% (Tukker et al., 2005). In the UK, the food and drink sector is responsible for 14% of industrial energy consumption and 7 Mt of carbon emissions per year; it also uses 10% of all industrial water supplies and produces 10% of the industrial and commercial waste stream (DEFRA, 2006).

The food and drink industry in Europe, of which 99% are small and medium enterprises, is highly fragmented, and food chains are very complex. Hence, to assess the environmental sustainability of a product there is a need for applying integrated, harmonized and scientifically robust methodologies, together with appropriate communication strategies for making environmental sustainability understandable to the market. However, there are difficulties in developing a commonly agreed methodology for environmental impact assessment that still need to be overcome. Challenges are the complexity of food chains, the large number of agents involved, different suitable environmental indicators depending on the business sector, regional differences related to biodiversity among other challenges, including climate change and complexity of the current sustainability assessment tools - high data intensity, costs and expertise required.

Nowadays the calculation of the potential environmental impact of products can lead to great benefits to the industries which, in most cases, can lead to brand differentiation. However, most of the industries in the food sector, especially SMEs, neither have a strong background nor the capability to assess the sustainability of their products.

The European research project SENSE aims to deliver a harmonized system for the environmental impact assessment of food and drink products. The research evaluates existing relevant environmental impact assessment methodologies, and considers socio-economical, quality and safety aspects, to deliver a new integral system that can be linked to monitoring and traceability data. The system will integrate:

(a) (regionalized) data gathering system;
(b) matrix of key environmental performance indicators;
(c) methodology for environmental impact assessment; and
(d) a certification scheme

The methodology will be transferred to food & drink sectors and stakeholders by means of specific communication strategies.

The sustainability information collected along the supply chain of any food stuff and reflected into an Environmental Identification Document (EID) will be accessible by the EID-Communication Platform. This should contribute to making the environmental sustainability part of the usual purchasing behavior of consumers and provide a competitive advantage to those products (and companies) which choose to use the EID. Through a comprehensive environmental communication between the industry and consumers the latter are empowered to choose food products which are environmentally friendly.

2. Methods

2.1. Harmonised methodology for the environmental assessment of food and drink products

A set of consistent environmental impact assessment methods and impact indicators for three food chains (dairy/beef, orange juice and salmon aquaculture) and their supply chains has been selected based on literature reviews. The methodology is based on the key environmental challenges identified for each sector and the related impact categories. For the selection existing methodologies has been reviewed as well as current developments. The ILCD handbook (JRC, 2010) recommends LCIA methods for many impact categories and this has been a starting point for the review. The LCIA methods have also been reviewed on their suitability for the food sector and their practicability to use.

The life cycle assessment methodologies chosen for each impact category are listed in Table 1 along with the corresponding indicators and references. These are the same methods as later recommended by the European Commission on the Product Environmental Footprint (EC, 2013) and in the ENVIFOOD protocol except for water depletion where a revised approach to water footprinting is recommended in the ENVIFOOD protocol (ENVIFOOD, 2012).

Table 1. Life cycle impact assessment methodologies to be used in the SENSE-tool

Impact category	Unit	Selected LCIA method	Reference
Climate change	kg CO2-eq	Bern Model – IPCC	Solomon, 2007
Eutrophication, Terrestrial	molc N-eq	Accumulated Exceedance	Posch et al., 2008
Eutrophication, Freshwater	kg P-eq	EUTREND Model	Goedkoop et al., 2009
Eutrophication, Marine	kg N-eq	EUTREND Model	Goedkoop et al., 2009
Acidification	molc H+-eq	Accumulated Exceedance	Posch et al., 2008
Human toxicity	CTUh	USEtox Model	Rosenbaum et al., 2008
Ecotoxicity	CTUe	USEtox Model	Rosenbaum et al., 2008
Land use	kg $C/m^2/a$	Soil organic matter model	Milà i Canals 2007
Abiotic resource depletion	kg Sb eq	CML 2002	Guinée et al., 2002
Water depletion	m^3 H_2O eq	Ecological scarcity model	Frischknecht et al., 2009

2.2. Key Environmental Performance indicators for food and drink chain

The key environmental performance indicators were proposed as simple parameters to be used in the SENSE tool to calculate the environmental impacts. For the selection of those parameters three LCAs have been done in the beef and dairy, orange juice and aquaculture sectors. The LCA results confirmed the validity of the selected KEPIs taking into account their relevance for the environmental impact, the data availability and the easiness of measurement.

The KEPIs selected for the production of all the food supply chains are shown in Table 2. The selected KEPIs covered 95%, on average, of the environmental impacts of the respective food supply chains (Doubet et al., 2014)

Table 2. Selected key environmental performance indicators for the European food and drink sector.

INPUT	UNIT		DS
Land use	Ha*year	Land occupation for agricultural uses: permanent crops, arable land or grazing.	EcoInvent
Fertilizers	Kg N, P or K/year	Inorganic fertilizer consisting of nitrous compounds such as ammonium nitrate or ammonium sulphate and phosphorous or potassium compounds.	EcoInvent ESU
Organic fertilizer	Kg/year	Fertilizers derived from animal or vegetable matter (e.g. compost, manure	EcoInvent
Pesticides	Kg AI/year	Pesticides are plant protection products. The term "pesticides" covers insecticides, acaricides, herbicides, fungicides, plant growth regulators, rodenticides or biocides. The user has to provide the commercial name for the pesticide (i.e. RoundUp ®) in the free-text box and introduce the amount per hectare used. Once it is defined, an addition table will appear where they have to specify the percentage of active ingredient (AI) (i.e. glyphosate). If the AI is not in the list, generic pesticides could be used, such as, “fungicides” or “herbicides” or “pesticides”. When those AI are used, please introduce the 100% of the content.	EcoInvent
Energy	energy unit kwh, L of diesel, m^3 of natural gas / year	Energy consumption in agriculture systems are mainly related to fuel used during land labors (tractor), energy required for buildings maintenance and greenhouses maintenance, in the fisheries systems to the use of fossil fuel for the fishing vessels and in aquaculture, livestock and food processing systems the energy use is mainly related to the machinery requirements and building general consumption.	ESU
Freshwater use	L or m^3/year	For water requirements the user has to introduce the total water requirements for 1 year. Rain water is not taken into account, only tap-water	EcoInvent
Feeds	Kg/year	Data on feed can be obtained directly from the feed supplier as guest user and should then be added as an incoming product or Data on feed can be selected from a drop down menu, offering different kind of feed ingredients (crop and marine). In the questionnaire, the user should specify the different feed ingredients and add the relative amount by weight.	EcoInvent
Packaging	Kg/year	For the packaging the user should specify the type of final packaging (glass, plastic bottle or so) and the amount used per year. In some cases, intermediate packaging will be relevant too.	EcoInvent
Livestock	nº animals /year	For the livestock, the specific animal has to be selected. Specify the amount produced in one year and the share of the product in turnover (%).	IPCC
OUTPUT			
Wastewater	L or m^3/year	For inland aquaculture systems the user need to specify the amount (l or m3) of wastewater discharges per year. For marine aquaculture systems an average N direct emissions to the marine environmental due to faeces and uneaten feed per kg of fish has been taken into account (Solbakken, et al. 2008).	EcoInvent
Wastes	Kg/year	The user should first choose the waste material (organic waste, plastics, cardboard, glass or other type) and the disposal way (incineration, recycling landfill)	EcoInvent

2.3. Scientific validation of the SENSE tool

The validation of the integrated SENSE tool is based on performing simplified environmental impact assessment oriented to key indicators in the food supply chains representing three food chains (fruit juice, meat and aquaculture fish) in different European regions.

3. Results

Taking into account the methodology selected and the selected KEPIs, a web based tool, the SENSE tool, has been designed and developed with a common server and database allowing an active interaction between users. The developed tool aims to be used by industrial actors without a strong LCA background and to provide easy to be interpreted environmental information.

The tool compiles the information available at different levels in the food chain. The collected data are characterized and evaluated in order to obtain the key indicators associated to the evaluated product. This tool provides a common framework in which users from different stages of the supply chain introduce a simplified set of environmental data and compare respective environmental impacts. As far as the aim of the tool is to provide a tool for the SME's it has been designed as user friendly and very intuitive.

The tool is accessible via internet; therefore it is not necessary to install the program, making its use even simpler. This computer application has been developed using Visual Basic .Net, on Visual Studio 2010. The used database engine is SQL Server 2008 R2, where all the application's information is stored. As far as the application imaging, both design and used pictures, have been done using Photoshop CS 6 y Gimp 2.8.

For the allocation, economic allocation has been selected; however, the tool offers the possibility for system expansion option or to introduce manually the percentage of the economic allocation of different incoming materials, such as packaging or main ingredients.

Moreover, in order to facilitate the data gathering, the tool offers the possibility to send the questionnaires to the main suppliers of the chain. This data is confidential and it will be visible to the user just if the suppliers give the authorization for that.

For the impact characterization, the program sums up the environmental impact of each process involved in the food chain (**Error! Reference source not found.**).

$$T_{x,y} = \sum_{i=x}^{i=z} EI_{i,y} \qquad \text{Eq. 1}$$

Where for any of selected environmental impact, such as climate change or water depletion (Table 1):

- $T_{x,y}$ is the summation of the environmental impact of all inputs *j* of the product *y* from the process *x* to the last process *z* (where final product are generated)
- $EI_{i,y}$ is the environmental impact of the process *i* in the product *y*

For the impact assessment of each process, the proportional impact of each input into the final product has been added according to equation 2 (**Error! Reference source not found.**).

$$EI_{x,y} = \sum_{\forall j} I_{j,x,y} \qquad \text{Eq. 2}$$

Where:

- $EI_{x,y}$ is the environmental impact of the process *x* in the product *y*
- $I_{j,x,y}$ is the partial environmental impact of the input *j* of the process *x* in the product *y*

Finally, to calculate the proportional environmental impact of each input in the final product, the conversion factor of each input to each environmental impact has been multiplied for the amount of the input used in each process. Then a factor is applied to calculate the weighting of this input into the target product. This factor is calculated taking into account the share of product turnover of the processes involved and the ratio of the product of each process used in the next process (Eq. 3).

$$I_{j,x,y} = CF_j \times M_{j,x} \times \prod_{i=x}^{i=z} (S_{y,i} \times R_{y,i}) \quad \text{Eq. 3}$$

Where:

- CF_j is the environmental characterization factor for the selected impact category of the input *j*
- $M_{j,x}$ is the quantity of the input *j* in the process *x*
- $S_{y,i}$ is the share of product turnover in the process *i* for the product *y*
- $R_{y,i}$ is the ratio of the product flow between the process *i* and *i+1* for the product *y*

For example, for the dairy chain described in
Figure 1, in order to calculate the impact of the farm process on the final product (i.e. sour cream) accordingly to the formulas described above, the procedure will be the following:

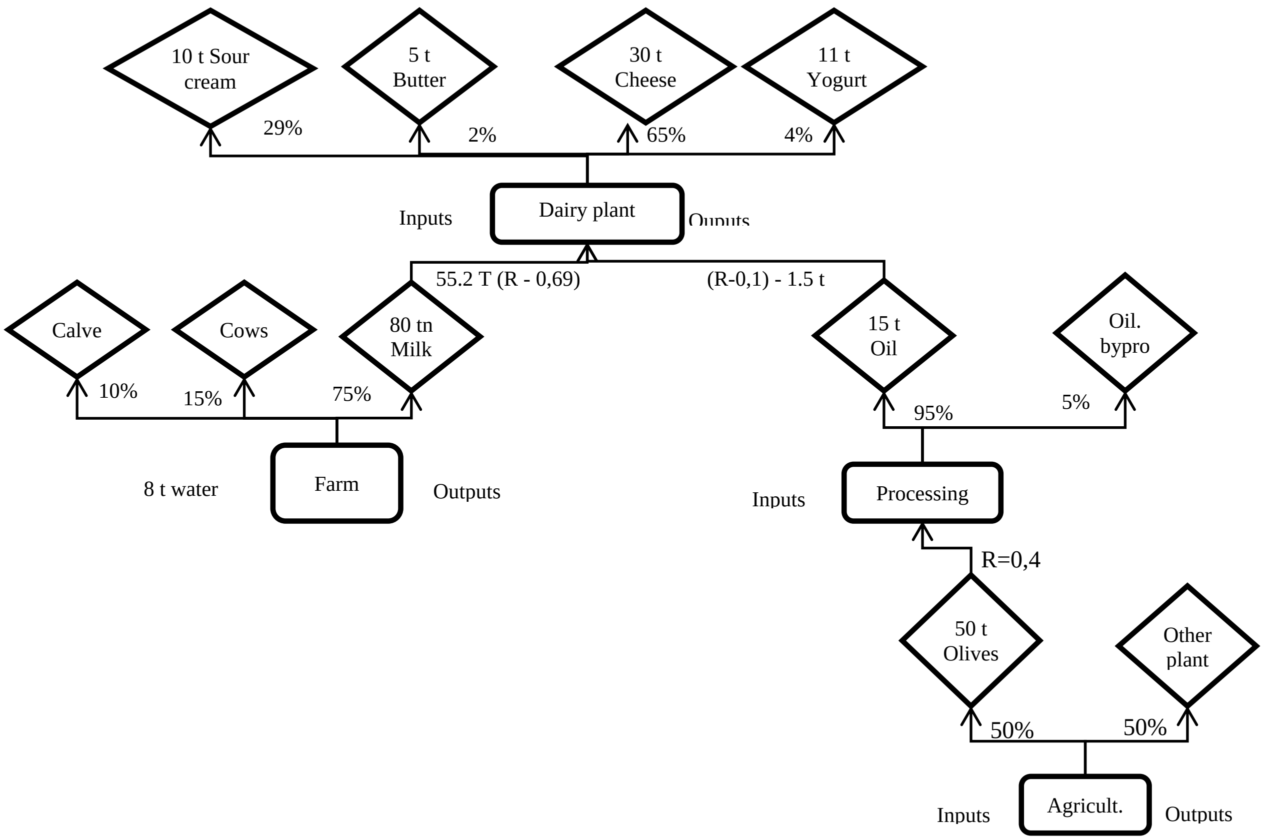

Figure 1. A hypothetical dairy plant which produces sour cream, butter, cheese and yogurt. Main ingredients are raw milk from a farm and oil. Percentages in the lines represent the share of product turnover and the Ratios (R) represent the ratio of product taken from the previous stage.

Taking into account that 8 tn of water enters the farm and that the characterization factor for the climate change of water is 0,0003 kg CO2 eq/kg water, the proportional climate change potential of the water consumption regarding the sour cream yearly production will be the following:

$$I_{j,x,y} = 0{,}0003 \times (8 \times 1000) \times 75\% \; x \; 0{,}69 \; x \; 29\% = 0{,}36 \; kg \; CO2 \; eq$$

Hence, adding all the proportional climate change impact of all the inputs to the farm stages, the user could differentiate the impact of that specific process. Thus, adding the processes involved in the whole chain, the complete impact will be obtained.

The SENSE tool application calculates the environmental impacts that are related to the previously described impact categories. The impact characterization can be shown for the production of one year, or for one unit e.g. kg product as defined in the user profile.

The results are presented in the following ways:

- Environmental impact per process and year. Those results are shown in a bar chart and show the impact generated for the selected environmental indicator and process. A table with the impact value is also shown under the graphic. (Figure 2)

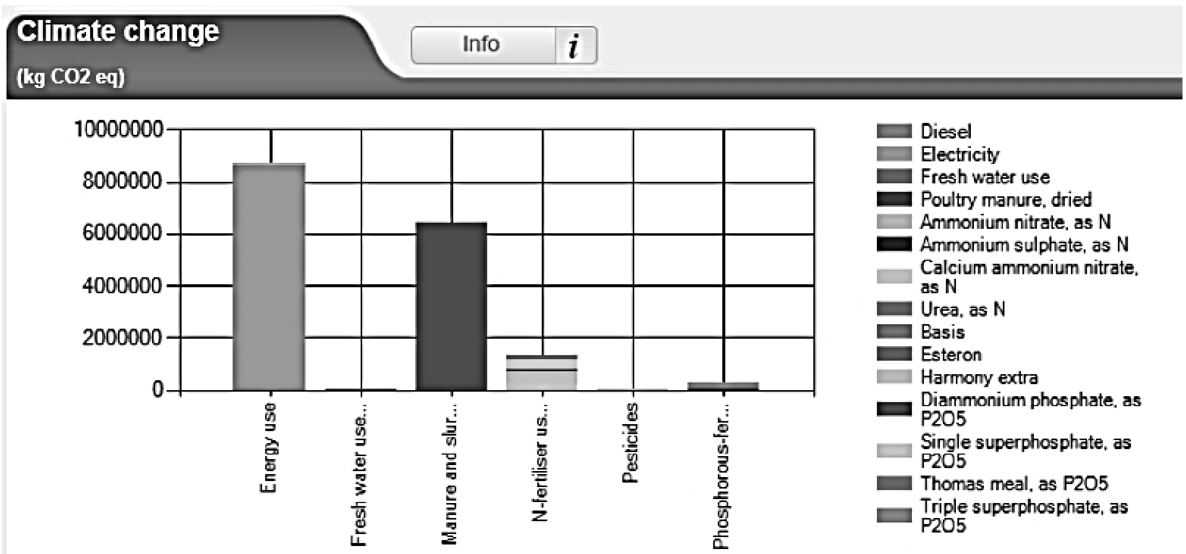

Figure 2. Captured figure of the sense-tool results for the climate change potential characterization results for the farm stage of the dairy production chain.

- Complete impact analysis: For each impact category a pie graph is shown with the contribution of each process to the total impact. An histogram is also shown with the summary of all the impact and processes (Figure 3)

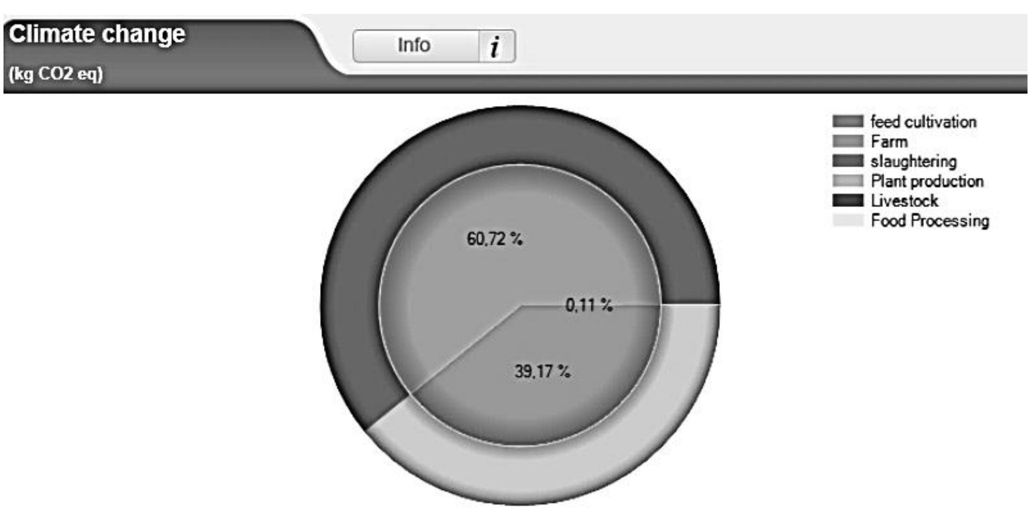

Figure 3. Captured figure of the sense-tool results for climate change potential characterization for a dairy production chain expressed in pie chart.

The contribution (%) of each process to the final impact is shown.

- Compare products. It is possible to compare product by process or by impact. When comparing the environmental impact by process, the weight of the different processes on the final impact of each product will be shown for each impact category. When comparing by impact, a complete graph will be shown comparing the final impact of each product.
- Evolution of the product impact. A line chart is shown with the evolution of the environmental impacts of the product along the years. With this data the tendency can be assessed.
- Product benchmarking: In the future this option will allow the user to benchmark its products internally (comparison between the same products in different years) and externally (with other similar products). When selecting benchmarking a spider graph will be shown with the deviation of the actual product impact assessment from the average value for that product. For the moment, there is no enough data for the external benchmarking; however the tool is ready for the future improvements.

Coupled with those graphics, there is a possibility to extract the Environmental Identification Document (EID). In this document a summary of main environmental results is described.

4. Discussion

4.1. Validation of the tool

The tool has been technically validated in two case studies by comparing the outcome of the SENSE tool with calculations performed by SimaPro commercial software Simapro. The functionality of the SENSE tool was tested when entering data for the beef-and-dairy, orange juice. Acuaculture chain has been also validated with GaBi software, but the results of this comparison are out of the scope of this publication. The validation is based on using only pre-selected input data (e.g. energy use, material use, etc.) which have been defined in the project as key performance indicators (KEPIs). The KEPIs were chosen based on their contribution to the key environmental impacts of the food supply chains studied namely, beef and dairy, orange juice and aquaculture fish (Doublet et al., 2014). This iterative process was important to ensure that the developed SENSE tool would be fully functional and validated before it was delivered for implementing and testing by SMEs.

The relative percentage difference between the environmental impacts of the SENSE tool and the LCA on Romanian beef and dairy products (Doublet et al. 2013a) is highly dependent on the impact category. Results for climate change, human toxicity cancer and non-cancer effects, ecotoxicity, freshwater and land use have a difference smaller than 10 %. However, differences in the modelling of the emissions due to the land use and the application of, manure as well as the additional data taken into account in the complete LCA for the pesticides can explain the large deviation in the results of the acidification, eutrophication terrestrial and marine.

For the orange juice supply chain, the difference between the environmental impacts calculated in the SENSE tool and the LCA is below 10 % for climate change, human toxicity, acidification, eutrophication terrestrial, eutrophication marine, abiotic resource depletion and water depletion.

4.2. Allocation procedures

Since the aim of the project is to obtain a simplified environmental analysis of the food and drink products, some limitations have been identified. The method used when distributing the environmental burden between the main product and its by-product can have a significant impact on the final results of a LCA (Svanes et al., 2011). Although it may be controversial, economic allocation is chosen as the default allocation approach in the SENSE tool.

The allocation procedures applied in the LCA on beef and dairy products in Romania are beyond the common knowledge of SMEs. The allocation procedures recommended by the international dairy federation to allocate the environmental impacts of beef and milk production at farm as well as the allocation matrix to distribute the environmental impacts of the individual dairy products are too complex and time-consuming for somebody not familiar with the field of life cycle assessment. Witczak et al. (2014) conclude that SMEs do not have time to collect and evaluate data and expect quick results based on a small amount of data. ISO recommends avoiding allocation by expanding the system but this is out of the scope of an internet tool to be used by SMEs. Allocation cannot be avoided and allocation rules should be made as simple as possible. The easiest allocation approaches are mass and economic allocation.

The results for single dairy products are quite sensitive to the allocation approach chosen (Feitz et al. 2007). Physico-chemical allocation, mass allocation, protein allocation and economic allocation were used to assess the environmental impacts of individual dairy products. Mass allocation may be discredited in the dairy production chain since it results in considerable deviations from physicochemical allocation. Economic allocation introduces similar order of magnitude sized variations. Feitz et al. (2007) suggested using economic allocation for inter-industry sectorial flows. Kim et al. (2013) allocated the incoming raw milk to the individual dairy products on a milk solids basis. Energy and resource use were allocated based on an economic allocation.

The allocation of environmental impacts to by-products is also an issue for the slaughtering process in the beef chain. Due to lack of comprehensive global data, Opio et al. (2013) could not perform an allocation to slaughter by-products. Cederberg et al. (2009) explained that no greenhouse gas emissions were allocated to the meat production by-products. In our case study, this approach was followed and all environmental impacts are allocated to the beef.

In the aquaculture chain, the use of economic allocation has been criticized as it does not reflect the biophysical properties of the production system and is sensitive to changes in market prices (Pelletier & Tyedmers, 2011; Svanes et al., 2011; Ytrestøyl et al., 2011). Mass allocation methods have been applied in studies on feed and aquaculture as well as fisheries (Boissy et al., 2011) while others have used gross nutritional energy (Pelletier et al., 2009) or economic allocation (Ellingsen et al., 2009). Winther et al. (2009) justified the use of mass allocation for salmon after evaluating both economic allocation and gross nutritional energy. In mass allocation, the environmental cost associated with the by-products is the same as for the products for human consumption. Using mass allocation in LCA is beneficial for producers of products for human consumption if they can recycle their by-products into other production systems. Therefore, mass allocation creates a positive incentive for full utilization of by-products compared to economic allocation, where by-products of insignificant value otherwise carry a zero environmental burden. However, the use of by-products from environmentally costly productions such as livestock production or demersal fish trimmings in salmon feed production contribute substantially to the outcome of an LCA analysis in terms of energy use and CO2 emissions (Pelletier et al., 2009; Ytrestøyl et al., 2011). Currently about a quarter of the fish meal produced comes from by-products from fish processing for human consumption (i.e., by-products from fish filleting plants). In the case study, the economic allocation was used in the LCA on aquaculture. It gives a higher burden on the main product than if mass allocation would have been used. At the aquaculture farm 10 % of the biomass at the farm is guts which are given away for free. The by-product, guts, therefore has zero environmental loads. If mass allocation would have been used the impacts of the salmon product would be reduced by 10 %.

The recommendation regarding economic allocation rules for the SENSE tool may be the simplest approach for SMEs. However, since the SENSE tool offer the possibility to implement different allocation factors for the incoming product; this is a good approach that could be used if SMEs are willing to invest more time to obtain a more scientific environmental assessment.

4.3. Usefulness in SMEs

Additional case studies where the SENSE tool is tested by users are currently ongoing in the project in at least 30 companies and their supply chains. First impressions with the SMEs state that the companies are quite reluctant to implement the SENSE-tool into their company mainly due to lack of resources (time or people). However, after this first obstacle, those companies which are taking part of this validation find it very useful. Main benefits of the tool for those companies are i) the possibility to identify the hot-spot of their processes and ii) the benchmarking possibility (not implemented yet).

5. Conclusion

In conclusion the SENSE tool has been designed to be suitable for the food and drink SMEs. However, it is important to remark that the main aim is to obtain a simplified tool, and thus it won’t be an alternative for the complete LCA studies.

For future developing two mains aspects will be considered. First the Certification Scheme Concept voluntary system (CSC) for use of the EID in food and drink products will be developed. This Scheme will be based on the different voluntary systems (ISO, EMAS, others). The CSC will define the rules for development of its own regulations for the certification process, the definition of the requirements (independence, transparency, etc.) and the protocol of the regulatory/certification system which will be in charge of the approval and updating of the EID. The second important aspect to develop in the future is the communication systems which will be differentiate between business-to-business (B2B) and business-to-consumer (B2C) communication levels.

ABSTRACT

This paper presents a tailored version of PestLCI 2.0, the most advanced life cycle inventory model for quantification of organic pesticide emissions from arable land, customized to appropriately account for viticulture specificities affecting pesticides emissions from vineyards. PestLCI 2.0 customization is further supported by the calculation of USEtox™ freshwater ecotoxicity characterization factors for active ingredients relevant in viticulture. Case studies on two different vineyard management systems illustrate PestLCI 2.0 model application. The customization of the PestLCI 2.0 model includes addition of 29 active substances, 9 application techniques, interception by a dual canopy (vine /grass cover), new soil and climate databases and further account of multiple vinerow treatment. Four substances dominate the overall toxicity profiles. Comparing the results obtained with PestLCI 2.0 with existing static emission quantification approaches results reveals that PestLCI 2.0 yields considerable lower emission loads and consequently, lower toxicity impact burdens. The issue of accounting for inorganic substances is discussed.

Keywords: plant protection product, LCA, vineyard, modelling, emissions, fate

1. Introduction

Wine production and hence viticulture are an important economic and cultural sector in main parts of the world including Europe. Viticulture is also a major pesticide consuming sector with app. 20 kg formulated pesticides/ha/year (of which app. 15 kg/ha are elemental sulfur) within the European Union (Endure 2010).

Pesticides emissions are therefore a crucial topic to be addressed when performing wine and/or grape production related life cycle assessments (LCAs). Due to the lack of specific inventory models suited for pesticide emission quantification, most of the published wine LCA studies either neglect pesticide emissions (Point et al. 2012; Pattara et al. 2012; Bosco et al. 2011; Ardente et al. 2006), simply assume that 100% is emitted to the soil (in accordance with the default Ecoinvent approach applied for pesticides (Nemecek and Schnetzer 2011)) or propose a fixed partition as (Neto et al. 2012) with 75 % of pesticides emitted to soil and 25% to the air.

PestLCI (Dijkman et al. 2012; Birkved and Hauschild 2006) is currently the most advanced LCI model for pesticides emissions quantification from arable land (van Zelm et al. 2014). Despite the fact that the model has been applied in wine/grape production LCAs (Villanueva-Rey et al. 2014; Vázquez-Rowe et al. 2012), PestLCI 2.0 still does not take into account certain viticulture specificities such as double cropping systems, vertical application techniques etc. which differentiate viticulture from other crops and influence the emission patterns of pesticides. Characterization of the impacts from pesticide related emissions specific to viticulture and fruits or vegetable crop production furthermore requires characterization factors for these chemical compounds.

This paper presents a PestLCI 2.0 version customized to appropriately account for viticulture specificities affecting the emission quantities and patterns of pesticides from vineyards. The application of the customized inventory model is illustrated by calculation of potential ecotoxicity impacts through combination of emission quantities and freshwater ecotoxicity characterization factors calculated using the USEtox™ characterization model. The combination of the PestLCI 2.0 and USEtox™ models is illustrated through two case studies on vineyard technical management routes[1] (Renaud-Gentié et al. 2014; Renaud-Gentié et al. 2013).

[1] technical management routes (TMRs): logical successions of technical options designed by the farmers (Renaud-Gentié et al. 2014))

2. Methods

2.1. Pest LCI

PestLCI is a dedicated inventory model intended to provide emission quantities for use in relation to the characterization of chemically induced impacts caused by emissions of pesticides from arable land/technosphere to the environment/ecosphere. The most recent version of the model, version 2.0, is described in Dijkman et al. (2012). This version of the model covers app. 90 active ingredients of various types of pesticides, 25 European climate profiles and 7 European soil profiles.

Despite the rather extensive coverage in terms of pesticides, climates and soils, the most recent model version was developed with conventional agriculture in mind and viticulture was hence not addressed specifically. In order to improve the viticulture specificity of the model, PestLCI version 2.0 was updated with 28 pesticides frequently used in European viticulture, 5 French soil profiles, 22 French temperate maritime climate profiles, 34 crop stages and cover crop combinations + 13 direct spraying situations as well as 9 pesticide application techniques typically applied in European viticulture.

2.2. Identification of specific needs for pesticides emissions modeling in viticulture

2.2.1. Pest and weed management in viticulture

The main pests damaging the vine canopy are primarily the fungi downy mildew *(Plasmopara Viticola)* and powdery mildew *(Uncinula Necator*), which necessitate fungicide treatments. The other fungi and the main insect pests (moths, leafhoppers and phytophagous mites) are not systematically treated. Vineyard management includes also weed control, since weed presence can affect vine growth by competition for water and nutrients. Most of these pests require specific pesticide active ingredient substances (ai.s). The risk of resistance acquisition by the pests implies frequent change of ai.s, in conventional[2] viticulture especially for ai.s presenting a single-site action. Vineyard treatment programs therefore usually involve a variety of pesticide ai.s. This is however not the case is in organic viticulture, where the fungicides used (primarily copper and/or sulfur based fungicides) have multi-site action, while weeds in organic viticulture are mechanically controlled.

2.2.2. Active substances

Vineyard management involves, in French context, on average 14 to 16 pesticide applications per year at full recommended application rates (Mézière et al. 2009; Ambiaud 2012b) with a high interregional and inter-annual variability mainly related to climatic conditions and winegrowers practices. Organic and inorganic or partially inorganic pesticides ai.s are used by viticulture.

Conventional pest management in viticulture relies on generic farming organic pesticides ai.s, but also on more crop specific organic pesticide ai.s typically used on vegetables or in orchards. All these crop specific active substances were not included in PestLCI 2.0 version presented by (Dijkman et al. 2012). The substances used in the cases studied in the project at hand were listed. Compilation of data on the properties of these substances used in viticulture, however missing in the PestLCI 2.0, was conducted applying specialized chemical databases: "e-phy" (MAAF and ONPV 2013) for correspondence between commercial name and active substance, "PPDB" (University-of-Hertfordshire 2013), "Toxnet" (US-National-Library-of-Medicine 2013) as well as "Chemspider" (Royal-Society-of-Chemistry 2013) for main chemical and physical characteristics. Data gaps were compensated for applying the Quantitative Structure-Activity Relationships included in the EPI Suite™ (US-Environmental-protection-Agency 2012).

However, conventional and organic viticultures also apply inorganic sulfur (S8) and copper-based fungicide ai.s. to manage powdery mildew (mainly sulfur) and downy mildew (mainly copper). They also use other inorganic ai.s like Ammonium thiocyanate (herbicide) or partially inorganic like Fosetyl-Al (fungicide). However, PestLCI 2.0 is designed only for modelling of organic pesticide a.i. emissions. For this reason, inorganic pesticides were not included in this study.

[2] « Conventional » is used in this paper to designate non-organic plant protection practices

Some pesticide ai.s applied in the studied vineyards, especially organic vineyards are derived from micro-organisms like Spinosyn, or plants like Pyrethrum. The physical-chemical and fate properties of these pesticide ai.s were found in Bio-Pesticide DataBase (BPDB) (University-of-Hertfordshire 2012) and some of the previously cited databases. A second fraction of “others pesticides and pesticide ingredients” are substances like algae extracts and pesticide formulation additives which are not considered in this study, due to lack of information about the nature and quantity of these substances. Formulation additives may however despite of their exclusion of this study, contribute considerable to toxicity of the pesticide formulation (Brausch and Smith 2007).

2.2.3. Spraying equipment

Vertical shoot positioning is the most frequent training system[3] for vineyards in France and is found in many other wine producing countries. The case studies assessed in the paper at hand only cover vertical shoot positioning trained vineyards.

The types of spraying equipment involved in viticulture are multiple, which makes the task of modeling their individual characteristics a challenge. Herbicides are most often applied using specific sheltered booms to avoid herbicide drift and hence deposition on vine leaves (which would damage/kill the wines). We chose to model these application techniques as “soil incorporation” in Pest LCI since they induce very low drift. The sprayers designed for canopy and grapes spraying can use different modes of droplets production:

- *non air-assisted spray*, the droplets are formed by the acceleration of the liquid under pressure in the nozzle, and applied to the leaves by the pressure,
- *airblast*, the droplets are formed through nozzles, and are then subsequently transported to the leaves by an air flux which further shakes the wine leaves, thereby facilitating the penetration of the substance into the canopy,
- *pneumatic* where air accelerated to app. 300km/h meets the liquid containing the pesticide formulation and fragments the solution into very fine droplets and conveys it to the leaves.

Different shapes of the ventilators and of the sprayers themselves lead to different patterns in terms of spraying quality and drift generation. These different shapes also permit either a direct spraying of each face of the canopy or a spraying from the top of the rows.

A last type of sprayer was designed for drift reduction: the tunnel sprayer where specific panels prevent from drift and collect the non-intercepted spray mixture and recycle it for re-use.

PestLCI 2.0 takes into account the type of sprayer in order to quantify the drift calculations through drift curves. Sprayers representing the above presented application techniques were however not available in PestLCI 2.0. In the present customization, 9 sprayers with different modes of action were included. For the customization and the viticulture specific application techniques we used data from (Codis et al. 2011) who conducted drift tests according to International Organization for Standardization (ISO) protocol (ISO 2005), on different vineyard spraying equipment types in France. The sprayers successfully tested by (Codis et al. 2011) plus a tunnel sprayer tested by (Ganzelmeier 2000) were included in the viticulture customized PestLCI 2.0 version. Defining within this list of the 9 sprayers, the ones that are the more similar to the ones we have in our case studies was done through discussion with the author S. Codis (Codis 2014).

Since the aforementioned drift tests used to derive spray drift curves were conducted on vines with one leaf area, PestLCI 2.0 was adapted in order to correct for spraying on vines with different leaf areas. Modelling of custom spray techniques covering various adaptations of existing spraying equipment is considered beyond the scope of this paper.

According to the type of sprayer, the winegrower can choose to spray 1 to 4 rows of vines simultaneously. The number of rows treated plays a role in wind drift calculation in PestLCI 2.0. It has been taken into account using the parameter” nozzle distance on the model”, the distance entered being the actual width (in meter) treated at the same time.

[3] Training system : type of trellis and shoot positioning resulting to a given shape of the vine canopy and position of grapes.

2.2.4. Accounting for primary distribution in double cropping system

The primary distribution process is defined in PestLCI by 3 factors: wind drift (f_d), pesticide deposition on soil (f_s) and pesticide deposition on leaves (f_l) (Birkved and Hauschild 2006). The two latter are based on (Linders et al. 2000) interception factors for single crops at different growing stages.

Concerning interception by vine canopy, PestLCI 2.0 includes interception values for vine at four different development stages I, II, III, and IV based on (Linders et al. 2000). A stage 0 has been added to take into account situations of leafless vines. The interception factor has been estimated from the orchard dormancy stage interception factor (0.2) given by (Linders et al. 2000) with a division by 2 due to the difference of perennial parts importance between fruit trees and vines. The value of f_l for vine 0 was therefore set to 0.1.

On-field measurements of spraying mixture deposition and losses on vineyards were made by Sinfort (Sinfort 2014) (Sinfort et al. 2009) and on artificial vineyard by (Codis 2014). Distribution ratios of spray mixture between vine canopy, soil and air at 2.5 m above the soil were obtained by these authors in vineyard conditions similar to the ones we study (rows width, types of sprayers). The fractions going to air during spraying measured by (Codis 2014) and (Sinfort et al. 2009) were considered for introduction in PestLCI 2.0 as being i)partly conveyed by wind drift out of the parcel (i.e. advective transport), and ii)partly falling back on vegetation and bare soil of the parcel (i.e. sedimentation). This is because no quantification of direct volatilization is possible (Jensen and Olesen 2014) due to the complexity of drivers combination (properties of the spray liquid, drops size and drops surrounding conditions)(Gil et al. 2007) and the lack of available data for some of them. As PestLCI 2.0 calculates the quantity of drifted pesticide on the basis of the dose applied and before calculating leaf interception, we decided to apply a drift quantity correction ratio based on the pesticide fraction going to air. Full vegetation (stage III) was given the 1:1 ratio because sprayers drift curves were established on that stage.

For accounting of direct spraying with hand hose in early stages or young vineyards, and direct spraying on grapes, 13 specific interception factors were defined through expertise.

Cover cropping on vineyard soil is a developing management scheme with nearly half of French vineyard temporarily or permanently covered (Ambiaud 2012a). It offers multiple advantages, provided the competition for water and nitrogen isn't excessive for the vineyard (Celette et al. 2009). This second canopy under the vineyard (e.g. spontaneous species, oats, clover or fescue) contributes to pesticide interception (primary distribution) and fate (secondary distribution). The interception by the cover crop varies according to the width of the cover crop strips estimated in percentage of the width of the vine inter-row, and according to cover crop canopy density.

In the case of mixed cropping (vine + cover crop), a complementary interception factor (*f*) needs to be added for cover crop. The structure of PestLCI 2.0 being fixed with 3 *f* entries, a combined *f* has been calculated from f_{vine} and $f_{covercrop}$. Based on calculation routines, 34 combined interception factors are now available in the customized PestLCI 2.0 model covering the most current situations spanning possible combinations of vine development stages, cover-crop strip width and cover crop canopy density. Examples of such combinations are given in Table 1.

Table 1: Examples of combined interception factors for vine/cover crop mixed cover (*f* = interception factor)

Stage	**cover density**	**% of soil surface covered by grass**	f_{vine}	$f_{covercrop}$	**% spray lost in air**	**% intercepted by vegetal soil cover *(calculation)***	f_{global}
0	none	0	*0.1*	0.3	*30%*	0%	0.10
II	weak (30%)	100%	0.5	0.3	*30%*	6%	0.56
II	high (70%)	80%	0.5	0.7	*30%*	11%	0.61
III	average (50%)	100%	0.65	0.5	*25%*	5%	0.70

2.2.5. Databases

Site specific climatic profiles appropriately addressing the case study areas were introduced in PestLCI 2.0: two sets of 30 years average 1971-2000 and 1981-2010 for the Beaucouzé Station, and for the five stations of the Middle Loire Valley, being the closest to the observed parcels, data for 3 years of production i.e. October n - September n+1, for 2009-2010 to 2011-2012, a set of averaged months over the 3 years is also available. Climatic data were provided by Météo France. The soils of the modelled parcels were characterized through measured data and observations, in accordance with the PestLCI 2.0 data requirements, and entered in PestLCI 2.0.

2.3. Case study

2.3.1. Choice and main characteristics

Two quite different technical management routes (TMRs) of *Chenin Blanc* cultivar in the middle Loire Valley (France), were observed during the production year 2010-2011. The prevailing Loire Valley climate is temperate maritime according to the classification used in PestLCI 2.0. This study is focused on vineyard TMRs designed for Protected Denomination of Origin (PDO) dry wine production from this cultivar. The case studies were chosen within the 5 types of vineyard TMRs resulting from a detailed survey and analysis of existing vineyard management practices in the area (Renaud-Gentié et al. 2014): 1 "systematic synthetic chemical use and limited handwork",2 "moderate chemical use", 3 "minimum synthetic treatments and interventions",4 "moderate organic", and 5 "intensive organic"(organic with many interventions and treatments).

The two cases presented here: TMRs 1 and 3 are real situations representing respectively type 1 and 3. Organic TMRs are not studied here because their treatment programs include mainly or exclusively inorganic pesticide ai.s. No surface water body lies at less than 100m of the parcels. The 2 plots are not drained nor irrigated.

In comparison to the 30 year average (1981-2010) of the area, the climate of the focus year is: i) a little warmer (0.2°C above the annual average) with a warmer spring but a cooler summer, ii) much drier especially during the growth season of the vine.

TMR 1's plot climate is described by Blaison-Gohier weather station, is on the soil "UTB131" according to the regional cartography of vineyard soils, with 5% slope. TMR 3's plot climate is described by Fontaine-Guérin station. Its slope is 3%, and soil is "UTB35". Field width and length were put at 100m for the two plots. Vineyard pest management programs, spraying equipment and pesticide ai.s used by the growers, as well as canopy development stage and grass cover density and extent are described in table 2.

Table 2: Characteristics of pesticide ai.s applications for 2011 on TMRs 1 and 3. *In grey: the inorganic and partially inorganic pesticide ai.s that were not included in this study.*: new entries in PestLCI 2.0. ▪ needed a new CF in USETox^{TM}*

	pesticide ai.s	Application rate	Crop type + development stage	Month of application	Application method	width treated at a time

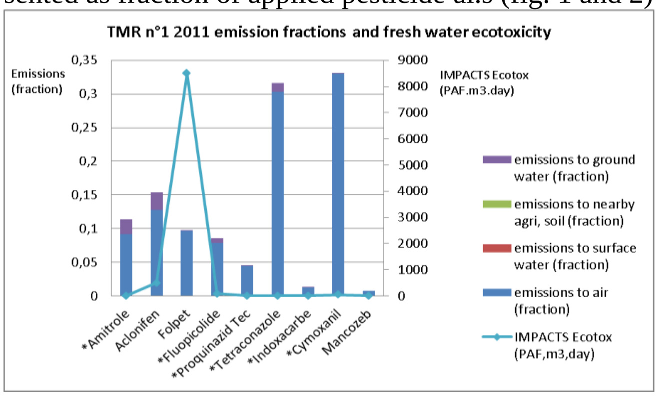
2.3.2. Calculating characterization factors in USEtox™

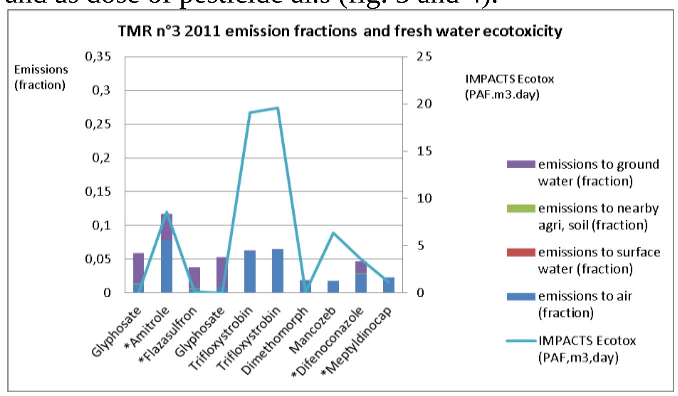
Characterization factors (CF) are needed to quantify the potential environmental impact from emissions of the life cycles of products and systems in LCA. CFs are substance and compartment specific and CFs for each of the emitted ai.s of the case study for compartments air, surface water and agricultural soil[4] are thus needed. We choose USEtox™ as characterization model since it was developed as a scientific consensus model, to represent the best application practice for characterization of toxic impacts of chemicals in LCA (Hauschild et al. 2008) and since its database (v. 1.01) covers ~2500 chemicals with calculated characterization factors for freshwater ecotoxicity (Rosenbaum et al. 2008). Some of the ai.s were not covered by the database and we therefore applied the USEtox™ model to calculate them. USEtox™ requires a number of chemical and physical properties in addition to toxicity data. Primary and secondary sources for these data are available upon demand to the authors.

3. Results

3.1. Emissions and Freshwater ecotoxicity on the case study

Pesticide ai.s emissions were calculated by PestLCI 2.0 for each organic substance application. They are presented as fraction of applied pesticide ai.s (fig. 1 and 2) and as dose of pesticide ai.s (fig. 3 and 4).





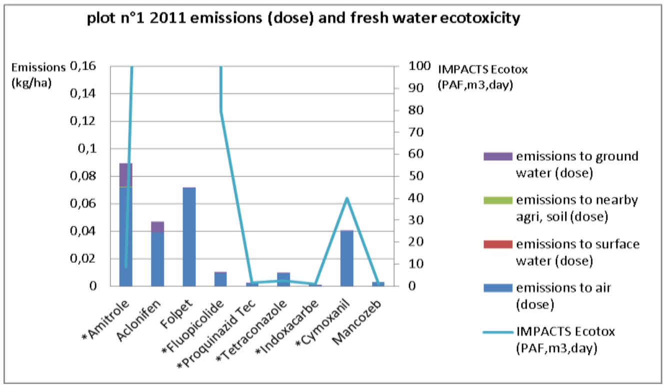
Figures 1 and 2: fraction of applied pesticide ai.s emitted in the 4 compartments: fresh and ground water, nearby agricultural soil and air (left axis) and the resulting freshwater ecotoxicity (right axis, scales adapted to results)

The total emission fractions do not exceed 0.35, and are lower than 0.15 for most of the pesticides. The emissions loads are dominated by air emissions in figure 1, followed by ground water emissions. In figure 2, groundwater emissions dominate, for the 4 herbicides. Emissions to nearby agricultural soils are negligible, and thus don't appear on the charts. The absence or quasi-absence of freshwater emissions are due to the absence of water body around the parcels.

The higher total emission fractions relate primarily to Tetraconazole (fungicide of the Triazole group), Cymoxanil (fungicide of Cyanoacetamide Oxime group) and Mefenoxam (fungicide of the Phenylamide group). These fungicides are emission load wise followed by two herbicides: Aclonifen (Diphenyl ether group) and Amitrole (Triazole group) and another fungicide: Folpet (Phtalimides group).

In some cases, the same substance is applied under two different conditions. Amitrole, for example, is applied with the same type of boom (herbicide sheltered boom) and on the same canopy (grass). However, the emissions of this compound vary according to the conditions of application (month of application and soil vary). An application of Amitrole in April (figure 1) compared to an application of Amitrole in March (figure 2) shows lower emissions to air for the early application, while emissions to groundwater are higher for the latest application.

[4] USEtox contains no ground water compartment. Ecotoxicological impacts in freshwater from chemical emissions to groundwater are considered negligible and thus not further considered in this study.



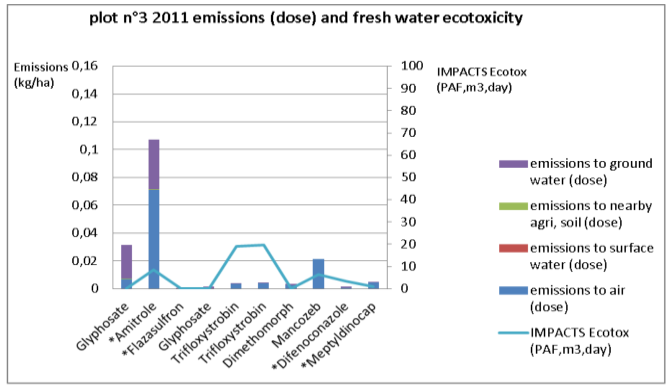


Figure 3 and 4: Quantity of applied pesticide ai.s emitted in the 4 compartments and freshwater ecotoxicity (Impacts Ecotox (same values as fig 1 and 2) scale was fixed here to a maximum of 100 to see smaller differences)

When expressing the emissions in kg/ha, see figures 3 and 4, the quantity emitted to the ecosphere per application is not higher than 0.12 kg/ha. Amitrole dominates the emissions air in both scenarios (fig. 3 and 4), followed by Folpet and Aclonifen.

Freshwater ecotoxicity (FwEtox) was calculated applying USEtox™ characterization factors. Figures 1 and 2 reveal considerable differences for the different application times. In figure 1, FwEtox is dominated by Folpet (8000 PAF·m^3·day), Aclonifen (500 PAF·m^3·day), Fluopicolide (80 PAF·m^3·day) and Cymoxanil (40 PAF·m^3·day). The high impact from Folpet emissions is primarily caused by emissions to air and can be explained from a combination of the substance's relatively low vapor pressure (meaning that a substantial amount of emissions of Folpet to air ends up in the freshwater compartment) and its relatively high toxicity to freshwater organisms. TMR3 shows a much lower total FwEcotox (58.5 PAF·m^3·day) than TMR1 (9132 PAF·m^3·day).

3.2. Comparison with static emission quantification approaches

The Ecoinvent approach applied for pesticides is to consider that 100% is emitted to the soil (Nemecek and Schnetzer 2011), (Neto et al. 2012) in their LCA of Portuguese wine Vinho Verde propose a static partition as with 75 % of pesticides emitted to soil and 25% to the air. Table 2 compares results between the 3 approaches.

Table 3: Comparison of pesticides emissions calculated by PestLCI 2.0, Ecoinvent and Neto et al. (2012) approaches and FwEtox calculated with USETοxTM characterization factors

Emissions	average fraction emitted	standard deviation on fractions
PestLCI 2.0-emissions to air	7.39E-02	9.30E-02
PestLCI 2.0-emissions to surface water	0	0
PestLCI 2.0-emissions to nearby agri. soil	8.06E-05	1.19E-04
PestLCI 2.0-emissions to ground water	1.32E-02	1.68E-02
PestLCI 2.0-total emissions	8.72E-02	9.21E-02
100% emitted to soil (Ecoinvent)	1	0
75% emitted to soil (Neto etal 2012)	0.75E-01	0
25% emitted to air (Neto etal 2012)	0.25E-01	0
Impacts	**average impact**	**standard deviation on impacts**
Impacts FwEcotox PestLCI 2.0 (PAF·m3·day)	4.84E+02	1.94E+03
impacts FwEcotox Ecoinvent (PAF·m3·day)	1.52E+04	6.46E+04
impacts FwEcotox Neto et al. (PAF·m3·day)	1.26E+04	5.35E+04

In the present cases, the average of total emission fraction modelled with PestLCI 2.0 is more than 31 times lower than the total soil emission fraction estimated by Ecoinvent approach. The average PestLCI 2.0 modelled emission fraction to air is 3.4 times lower than the total emission fraction to air estimated by Neto et al. (2012) approach. This leads to differences in FwEtox estimates: 31 times lower with PestLCI model than Ecoinvent approach, and 26 times lower with PestLCI model than with Neto et al. (2012) approach. Very high standard deviations must be noticed on FwEtox, due to high differences in the ai.s' FwEtox potential.

4. Discussion

While having been intended mainly for arable crops, PestLCI 2.0 inventory model, due to its rather flexible framework, has here been adapted for viticulture without compromising the model framework. The calculation of toxicological impact potentials, beyond emission load quantification, was further complicated by ai.s not covered by the USETox^{TM} database, thus necessitating the calculation of CFs using the USETox^{TM} mode.

The case study results show that emission fractions vary in a large extent due to the ai.s properties and parcel and application conditions. High emissions fractions for most of the ai.s are compensated by very low application doses (cymoxanil, teraconazole) leading to moderate emissions (dose) but the ecotoxicological profile of the ai.s then has high importance on the final FwEtox results as shown by the FwEtox of Folpet and Aclonifen. Multiple factors differentiate the two case vineyards TMR1 and 3. The main factors are considered to be soil, sprayer equipment and type of pesticides applied. TMR1 shows higher emissions fractions than TMR3, however the total emission load is lower because of the low doses applied for some substances. Characterization through USETox^{TM} reveals different results for the two cases, mainly due to the high ecotoxicity potential of Folpet and to a lesser extent, of Aclonifen, even if both ai.s are applied via sheltered boom and tunnel sprayer (both limiting wind drift) (TMR1).

Inorganic pesticide ai.s, which are not modelled here, were also applied to the case vineyards: five applications for TMR1 including copper based ai.s and one application for TMR3 (Table2). The copper based pesticide ai.s are expected to further increase the FwEtox of TMR1 if included (Mackie et al. 2012; Vázquez-Rowe et al. 2012). A comparison of the present TMRs FwEtox profiles with the results obtained by (Vázquez-Rowe et al. 2012) with PestLCI 1 in Galician vineyards shows very good performance of the present TMR. Hence, TMR1's FwEtox is half of the lowest FwEtox mentioned by this author (Copper impacts removed) while TMR3's FwEtox is 400 times lower as this author's lower result.

Huge differences were found between the two static approaches (Ecoinvent and Neto et al. 2012) and PestLCI 2.0 based emission quantification. Accounting for the sole emissions that cross the parcel borders is a first element lowering the quantity of emitted pesticides as modelled by PestLCI 2.0, compared to the other approaches tested. However that is not the only cause of lower emissions and FwEtox; considering, for these emissions calculations, processes of evaporation, runoff and leaching, canopy influence, including the actual properties of the pesticide ai.s applied, of soils and sprayers allows for a more accurate adjustment of estimates to the real phenomenons. Degradation of pesticide ai.s and their uptake by the plants are actual processes that aren't considered in the static approaches tested, but accounted for in PestLCI 2.0 (Dijkman et al. 2012). The uptake of pesticides in crops including edible parts, is in PestLCI only considered as a fate/removal process and hence export from the field of pesticides via crops and crop residues is not considered nor quantified. Plant pesticide uptake processes are complex systems of coupled processes demanding dedicated models such as DynamiCROP (see e.g. (Fantke et al. 2011)).

In organic viticulture, sulfur and copper are the only means available to manage respectively powdery and downy mildew, and represent important quantities of applied pesticides. Sulfur and copper are not available in PestLCI 2.0 as the model is designed for modelling of organic pesticide ai. emissions. Thus, a comparison between conventional and organic viticulture or inclusion of organic managed cases in a study cannot be dealt with solely through PestLCI 2.0; a model similar to PestLCI is needed for inorganic pesticides. Considering the complex chemistry of inorganic chemicals, such a model will however have to deal with multiple species nature of inorganic chemicals in order to appropriately reflect the behaviour of these chemicals in soils.

PestLCI 2.0 could be improved by further developments of the accounting of airborne drift, which can be considerable (Jensen and Olesen 2014) but the complexity of the phenomena (Gil et al. 2008) and the lack of (generic) data are considered major obstacles for this improvement. More or less for the same reasons, pesticide metabolites are not accounted for in the present version of PestLCI 2.0. Accounting for application parameters as sprayers' speed, droplets size, temperature, relative humidity would be ideal for further refinement of the modelling of the spray mixture behaviour and fate, but these parameters are too difficult to obtain from the growers, and would further entail an even more complicated inventory.

High percentages of stones can be found in many vineyard soils; and modify water flow in the soil. These aspects could not be included in the present customization of PestLCI 2.0. However we recommend improvement of the way soil texture affects macropore transport in PestLCI 2.0 as an important issue to be considered in the coming PestLCI versions.

PestLCI 2.0, calculations must be carried out for each pesticide ai.s and application and thus remain a tedious task. Ideally, a possible connection with an external Excel database could potentially facilitate the automation (batch) of calculation and further pave the road for more detailed sensitivity analyses.

5. Conclusion

The PestLCI 2.0 customized version for viticulture, presented in the paper at hand, facilitates the calculations of emission loads for vertically trained vineyards with a wide range of sprayers and further provides a considerable PestLCI pesticide database update (even if non-exhaustive), of viticulture specific pesticides ai.s, and is complemented by the corresponding UseTOX^{TM} FwEtox characterization factors. A range of rather important specificities of viticulture that were not included in PestLCI 2.0. has been added like: i) specific sprayers drift characteristics, ii) the presence of a secondary canopy (cover-crop), iii) specific data like specific pesticide ai.s in the PestLCI database.

Application on two different case studies shows that emissions differ from a pesticide ai.s application to the other due to different emissions fractions related to environmental conditions and ai.s properties.

Huge differences were found between the two static approaches (Ecoinvent and Neto et al. 2012) and PestLCI 2.0 based emission quantification and FwEtox, The static approaches over-evaluate emissions and hence FwEtox from 2 to 31 times compared to PestLCI 2.0, due to different technosphere/ecosphere boundaries and accounting of degradation and plant uptake phenomena by PestLCI 2.0.

Some of the new PestLCI model parameters can also be used for other perennial or bush crops as long as equipment, shape of the canopy and pesticides a.i.s stay in the range of available options.

Aknowledgements: The authors thank Interloire and Region pays de la Loire for funding, the winegrowers for their time and data, Miss D. Boudiaf for her help in data collection, Mrs F. Jourjon and Mrs E. Mehinagic for their core reading and advices.

ABSTRACT

Soils function is an important environmental value in Australia particularly for agriculture. However it has not been considered in life cycle assessment (LCA) studies to date in Australia, which has precluded its consideration alongside other environmental impacts. The agriculture sector and LCA community in Australia desire that soil function be captured in national life cycle inventory (LCI) and impact assessment frameworks. CSIRO has commenced a project to this end, with the first step being a workshop that brought together prominent soil scientists and LCA researchers to lay some groundwork for the project by i) prioritising the soil function and quality parameters of most importance and relevance for Australia, ii) considering how soil-related indicators can assign with evolving land use impact assessment frameworks, and iii) exploring the utilisation of spatial datasets to generate LCI for flows related to soil function to allow for more regionally-specific assessment of soil-related impacts.

Keywords: soil, LCI, LCIA, Australia, national inventory databases, agriculture, soil carbon, erosion, acidification

1. Introduction

This paper describes the outcomes from an Australian workshop, at which a proposed approach for integrating indicators of soil function and quality into the Australian national life cycle inventory database was developed.

Soil function and qualities and their influence on productivity and ecosystem services have been under-represented in LCA to date. Recent efforts by the UNEP SETAC Life Cycle Initiative have devised an impact assessment framework that captures the eco-system service functions of land, including soil functions (Koellner et al. 2013). However this has yet to translate into the representation of soil-related impacts in life cycle studies.

Soil-related impacts are pertinent to many production systems that involve transformation of land. However interest in soil impacts has been expressed most keenly by those working on agriculture-based production systems. This is because soil function is inherently linked to agricultural productivity, and the long-term sustainability of agriculture relies on protecting and enhancing it. Hence there is more incentive to influence the protection of soil in agriculture than in any other sector.

The absence of soil function considerations in LCA to date is in contrast to the recognition of soil-related problems by the agriculture sector. Compared to soils on other continents, Australia’s soils are very old, highly weathered and relatively infertile (DAFF, 2014). While there are areas of highly fertile soil, Australia’s soils often have poor structure with low levels of organic matter and are affected by salinity, sodicity, and acidification, and in some regions are subject to wind and water erosion. So, for Australia in particular, declining soil quality is a major concern. The level of investment by the agriculture sector and governments to rectify soil-related impacts in Australia (estimated at A$124 million in 2011; DAFF 2014) is higher than for other environmental impacts such as eutrophication and pesticide impacts on sensitive environments and global warming.

Therefore the agriculture sector and LCA community in Australia desire that soil function and qualities be captured in national inventory and impact assessment frameworks. The Commonwealth Scientific and Industrial Research Organization (CSIRO) commenced a project to this end, with the first step being a workshop that brought together soil scientists and LCA researchers to lay some groundwork for the project.

This project follows on from a prior program of work completed in 2013 to establish a national life cycle inventory (LCI) dataset for Australian agricultural processes (AusAgLCI) (Eady et al. 2013) which is available within the AusLCI database (alcas.asn.au/AusLCI). The developed data sets currently contain inventory that allows for the assessment of resource depletion, global warming, eutrophication, acidification, and human- and eco-toxicity. The current project aims to extend the inventory to enable the assessment of soil-related impacts.

2. Methods

A two-day workshop was held in Canberra on the 8 and 9 April, 2014, which was attended by around 50 soil scientists, LCA researchers and, government and research investment managers (25 in person and 25 by webinar) (see www.alcas.asn.au/events/roundtables). The aim of the workshop was to connect LCA researchers with Australian soil scientists, for the purpose of reviewing the latest science related to soil processes in Australia and considering how best to characterise soil-related impacts in LCA in the Australian context.

After some introductory sessions on LCA and international developments in land use impact assessment, the forum heard presentations from prominent Australian soil scientists about notable soil characterization developments in Australia. The forum also connected via webinar with overseas LCA researchers (from Europe, North America and New Zealand) to gain insights into international developments and interest in this field.

The soil issues covered in the workshop were those for which there is active and significant research taking place in Australia, and which have been identified as the key soil condition indicators (Australian Government, 2011). They were compaction, soil organic carbon, erosion, contamination, soil biota and acidification. While not covered in the structured presentations, the additional issues of soil salinization and structural decline were also discussed.

Based on the structured discussion at the workshop it was possible to i) nominate the soil function and quality parameters of most importance and relevance for Australia, ii) propose how soil-related indicators of interest in Australia can align with evolving impact assessment frameworks, and iii) identify how Australian spatial datasets can be utilised to generate LCI for soil-related flows to allow for more regionally-specific assessment of soil-related impacts.

3. Results and discussion

3.1. Priority soil function and quality parameters for Australia

The geochemical processes that influence soil characteristics vary in different parts of the world, with a general distinction drawn between the high latitude countries where glacial weathering has a significant renewal effect on soil quality or those areas where significant volcanism or annual flooding has rejuvenated landscapes, and continents such as Australia where under the influence of flat topography and long periods of weathering, low rainfall and wind erosion, most soils have lower resilience and are more vulnerable to degradation. This means there may be differences in the way soil-related impacts are best represented in Australia (and other similar geological regions e.g. parts of Africa) compared with Europe, which has been the context for life cycle impact assessment development to date. Therefore, it was worth considering the soil function and quality parameters that are of relevance and importance for Australia, to ascertain if they can be adequately captured in evolving land use impact assessment frameworks. Furthermore, the practicality of collecting data for these parameters for inventory development needs to be considered.

Participating soil scientists were asked to rank the soil characteristics according to their environmental importance in Australia and the expected difficulty of inventory development. The results of participant feedback are shown in Figure 1.

The priority soil attribute raised at the workshop (those in the top left-hand quadrant of Figure 1) were consistent with those identified in Australia's State of the Environment reporting (Australian Government 2011) and the national soil R&D strategy (DAFF 2014). The leading challenges are acidification, erosion and loss of soil carbon. This degradation will increasingly affect Australia's agriculture unless carefully managed, and in some cases ameliorated. Assessment of soil condition for regions with cropping and/or intensively managed grazing systems (approximately 75 million hectares) showed that for:

– **acidification**—50 per cent of regions were in very poor or poor condition, while 95 per cent of regions showed a deterioration in soil pH
– wind and water **erosion**—53 per cent of regions were assessed as in poor condition, while soil cover in 11 per cent of regions was deteriorating
– **soil carbon**—33 per cent of regions had very poor or poor soil carbon content, while 85 per cent of regions had ongoing deterioration in soil carbon content.

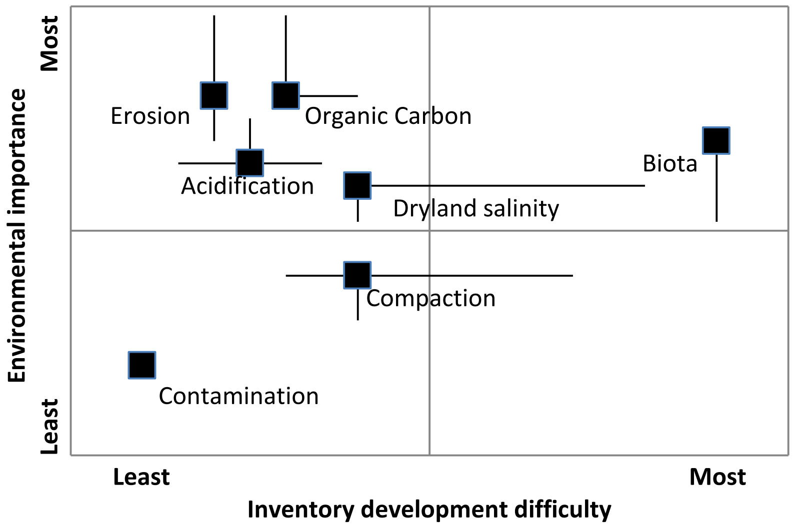

Figure 1. Ranking of environmental importance and difficulty of inventory development (with the horizontal and vertical bars indicating spread in opinion).

Dryland salinity has also been identified as an ongoing threat, although the millennium drought may have slowed its spread temporarily. However, salinity is less easily linked to on-site agricultural management. While its expression (in contaminated soil or near-surface groundwater) can adversely impact on agricultural production, its cause may be substantially removed in space and time (e.g. clearing or irrigation elsewhere in the catchment at other times) and the risk components are complex (Grundy et al. 2007). Compaction was assessed to be of lesser overall importance while diverse and high populations of soil biota were considered to be important but difficult to quantify. Soil contamination was also thought to be less of an issue as it is mostly related to point source pollutant emissions and hence quite localized, and impacts can be adequately captured in existing inventory and impact assessment (e.g. heavy metals in fertilizers).

In relation to the practicality of inventory development, it was considered that datasets of sufficient representativeness exist for soil organic carbon, erosion and acidification. For organic carbon, data on stocks and flows are available from cropping systems models such as APSIM, continent scale models such as FullCAM, and geospatial modeling (Viscarra Rossel et al. 2014). For erosion, there are model data assimilation approaches such as those used by Chappell et al. (2013) to estimate net rates of erosion. For acidification, data are available from the Australian Soil Resource Information Systems (www.asris.csiro.au). For salinity and compaction more work may be required to adapt existing datasets; detailed data are available for areas of salinity high risk e.g. the south-west cropping lands (Furby et al. 2009). There is a considerable paucity of measurement methods available for soil biota at the spatial scale required for national inventory making it impractical at this time to consider including biota-related inventory.

It was noted that in the Australian context the sustainability objectives for soil function and quality were both the maintenance of eco-systems services and the maintenance of the soil resource itself. As will be discussed further in the next section, existing LCA frameworks are mostly concerned with the eco-system services function of soils. Soil is not captured by resource depletion indicators in LCA as fossil fuels and minerals are. In the Australian context avoiding the depletion of soil resources is important. This is because the natural reference state for land in Australia is already highly eroded with very shallow soil profiles and high propensity for ongoing erosion. Consequently it is easy for tipping points to be reached.

In summary, the set of characteristics considered to be important because they significantly influence the productivity, the soil resource base, and ecosystem services, they are related to land management in the agricultural system and for which there are reasonable data available, are soil organic carbon, erosion and acidification. These will become the priorities for further investigation in the CSIRO project.

3.2 Alignment with land use impact assessment frameworks

The alignment of inventory with impact assessment is an important consideration in developing regional inventory datasets. The authors appreciate the challenges of regionalized impact assessment and the need to harmonize impact indicators (Saad et al. 2013), and acknowledge that Australia-specific inventory needs to enable impact assessment using internationally consistent indicators and impact assessment methods.

A good starting point is the guideline for land use impact assessment developed under the UNEP/SETAC Life Cycle Initiative (Brandão and Canals 2013; Koellner et al. 2013; Saad et al. 2013). It is the most developed model relating to land use to date, and proposes a characterization model that links land characteristics with indicators of eco-system services. Figure 2 presents an extract from this model showing the cause and effect chains related to soil characteristics and including the midpoint indicators proposed to date.

Overlaid on this model are the priority soil characteristics identified for the Australian context (shaded in light grey in Figure 2). Two of these, soil organic carbon and erosion, are already captured in the land use impact assessment model (light grey). Soil organic carbon (tC/ha) is proposed in the model as a proxy for fertility, influencing biotic production (Brandão and Canals 2013). It is also the indicator used to quantify soil carbon sequestration. Erosion regulation potential is captured in the model, with the proposed proxy indictor being erosion resistance potential (t soil/ha/yr) (Saad et al. 2013).

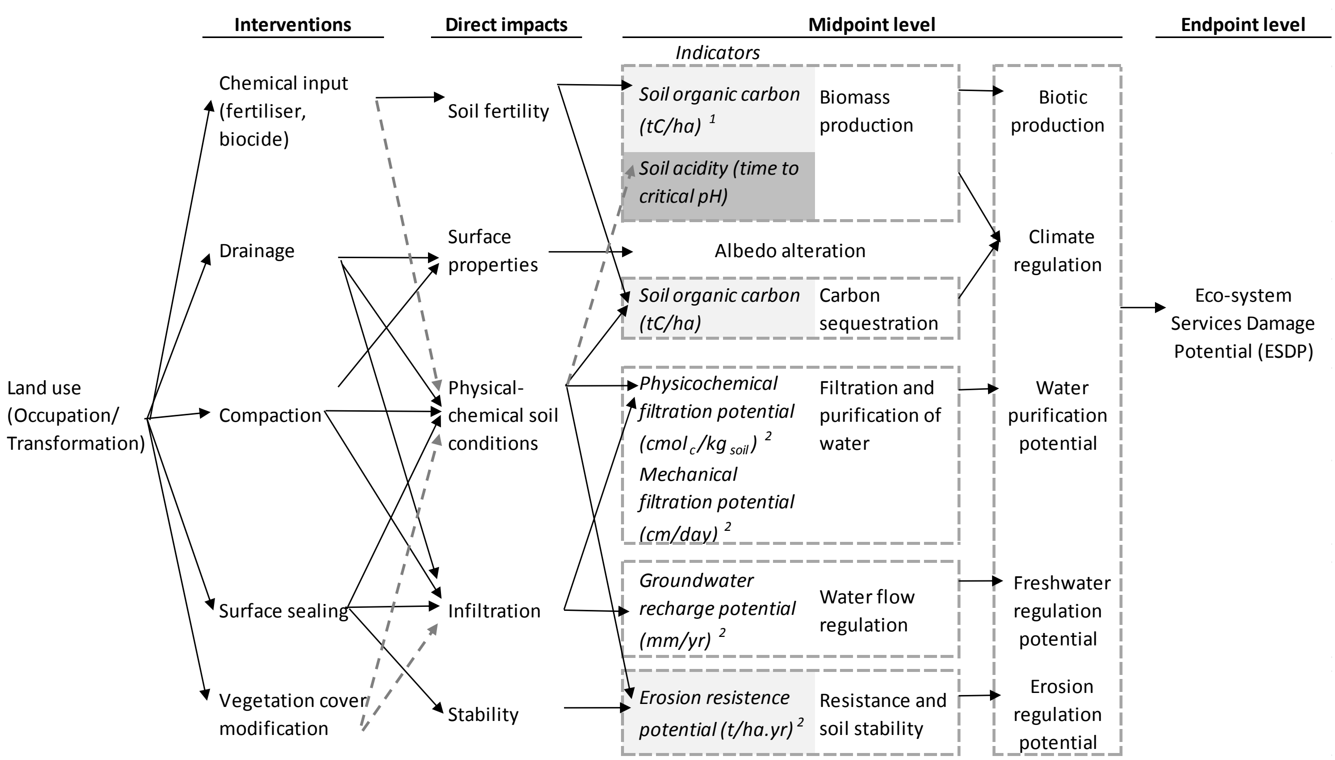

Figure 2. Extract from the land use impact assessment model developed under the UNEP/SETAC Life Cycle Initiative (Koellner et al. 2013), and incorporating the midpoint indicators proposed for biomass production (1) (Brandão and Canals 2013), and other eco-system services (2) (Saad et al. 2013). The shaded indicators are those identified as important in the Australian context.

Soil acidity is not captured in the model (dark grey in Figure 2). It adversely influences agricultural productivity in Australia (Australian Government 2011) and could be considered as a moderator of biotic production along with soil organic carbon. Some consideration may need to be given to how it can be integrated into the model.

In summary, soil-related inventory developed for Australia for soil organic carbon and erosion could align with the emerging land use impact assessment framework. Even though compaction is not currently a priority for inventory development, it could also be accommodated at a later date as midpoint indicators reflecting the impacts of compaction have been proposed (physicochemical and mechanical filtration potentials and groundwater recharge potentials) (Saad et al. 2013). An adaptation to the impact assessment framework to accommodate Australian conditions, could be the inclusion soil acidity as a moderator of biotic production. Furthermore, including soil within abiotic resource depletion impact categories would allow for consideration of Australia's soil resource conservation objective.

3.3 Utilisation of spatial datasets to generate LCI for flows related to soil function

The spatial scale of the agricultural LCI datasets (AusAgLCI) is at the level of agro-ecological regions (Williams et al. 2002). To enable cost effective inventory development across the breadth of Australia's agricultural regions, GIS-enabled spatial data are utilized. As previously noted, spatially-linked data for soil organic carbon, erosion and acidification are available, and it is proposed that these be used to supply soil-related inventory (see an example in Figure 3).

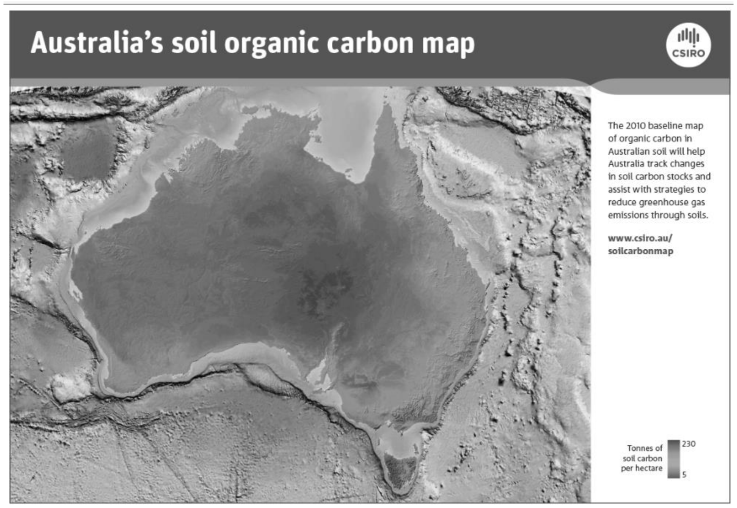

Figure 3. The 2010 baseline map of soil organic carbon in Australian soil; a base to track changes in soil carbon stocks and assist with strategies to reduce greenhouse gas emissions through soils (Viscarra Rossel et al. 2014).

As part of the UNEP/SETAC land use impact assessment framework generic characterization factors for global application have been developed, which characterize the mid-point indicator per unit of land, based on regionally-disaggregated modeled estimates (Brandão and Canals 2013; Saad et al. 2013). For the purposes of extending Australian agricultural inventory, region- and production system-specific inventory flows derived from the spatial data are proposed to be employed rather than defaulting to the generic characterization factors. These will give a more robust and representative estimate of the key soil-related impacts in the Australian context. Spatial data for soil organic carbon, acidity (pH) and net soil erosion already exist, and are represented as 'stocks'. The challenge will be to couple these estimates of 'stocks' with a means of estimating 'flows' (stock changes), and to link flows to management practices and interventions.

A similar approach was taken in the previous inventory development project (Eady et al. 2013) to generate region- and production system-specific pesticide flows by using PestLCI to partition flows between soil, air and water compartments. This meant that more robust regional inventory is possible, rather than relying on generic characterization factors embodied within the impact assessment methods, that do not account for the climate and soils of the region. Hence, we propose to take a similar approach for soil attributes and use the best existing data to describe mid-points indicators.

4. Conclusion

An approach for extending Australian agricultural LCI datasets to include soil-related flows has been proposed, which can be consistent with evolving international frameworks for land use impact assessment. Spatially-linked data for soil organic carbon and erosion are available to generate inventory flows that align with proposed midpoint indicators for biotic production and erosion regulation. Acidification is a major constraint to soil function in the Australian context, and a way of adapting the biotic production mid-point indicator to be moderated for acidification may need to be considered. The tasks for the project will be to convert the ‘stock’ information available from the datasets into ‘flows’ (stock changes) for the inventory, and to link the flows to management practices and interventions. The inclusion of soil resources within adiabatic resource depletion impact categories would also allow for consideration of Australia’s particular soil resource conservation objectives.

5. Acknowledgements

The workshop was sponsored by the Australian Grains Research and Development Corporation (GRDC) through a conference sponsorship grant.

The authors acknowledge the soil scientists who presented at the workshop and thereby contributed knowledge to this paper - Jeff Baldock, Andrew Bissett, Adrian Chappell, Ryan Farquharson, Rai Kookana, Keryn Paul, Gupta Vadakattu, Enli Wang and Mike Webb. In addition, the workshop attendees contributed to the discussion that allowed us to arrive at a general consensus on the relative importance of soil attributes and possible mechanisms for estimating inventory flows.

ABSTRACT

To help advance the source reduction of food waste in the U.S. municipal solid waste (MSW) stream, ICF International is working with the U.S. Environmental Protection Agency to develop life-cycle energy and greenhouse gas (GHG) emission factors for food waste to compare the impacts of source reduction and disposal options for common food waste types in the U.S. MSW stream. ICF has developed cradle-to-retail source reduction energy and GHG emissions factors as part of EPA's Waste Reduction Model (WARM) for four food waste types: grains, bread, fruits and vegetables, and dairy products. These factors are expected to have broad appeal across the food service, restaurant, and materials management industries and governmental organizations and are expected to be used as part of EPA's Food Recovery Challenge to encourage reduction and recovery of food waste.

Keywords: food waste, greenhouse gases, source reduction, organics

1. Introduction

In 2012, food waste was the largest single component in the U.S. municipal solid waste (MSW) stream, comprising over 21% of MSW discards my mass (U.S. EPA 2014a). The U.S. Environmental Protection Agency's (EPA) food recovery hierarchy identifies source reduction as the most preferred method for addressing food waste (U.S. EPA 2014b). In the context of MSW, source reduction is defined as the reduction of waste generation at its source by means of altering the waste generation source (e.g., via more efficient consumer use of materials, reuse, or improved product design). In the case of food waste, source reduction refers to upstream reductions in food production. It can result from any activity (e.g., lowering consumption, reducing food spoilage, avoiding disposal of uneaten food) that reduces the amount of an agricultural input needed and therefore used to make food. As a result, there is demand for a simple tool allowing waste managers, food service managers, and other stakeholders to estimate the energy and greenhouse gas (GHG) emissions avoided through food waste source reduction. To help meet this demand, ICF International worked with EPA to develop life-cycle energy and GHG emission factors for food waste to compare the impacts of source reduction and other disposal options for common food waste types in the U.S. MSW stream using EPA's Waste Reduction Model (WARM).

EPA created WARM to help solid waste planners and organizations track and voluntarily report GHG emissions reductions from several different materials management practices. WARM calculates and totals the relative GHG emission and energy impacts of baseline and alternative materials management practices—source reduction, recycling, combustion, composting, and landfilling—using GHG emission factors that EPA has developed based on a materials life-cycle approach. ICF has provided EPA with ongoing support for the development of life-cycle emission factors and in the development of and updates to WARM since its creation.

WARM currently models life-cycle GHG impacts for over 50 material types. Prior to the development of the energy and GHG factors described in this paper, WARM included a general "food scraps" waste category representative of national average food waste composition. For the "food scraps" category, WARM modeled energy and GHG impacts from three end-of-life pathways—landfilling, combustion, and composting—but did not consider GHG emissions associated with raw materials acquisition, transportation, and processing of food products before they enter the U.S. MSW stream. Therefore, it was not possible to use WARM to estimate the energy and emissions avoided through reduced production of food, also known as source reduction.

To better understand and reduce the impacts from this growing waste stream, ICF worked with the EPA to expand WARM by developing life-cycle energy and GHG emission factors for food waste to include cradle-to-retail upstream energy and emission factors for four of the largest food waste types in the U.S. MSW stream (bread, grain products, dairy products, and fruits and vegetables) and a weighted average for mixed food waste. This paper summarizes the methods and results for developing the factors for these food waste types suitable for inclusion within the existing scope and boundaries of WARM.

2. Methods

When a food product is source reduced, GHG emissions associated with producing and transporting the product and managing the production and post-consumer waste are avoided. Consequently, source reduction of food waste provides GHG emission benefits by: (1) avoiding the "upstream" GHGs emitted in the raw material acquisition, manufacture, and transport of the source-reduced material; and (2) avoiding the downstream GHG emissions from waste management. This paper describes the development of energy and GHG emission factors to estimate the avoided upstream GHG emitted in the raw material acquisition, manufacture, and transport of source-reduced food waste using a methodology consistent with existing WARM factors.[1]

2.1. Scope and Boundaries

Food waste types to be modeled in WARM were selected based on: (1) their usefulness and practicality to WARM users; (2) the share of total U.S. food waste the materials would individually and collectively comprise; (3) the availability of relevant, high-quality LCI data; and (4) the practicality of emission factor development. U.S. Department of Agriculture (USDA) Economic Research Service (ERS) loss-adjusted food availability data from 2010 were used to determine the food types constituting the largest share of the U.S. MSW stream (USDA 2012b). As summarized in Table 1, ICF evaluated the share of food waste generated in the United States for five food groups: grain products, fruits and vegetables, red meat, poultry, and dairy products. For each of these groups, ICF chose to model one or more food types that would cumulatively represent at least half of the waste generated for that group. This paper presents the methods for developing source reduction factors only for the basic categories of grains, fresh fruits and vegetables, and dairy. Future work will address source reduction factors for beef and chicken.

Table 1. Share of Total 2010 U.S. Food Waste Stream Represented by Materials Modeled in WARM.

Food types modeled in WARM		**Share of U.S. food waste in 2010**	**Share of weighted average food type in WARM**
Grains	Wheat	5.3%	68.3%
	Corn	1.3%	16.8%
	Rice	1.2%	14.9%
	Total	*7.8%*	*100%*
Fruits and vegetables	Potatoes	8.1%	27.5%
	Tomatoes	7.9%	27.0%
	Citrus	6.1%	21.0%
	Melons	2.7%	9.3%
	Apples	2.4%	8.2%
	Bananas	2.0%	6.9%
	Total	*29.3%*	*100%*
Red meat	Beef	5.5%	100%
Poultry	Chicken	6.5%	100%
Dairy	Fluid milk	7.3%	60.3%
	Cheese	1.2%	12.0%
	Yogurt	0.6%	5.4%
	Other dairy	1.6%	22.3%
	Total	*10.9%*	*100%*
All food materials modeled in WARM		61.4%	

Source: USDA 2012b.

The scope of the food waste source reduction energy and emission factors included in WARM is cradle-to-retail, meaning that the factors include the upstream impacts of all unit processes prior to retail storage and consumer use. The main GHG emission sources considered in the source reduction factors include: (1) the upstream production of agricultural inputs, such as fertilizer, irrigation, livestock feed, and fuel; (2) on-farm energy use; (3) on-farm non-energy emissions, including fertilizer application, manure management, and enteric fermentation; (4) some energy from food processing, depending on food type; (5) energy use and fugitive emissions from refrigeration during processing and transport of some materials; and (6) retail transportation energy. In order to

[1] Full documentation for existing WARM factors is available at http://www.epa.gov/warm.

maintain consistency with other material categories in WARM, the impacts of consumer transport and material use are not included. Furthermore, these downstream emissions are outside the scope of "source reduction" as defined by the U.S. EPA.

Several key exclusions from the scope include: (1) infrastructure and capital equipment; (2) induced land-use change; (3) production, use, and end-of-life management of packaging materials; (4) energy use, fugitive refrigerants, and food loss rates at retail locations; and (5) consumer transport, refrigeration, and energy use for cooking. In most cases, these exclusions were made to ensure consistency with existing WARM energy and GHG emission factors or because impacts were considered negligible. WARM includes energy and GHG emission factors for the production and disposal of most common food packaging materials, including corrugated cardboard, other paper types, plastic resins, and glass. Packaging material wastes and food wastes are commonly managed using different waste management pathways (e.g., recycling of paper, plastics, and glass). Therefore, this aspect of the food life cycle was excluded from the food waste energy and GHG emission factors in order to avoid redundancy between the food waste factors and existing packaging material factors available within WARM and to more-accurately capture the end-of-life impacts from management of packaging materials.

Due to data limitations, certain differences in boundaries exist between the factors for different food waste types in addressing food processing. The dairy material type includes energy and GHG emissions associated with all processing steps for the main dairy-based products consumed in the United States, include additional upstream processing to freeze or otherwise modify the flavor or texture prior to sale. The boundaries of the grains material type includes energy used for grain drying prior to product-specific processing, but exclude processing steps such as milling, packaging and cooking due to unavailability of national average grains processing data for wheat, rice, and corn. However, ICF has developed a separate source reduction factor for wheat-based bread to account for the energy and emissions associated with milling and baking. Similarly, because all of the components included in the fruits and vegetable factors can be consumed as fresh fruits and vegetables and due to the lack of data on fruit and vegetable processing, ICF has assumed that all fruits and vegetables enter the waste stream as fresh fruits and vegetables.

The material-specific food waste source reduction factors in WARM are linked to existing end-of-life factors for landfilling, combustion, and composting of general food waste to cover the full cradle-to-grave life cycle of food products. While future updates to WARM will include the development of material-specific food waste disposal factors for landfilling, combustion, and composting, the development of such factors was outside the scope of the effort described in this paper. Future updates to WARM will also include modeling the energy and GHG emissions from anaerobic digestion of food waste.

2.2. Functional Unit

The functional unit for all food waste material types is one tonne of food at end-of-life.

2.3. Data Sources and Representativeness

ICF gathered LCI data for primary and secondary inputs to production of grains, bread, fruits and vegetables, and dairy products from industry, academic, and government sources, including LCI databases. ICF assessed the scope and boundaries of each data source to identify any smaller data gaps requiring secondary data and to determine appropriate boundaries for the upstream food waste factors that are both consistent across all food waste types and consistent with existing WARM methodology. A summary of the key primary LCI data sources is provided in Table 2.

Table 2. Key Primary LCI Data Sources for Food Types Modeled in WARM

Food types modeled in WARM		Data Source
Grains	Wheat Corn Rice	USDA Undated.
Bread	Wheat	USDA Undated; Espinoza-Orias 2011
Fruits and vegetables	Potatoes	Ecoinvent Centre 2007.
	Tomatoes Citrus Melons Apples	UC Davis 2013.
	Bananas	Luske 2010.
Dairy	Fluid milk Cheese Yogurt Other dairy	Thoma et al. 2010.

In developing food waste energy and GHG emission factors for WARM, ICF sought to use data sources that were most representative of current, national average practices with a goal of representing the main components of the U.S. MSW stream. All primary data sources are based on data collected in 2001 or later, with most based on data from 2008-2012. In order to develop national average source reduction energy and emission factors, several key assumptions were made. First, ICF assumed that all of food types modeled would be produced in the United States, with the exception of bananas[2], and would be produced using conventional (i.e., non-organic) farming practices. Secondly, the differences in production impacts across different breeds, varieties, or types components of each food waste category were not considered in the analysis. For example, LCI data for the production of Fuji apples were assumed to be representative of all apple production in the United States. Likewise, LCI data for the farming of oranges was assumed to be representative of all citrus production due to lack of data for production of other citrus fruits and food consumption data showing that oranges comprise 65% of citrus fruits consumed in the United States in 2012 (Boriss 2013).

2.4. General Methodology

A similar methodology was applied for developing the energy and GHG emission factors for all food waste categories. Any differences in methodology are identified in each of the material-specific subsections below. In general, the emissions were calculated in two separate stages: first, energy-derived emissions were calculated by determining the cumulative energy demand for producing one kilogram of each food type. Secondly, non-energy emissions were estimated and added to the fossil fuel-derived emissions.

To estimate the energy-derived emissions, ICF calculated the cumulative energy demand for each dataset within SimaPro through the Ecoinvent version 2 cumulative energy demand impact assessment method provided in the software. This method calculated the total life-cycle energy in MJ required to produce one unit of food product and then separated the total into several categories, including: petroleum, nuclear power, biomass, natural gas, coal, and renewables. Each energy source's contribution to the total energy demand was then multiplied by the fuel-specific carbon coefficients used in WARM for all materials to determine the total energy-derived emissions associated with the production of one unit of food product. The caloric biomass energy embedded in the food products themselves were excluded from the analysis because they did not contribute to the energy-related emissions associated with their manufacture.

Non-energy emissions were calculated using a variety of methods, depending on the emissions source, the food type, and the LCI data available. A summary of non-energy emissions methodology is provided in each material-specific subsection below. For all food types, ICF utilized the IPCC Tier 1 method for managed soils to calculate the total amount of N_2O and CO_2 released from fertilizer application, run-off, volatilization, and leaching (IPCC 2006).

[2] Foreign-grown bananas were included within this assessment because they are one of the largest sources of fruit and vegetable waste within the U.S. waste stream. They were assumed to be produced in Central America using conventional farming practices due to the lack of suitable climate for their cultivation on a large scale within the United States.

Additional detail on the methodology for developing food waste source reduction energy and GHG emissions factors is provided as part of the WARM Version 13 documentation chapter for Food Waste, available at http://epa.gov/epawaste/conserve/tools/warm/SWMGHGreport.html.

2.5. Grains and Bread Methodology

The grains energy and GHG emission factors includes milling of wheat into flour but assumes that wheat flour, corn, and rice can be purchased as dried grains without further processing or cooking. The emission factor for grains may understate the upstream emissions associated with corn and rice products that have undergone further processing. Therefore, ICF developed the bread factors to supplement the grain factors by including the additional energy used to process wheat flour into bread, which is the predominant use for wheat flour (USDA 2012a).

ICF identified recent LCI data for the three grain products—wheat, corn, and rice—available in the USDA National Agricultural Library's LCA Digital Commons database. The Digital Commons database is intended to provide LCI data for use in life-cycle assessment (LCA) of food, biofuels, and a variety of other biological products. All datasets in the LCA Digital Commons database are specific to grain production in U.S. states. The LCI data from the Digital Commons datasets only provide material inputs, outputs and, processes in units of magnitude per unit of agricultural product produced without any estimates of the energy or GHG impacts associated with production. For example, the LCI data include estimates of the amount of fertilizers needed for grain production but do not include data on the energy needed to for fertilizer production or the direct GHG emissions from fertilizer application. In order to translate these values into the actual energy demand and emissions associated with agricultural production, ICF identified matching unit processes and corresponding LCI data for those materials and processes within the life-cycle software, SimaPro. The unit processes within the database are taken from the Swiss Ecoinvent version 2 database and the U.S. LCI Database. Several life-cycle unit processes from Ecoinvent use European electricity grid assumptions. Therefore, ICF updated the LCI data for these unit processes within SimaPro to utilize U.S. electricity grid assumptions using the updated US-EI database update for SimaPro prepared by EarthShift.

ICF identified the most representative and recent state-level datasets for winter wheat, corn, and rice within the Digital Commons database. Representativeness of state-level data in the Digital Commons database was determined through a National Agriculture Statistics Survey (NASS) commodity data search of the production levels of each grain on a state by state basis. Arkansas and Kansas datasets were chosen for rice and winter wheat production, respectively, because they were the largest producers of those grains. For corn, due to the similarly large shares of corn produced by both Iowa and Illinois, ICF created a weighted average from datasets from both states.

The Digital Commons LCI data assumes that the production of each of the three grains included in WARM leads to the production of one or more co-products. These co-products include corn silage, corn stover, wheat straw, and rice straw. The amount of each of these co-products produced per ton of grain ranges from 0.04 tonnes for corn silage to 0.58 tonnes for wheat straw. Rather than be treated as a waste, each co-product has an economic value and therefore should be allocated some percentage of the total energy and emissions required for grain production. In keeping with ISO 14044 standards, ICF first investigated avoiding allocation by expanding the system analyzed to include the impacts from co-product use and disposal (ISO 2006). However, due to the prohibitive time and data requirements for system expansion, ICF chose to allocate impacts to co-products in proportion to the economic value of the products. Using data from the USDA ERS Commodity Costs and Returns database, ICF determined the economic value per acre of production for corn, corn silage, rice, wheat, and wheat straw for each of the LCI data years (USDA 2013a). This provided sufficient data to determine economic allocation percentages for wheat and wheat straw. Supplementary data from a 2009 study by van der Voet et al. provided prices for corn stover, allowing us to estimate the allocation percentages for corn, corn silage, and corn stover. However, ICF was unable to find a reliable source for the economic value of rice straw. An anecdotal article cited rice straw's value at approximately $10 to $20 per acre, which would translate to allocation of 1 to 3% of rice production energy and emissions to rice straw (Smith 2004). Due to the lack of reliable data and the likely low economic value of rice straw, ICF allocated 100% of energy and emissions to rice grain. These allocation calculations are summarized in Table 3.

Table 3. Allocation Assumptions for Grains Co-Products

Grain	Primary Product/Co-Product(s)	Weighted Average Economic Value across LCI Data Years
Wheat	Primary product: wheat grain	96.1%
	Co-product: wheat straw	3.9%
	Total	100%
Corn	Primary product: corn grain	85.8%
	Co-product: corn silage	0.6%
	Co-product: corn stover	13.6%
	Total	100%
Rice	Primary product: rice grain	100%
	Co-product: rice straw	0%
	Total	100%

The final results for each grain were calculated by summing the energy emissions and non-energy emissions and then combining each grain into a weighted emission factor based on production in the selected states during their respective data years. From there, the three grain emission factors were combined into a final weighted emission factor based on the relative shares of each within the U.S. municipal solid waste stream. Retail transport energy and emissions were estimated with the Bureau of Transportation Statistics commodity flow survey, consistent with other materials in WARM, and are equal across the three types of grains.

Energy and GHG emissions from bread production were estimated by taking an estimate of bread production energy intensity from Espinoza-Orias et al. 2011, which contained LCI data characterizing the energy use associated with producing bread. For the purposes of this analysis, white bread was chosen as it is more common than wheat bread. The study found that wheat milling and baking, respectively, had energy demands of 0.059 kWh and 0.600 kWh per loaf of bread, which was assumed to be 0.8 kg. This equated to 2.66 MJ of cumulative energy demand to prepare one tonne of bread, of which the entirety was assumed to be taken from the national average electricity grid. To estimate the total farm-to-retail energy associated with bread, ICF summed the bread production energy emissions with those for wheat flour, but did not include corn or rice. Corn and rice were excluded from this process because the energy use data for milling and baking were based on wheat bread production and because wheat-based bread is the predominant bread category in the United States (USDA 2012a).

2.6. Fruits and Vegetables Methodology

LCI data used to develop the energy and emission factors for fresh fruits and vegetables in this memo came primarily from three sources. Data for the production of apples, melons, tomatoes, and oranges came from the University of California Cooperative Extension's (UCCE) sample cost production studies (Fake et al. 2009, O'Connell et al 2009, Stoddard et al. 2007, Wunderlich et al. 2007). These studies are intended as hypothetical guides for farmers to produce crops, and include yield projections and sample requirements for fuel, fertilizers, irrigation, and plant protection products. Data for the production of bananas was acquired from a 2010 LCA conducted by Soil and More International, on request of the Dole Food Company (Luske 2010). The banana LCA study characterizes the cradle-to-retail GHG emissions associated with banana production in Costa Rica and retail in Western Europe. In developing the source reduction energy and emission factors, ICF used supplementary data to model international shipping and retail transport to the United States. Lastly, the data for potato production was acquired from the Ecoinvent version 2 database, available within the SimaPro LCA Software.

In assessing energy and GHG emissions from production of bananas, ICF supplemented the primary data source with secondary data and applied a different methodology to maintain consistency with the other fruits and vegetables within the weighted emission factor and with the scope of WARM. First, to narrow the scope of the data to cradle-to-retail, ICF did not assess the impacts of retail storage at the destination country. Secondly, to make the dataset more relevant to bananas sold within the United States, ICF assumed an average transportation distance from Central American banana plantations to U.S. ports, acquired from a separate study on fruit transportation distances (Bernatz 2009).

Unlike the other components of the fruit and vegetable energy and emission factors, bananas are shipped internationally in specially-made, refrigerated cargo containers to prevent over-ripening prior to sale. The average transportation distance to the United States was multiplied by a separate factor for emissions per ton-kilometer of refrigerated ocean cargo transport (BSR 2012). Additionally, due to the role of refrigeration in the ocean transport of bananas, ICF incorporated Luske 2010's estimate of fugitive refrigerant emissions during processing and transport.

For this analysis, distribution of fruits and vegetables to their final point of sale was assumed to have two components: the energy and GHG emissions associated with fossil fuel combustion from vehicle operation in addition to the GHG impact of fugitive refrigerants emitted from refrigerated vehicles. The GHG emissions from vehicle operation were a product of diesel fuel combustion. Fugitive emissions of refrigerants consisted of a mix of 1,1,1,2-Tetrafluoroethane (R-134a), Chlorodifluoromethane (HCFC-22), Monochloropentafluoroethane (R-155), and 1,1-Difluoroethane (HFC-152a). Due to lack of data for fruit and vegetable-specific transportation, the fugitive emissions associated with refrigerated vehicle transport were assumed to be the same as for refrigerated dairy delivery via a medium-sized truck (Thoma et al. 2010). In the Thoma et al. 2010 study, estimates of fugitive emissions of refrigerants during the transport phase were estimated via a sales-based approach, which equated purchases of refrigerants for the truck fleet to fugitive refrigerants released via leakage.

For this analysis, distribution of fruits and vegetables to their final point of sale was assumed to have two components: the energy and GHG emissions associated with fossil fuel combustion from vehicle operation and the GHG impact of fugitive refrigerants emitted from refrigerated vehicles. The GHG emissions from vehicle operation were a product of diesel fuel combustion. Fugitive emissions of refrigerants consisted of a mix of 1,1,1,2-Tetrafluoroethane (R-134a), Chlorodifluoromethane (HCFC-22), Monochloropentafluoroethane (R-155), and 1,1-Difluoroethane (HFC-152a). Due to lack of data for fruit and vegetable-specific transportation, the fugitive emissions associated with refrigerated vehicle transport were assumed to be the same as for refrigerated dairy delivery via a medium-sized truck (Thoma et al. 2010). In the Thoma et al. 2010 study, estimates of fugitive emissions of refrigerants during the transport phase were estimated via a sales-based approach, which equated purchases of refrigerants for the truck fleet to fugitive refrigerants released via leakage. Retail transport ton-miles per shipment for all fruits and vegetables were informed by the Bureau of Transportation Statistics (BTS) 2007 Commodity Flow Survey (BTS 2010). Bananas were assumed to have land-based domestic transport in addition to refrigerated ocean transport described above.

Retail transport of perishables such as fruits and vegetables also results in losses due to spoilage and physical damage to the produce that would render it unfit for sale. Loss rates for the transport of fresh fruits and vegetables from production to retail were derived from USDA Economic Research Service (ERS) loss-adjusted food availability data (USDA 2012b). Loss rates for each fruit and vegetable in the analysis were compiled from USDA (2012b) and then re-weighted based on each product's share of the waste stream. The loss rates were specific to losses incurred strictly during the transport of fresh fruits and vegetables instead of a weighted mix of fresh and processed fruits and vegetables in order to maintain consistency with the scope and methodology of the analysis. The calculated weighted loss rate of 7.1 percent was applied to both production and transportation emissions of all fruits and vegetables in the study.

Impacts from co-products were not included in this analysis due to data limitations. For apples, oranges, melons, and tomatoes, the datasets did not include any information about co-products. However, differences between the amount of fruits and vegetables harvested in these scenarios and the final amount available for sale indicates that a portion of the production was unsalable for a variety of reasons. Due to a lack of data on the pathways for these fruits and vegetables and their assumed value, ICF determined that the impacts from any possible co-products from apples, oranges, melons, and tomatoes are outside the scope of this effort. Luske 2010 determined that approximately 10% (by mass) of the bananas produced within the scope of its assessment were unsuitable for international sale and sold to a separate distributor for a much lower price for local distribution. Relative to the price of the bananas destined for international sale, these bananas had approximately 0.3% of the value of the entire yield. Because of the low value and lack of distribution to the United States, ICF deemed that impacts from this co-product were outside of the scope of analysis. The LCI data used to develop included a co-product of potato leaves; however, in the dataset, it was allocated at 0.0% due to its low economic value. Consequently, it was not included in this analysis.

2.7. Dairy Methodology

The LCI data for dairy production used for developing the energy and emission factors in WARM are provided by the Innovation Center for U.S. Dairy, an industry group. The Innovation Center conducted its own LCA for dairy production (Thoma et al. 2010). The study followed the ISO 14040 protocols for LCA and was subject to external review. The Innovation Center's LCA's scope is larger than the scope used to develop the WARM energy and emission factors, covering the cradle-to-grave life-cycle of dairy products including retail storage, consumer use, and disposal. Therefore, ICF removed portions of the unit processes in the LCI data set that were outside the scope of the analysis, such as retail storage, consumer transport, packaging, and consumer use (e.g., cooking and consumer food loss).

The broad category of dairy foods includes a wide variety of products with differing inputs and processing stages. This made it necessary for ICF to develop weighted average energy and emission factors based on the Innovation Center's LCI data that reflect the relative contribution of different products to the total U.S. waste stream. ICF used the USDA Economic Research Service (ERS) loss-adjusted food availability data from 2010 to determine the relative shares of various dairy products within the U.S. waste stream. This dataset includes a variety of more granular product categories than the products addressed in the Innovation Center's LCI data, such as sub-categories of milks and cheeses. In order to make the USDA food loss dataset more consistent with the more general LCI data, ICF consolidated several product categories into more general categories. For example, ICF consolidated a variety of Italian-style cheeses into the Mozzarella category and categorized flavored milk (e.g., chocolate milk) and buttermilk as "generic milk".

In the Innovation Center's LCA, dairy production is linked to several other systems that produce products outside the scope of the WARM food waste source reduction factors, including feed co-products (e.g., dried distillers' grains) and beef. In the data set from the Innovation Center, impacts for most co-products are allocated economically. However, causal allocation is used for both beef based on feed nutrient content and for corn silage based on crop nitrogen requirements determined from reported yield. Causal mass balance is used for different fat-content milks during production (Thoma et al. 2010). Because the Innovation Center's data set already allocated impacts to co-products, ICF did not further modify the data to account for impacts from products outside the scope defined in this memorandum.

ICF analyzed retail transportation of dairy products as a separate unit process and assumed it applied to all dairy products equally. The Innovation Center dataset includes complete LCI data on the retail transportation process for dairy products including energy and emissions from onboard refrigeration equipment to prevent spoilage. This approach differs from the methodology used for estimating retail transport for other materials currently in WARM, which rely on average commodity retail transportation distances provided by the U.S. Census Bureau data. As for dairy production, ICF estimated the energy-derived emissions from transport by calculating the cumulative energy demand within the software. Non-energy emissions in the form of fugitive refrigerants were evaluated with the non-fossil-derived GHG emissions impact assessment method within the software.

3. Results

Using the methodology described in Section 2, ICF developed energy and GHG emissions factors for source reduction of grains, fruits and vegetables, and dairy products. The GHG emissions factors and energy factors are presented in Table 4 and Table 5, respectively, for each category. These factors are integrated into WARM Version 13, available at http://epa.gov/epawaste/conserve/tools/warm/index.html.

Table 4. GHG Emission Factors for Food Waste Categories in WARM

Category	Component	Energy emissions ($MTCO_2e$/tonne)	Non-energy emissions ($MTCO_2e$/tonne)	Total emissions ($MTCO_2e$/tonne)
Grains	Wheat flour	0.27	0.34	0.61
	Corn	0.48	0.20	0.67
	Rice	0.66	0.34	1.00
	Weighted average	0.37	0.31	0.68
Bread	Wheat bread	0.40	0.34	0.74
Fruits and vegetables	Potatoes	0.29	0.06	0.35
	Tomatoes	0.46	0.09	0.55
	Oranges	0.53	0.07	0.59
	Melons	0.32	0.06	0.37
	Apples	0.52	0.02	0.54
	Bananas	0.38	0.12	0.51
	Weighted average	0.41	0.07	0.48
Dairy	Weighted average	0.94	0.98	1.92

Note: $MTCO_2e$ = Metric tons of carbon dioxide equivalent.

Table 5. Energy Factors for Food Waste Categories in WARM

Category	Component	Process and transport energy (GJ/tonne)
Grains	Wheat flour	4.98
	Corn	8.42
	Rice	11.54
	Weighted average	6.54
Bread	Wheat bread	7.57
Fruits and vegetables	Potatoes	4.67
	Tomatoes	7.05
	Oranges	8.01
	Melons	4.75
	Apples	7.98
	Bananas	5.51
	Weighted average	5.90
Dairy	Weighted average	16.61

For grains, wheat has the smallest upstream GHG and energy footprint but constitutes the largest share of the three grains in the waste stream and therefore has the largest impact on the final emission factor. Though the total emissions from rice are significantly higher than both corn and wheat, its smaller share of the overall waste stream reduces its impact on the final weighted emission factor. The largest contributors to the emission factors for all three grains were irrigation, fertilizer production and application, and grain drying—though irrigation was a much lower contributor for wheat production than both corn and rice. The remaining unit processes contributed, on average, less than 10% of the remaining life-cycle impacts.

For bread, roughly one-third of the total energy demand comes from bread baking, leading to an increase in upstream GHG footprint relative to wheat.

For fruits and vegetables, the largest components of the total emission factor are process emissions from cultivation, including on-farm fuel use and upstream production of inputs such as fertilizer. Fertilizer application emissions did not constitute as large a share for these crops as they did for grains, likely due to lower fertilizer application rates for perennial crops. As expected, banana production had the highest life-cycle emissions of all of the fruits and vegetables assessed due to relatively higher fertilizer inputs and a substantial international transport component.

For dairy products, the largest components of the total emission factor are process emissions from dairy agriculture, including both fermentation and fertilizer. Interestingly, one of the largest contributors to energy demand is the production of feed for dairy cattle.

4. Discussion and Conclusion

The results show that the dairy products are both more energy and GHG emissions intensive than grains, bread, and fruits and vegetables. However, the grains and fruits and vegetable factors likely underestimate the GHG emissions associated with grains and fruits and vegetables due to the unavailability of national average LCI data for the processing of those food types into food products. Therefore, in future efforts, ICF will seek to estimate the additional energy and GHG emissions associated with some common processed food types, such as pasta and ketchup.

ICF is currently engaged in the development of similar factors for poultry and red meat. Future efforts will also involve the development of food type-specific end-of-life management factors for all relevant waste pathways in WARM, including composting, landfilling, combustion, and anaerobic digestion.

ICF expects that the streamlined energy and GHG emission factors for food products in WARM will have a broad appeal to parties who manage food waste with an interest in waste reduction. The factors are intended to expand the resolution of food waste modeling in WARM while keeping the tool streamlined, user-friendly, and appropriate for users without a technical background in LCA. EPA expects to apply these factors in a number of existing and future tools and programs. For example, the WARM factors are expected to be used as part of EPA's Food Recovery Challenge, a voluntary program for commercial, governmental, and non-commercial organizations. Food Recovery Challenge participants will use the source reduction factors to estimate the GHG emissions savings from food waste reduction efforts over the past calendar year.

ABSTRACT

It is well-known that the feeding of students is related to their health and well-being, contributing to a reduction in the risk of chronic diseases in adulthood. However, students' parents also take the cost of school lunches into account. In addition, we should not forget that the food sector contributes to 15-30% of the total greenhouse gas emissions and, as such, food choices can have a notable influence on climate change. Although these three aspects, health, environment and cost, need to be borne in mind in order to build sustainable lunches, they are not necessarily convergent. In this context, this study aims to develop a model with which building a sustainable school diet while taking nutritional, environmental and economic aspects into account. Interval goal programming can be very useful as a means of addressing this problem. By establishing two goals, an economic one and a carbon footprint (CFP) one, positive deviations can be minimized while keeping the recommended daily intake (RDI) fractions (macronutrients and micronutrients) and energy in the expected range.

Keywords: goal programming, nutrition, carbon footprint, sustainability, school lunch

1. Introduction

It is well-known that the feeding of students is related to their health and well-being, contributing to a reduction in the risk of chronic diseases in adulthood. However, students' parents also take the cost of school lunches into account. In addition, we should not forget that the food sector contributes to 15-30% of the total greenhouse gas emissions and, as such, food choices can have a notable influence on climate change. These three aspects, health, climate change and cost, need to be borne in mind in order to build sustainable lunches. The FAO definition of a sustainable diet reads "those diets with low environmental impacts which contribute to food and nutrition security and to healthy life for present and future generations. Sustainable diets are protective and respectful of biodiversity and ecosystems, culturally acceptable, accessible, economically fair and affordable; nutritionally adequate, safe and healthy; while optimizing natural and human resources" (FAO, 2010). However, these aspects are not necessarily convergent. In this context, this study aims to develop a model with which to build a school diet taking nutritional, climate change and economic aspects into account. The contribution of food to global warming has been assessed via carbon footprinting, a method for the quantification of greenhouse gas emissions emitted throughout the life cycle of a product (BSI, 2011). Although the carbon footprint (CFP) represents only one part of the environmental impacts of food products, the relationship between food consumption patterns and climate change is a subject of great concern (Carlsson-Kanyama and González, 2009). In spite of the limitations of assessing only one impact, CFP presents several advantages that have made it a commonly used indicator for the eco-labeling of food products. These advantages include a connection to global warming, which is internationally acknowledged as an important environmental concern. Furthermore, a major advantage is the reduced complexity when computing and interpreting the results (Weidema et al., 2008; Heller et al., 2013), which is related to the global character of climate change. Other impact categories, such as land use and toxicity, also relevant in food life cycles, are associated with regional impacts, making data sets less applicable depending on the region and adding uncertainty to the calculations.

Interval goal programming can be very useful as a means of designing diets which take the nutritional, climate change and economic aspects into account. By establishing two goals, an economic one and a CFP one, positive deviations can be minimized while keeping the recommended daily intake (RDI) fractions (macronutrients and micronutrients) and energy content in the expected range.

A case study is used to test the proposed model. From 20 starters, 20 main courses and 4 desserts, combinations were made to obtain 1,600 lunch menus. The criteria established for the composition of the menus tried to ensure the nutritional quality and familiarity of the foods and CFP data availability. The objective of the model is to design a lunch for an elementary school student for four school weeks, bearing in mind not only global warming, but also nutritional and economic aspects. An optimizing technique, specifically Goal Programming (GP), is used to choose those menus that fulfill the requirements. In the context of decision making, to optimize means to find the decision which gives the best possible value of some measures from amongst the set of possible decisions (Jones and Tamiz, 2010). Other optimization techniques, such as Linear Programming, have been previously used to assess whether a reduction in greenhouse gas emissions can be achieved while meeting dietary health requirements (Macdiarmid, 2012).

2. Methods

In order to make decisions which take several, non-convergent criteria into account implies the application of a weighting method, namely Multicriteria Decision Making Methods (MCDM). There is a wide range of MCDM, but in order to design sustainable menus we do need a flexible method that enables different kinds of goals to be integrated; i.e. to minimize cost and CFP levels, to ensure that the energy content is between a minimum and maximum and also to make sure that the kilocalories shared out among the macronutrients are set in the right intervals (50-55% carbohydrates, 12-15% proteins and 30-35% fat). Simultaneously, some micronutrients should be encouraged (vitamin A, vitamin C, vitamin D, calcium, iron, magnesium, …) while others should be limited (sodium, saturated fat,…) (Drewnowski, 2009). Moreover, the importance of each criterion can be different: e.g. we want to be sure that the amount of calcium is above 1000 mg for a 2,000-kcal diet on a daily basis (strong condition) and we would like the carbon footprint to be around a certain level (weak condition). Goal programming allows all these conditions to be addressed when designing diets.

2.1. Case study

A case study is used to test the proposed model. From 20 starters, 20 main courses and 4 desserts (Table 1), combinations were made to obtain up to 1,600 lunch menus that were assessed. The criteria for choosing the dishes tried to ensure the nutritional quality and familiarity of foods and the availability of CFP information.

The CFP of each dish was assessed based on literature about life cycle assessment and CFP studies into food products (around 50 literature sources). The PAS 2050:2011 guidelines (BSI, 2011) were used to analyze all CFP data sources in terms of their system boundaries, completeness and appropriateness. Where no data was available, the impact of packaging was assumed to be negligible (Jungbluth et al., 2000). Since some literature sources consider only primary production, when energy from the processing step was missing, adaptations were made following Sanjuan et al. (2014). The same procedure applied to the use phase, which was either part of the literature source or was included by using data from Carlsson-Kanyama and Faist (2000). The transport processes were either included in the literature sources or added manually, taking into account both the distance from the food origin to the consumption point (Valencia, Spain) and also the means of transport from Ecoinvent v 2.0. As regards transportation, the distance from the retailer to the consumer was not taken into account according to PAS 2050:2011. Cooling during transportation was added if not previously included. The operation of premises and the storage of products could not be included manually due to lack of data. However, where it was included in the literature, it was taken into account.

The cost was calculated from the market prices of the raw foods. The source for food prices was the web page of the three biggest supermarket chains in Spain. Only the price of raw materials has been taken into account, neither labor costs nor other direct costs have been computed. Additionally, the caloric content together with the macronutrient (protein, fat and carbohydrate) and micronutrient content (namely fibre, calcium, iron, potassium, magnesium, vitamin A, vitamin C, vitamin D, cholesterol and sodium) of each food were obtained from databases (USDA, 2011; software dietowin® 7.3).

In order to fix the threshold values of nutrients to be used as restrictions in the program, the reference daily values were obtained from the literature (Cuervo et al., 2009; Drewnowski, 2012; FAO, 2012). Fibre, calcium, iron, potassium, magnesium, vitamin A, vitamin C, vitamin D are considered as nutrients to be encouraged, while it was considered that two nutrients should be limited, specifically cholesterol and sodium. Table 2 shows the bounds used as a minimum, a maximum or as an interval.

Table 1. Dishes from which the daily menus were built

	Dish	CFP kg CO2-eq	PRICE €	CALORIES kcal	PROTEIN kcal	FAT kcal	CH kcal	Fibre g	Calcium mg

Table 2. Threshold values of the nutrients (expressed on daily lunch basis)

Nutrient	Minimum or lower bound	Maximum or upper bound
Caloric content (kcal)	600	800
% fat calories	30	35
% protein calories	12	15
% carbohydrate calories	50	55
Fibre (g)	7.5 g	
Calcium (mg)	240	
Iron (mg)	2.70	
Potassium (mg)	600	
Magnesium (mg)	75	
Vitamin A(μg)	120	
Vitamin C (mg)	16.50	
Vitamin E (mg)	2.40	
Cholesterol (mg)		116
Sodium (mg)		720

2.2. Goal program

Each goal program needs an objective function to optimize, which usually consists of minimizing the unwanted deviations of some goals. In our case study, these deviational variables come from the nutrient content, CFP and price constraints. Negative deviations are set from the nutrients to be encouraged and positive deviations from those to be limited. Caloric content and macronutrient content make up interval goals (lower bound-upper bound) and, therefore, negative deviations have to be minimized from the lower bounds and positive deviations from the upper ones.

The objective function is made up of four main addends, the first one includes positive deviations from the CFP and price goals, the second one includes the daily negative deviations from the lower bound of caloric content (600 kcal) and the daily positive deviations from the upper bound of caloric content (800 kcal). The third addend is referred to the macronutrient composition as the share of the energy content and includes a negative deviation from the lower bound and a positive deviation from the upper bound for each macronutrient and day. Other nutrients to be encouraged and limited build the fourth addend, specifically negative deviations from the lower bound of the nutrients to be encouraged and positive deviations from the upper bound of the nutrients to be limited.

A weight of 25% has been applied to each addend that represents the relative importance of the addend to the decision maker. At the same time, each deviational variable has been divided by a normalization factor that scales the deviations so they can be compared in the same units. The normalization factor is taken from the bound of the respective aspect (CFP, price, nutrients…). Since providing nutrients is the main function of food, 75% of the weight has been allocated to nutrient-related variables and the remaining 25% jointly to the price and CFP.

The decision variables are: (20 starters +20 main dishes + 4 desserts) x 20 days = 880 variables

Xs_{ij}: variable of starter *j* on day *i*

Xs_{ij}: variable of main dish *j* on day *i*

Xd_{ij}: variables of dessert *j* on day *i*

All of them are binary variables; they only can take the values 0 or 1. For example, if Xsij=1, it means that starter j is part of the lunch on day i, otherwise starter j is not part of the lunch on day i.

There are 6 groups of constraints in the goal program:

- Budget constraint: 1 constraint for the whole planning period
- CFP constraint: 1 constraint for the whole planning period
- Energy content constraints: (20 days x 2 levels [lower and upper]) = 40 constraints
- Macronutrient constraints: (20 days x 2 levels x 3 macronutrients) = 120 constraints
- Nutrients-to-encourage constraints: (20 days x 8 nutrients) = 160 constraints
- Nutrients-to-limit constraints: (20 days x 2 nutrients) = 40 constraints

There are also some other constraints related to the composition of the menus: the starter and the main dish can not be repeated more than twice in the planning period and the desserts can not be repeated more than five times. Since weights are included in the objective function and some constraints are defined as intervals, the program to be built is a mixture between weighted goal programming and interval goal programming.

Bearing all these features in mind, the goal program can be written this way, *i* being: number of day (1 to 20); *j:* number of dish (1 to 20 for starters and main dish, 1 to 4 for desserts); and *k:* number of nutrient (1 to 8 for nutrients to be encouraged and 1 to 2 for nutrients to be limited).

$$MIN\left[p_{budget} / RHS_{budget} + p_{CFP} / RHS_{CFP}\right]\cdot w_1 + \left[\sum_i^{20}\left(n\_cal_i^L / RHS_{cal}^U + p\_cal_i^U / RHS_{cal}^U\right)\right]\cdot w_2 +$$

$$+\left[\sum_i^{20}\begin{pmatrix} n\_fat_i^L / RHS_{fat}^L + n\_prot_i^L / RHS_{prot}^L + n\_CH_i^L / RHS_{CH}^L + p\_fat_i^U / RHS_{fat}^U + \\ + p\_prot_i^U / RHS_{prot}^U + p\_CH_i^U / RHS_{CH}^U \end{pmatrix}\right]\cdot w_3$$

$$+\left[\sum_i^{20}\begin{pmatrix} n\_water_i + n\_fiber_i + n\_calcium_i + n\_iron_i + n\_pota_i + n\_magne_i + n\_vitA_i + \\ + n\_vitC_i + n\_vitE_i + p\_cholest_i + p\_sodium_i \end{pmatrix}\right]\cdot w_4$$

$s.t.$

Budget constraint :

$$\sum_i^{20}\left[\sum_j^{20} Xs_{ij}\cdot price\_s_j + Xm\cdot price\_m_j + \sum_j^{4} Xd_{ij}\cdot price\_d_j\right] - p_{budget} + n_{budget} = RHS_{budget}$$

CFP constraint :

$$\sum_i^{20}\left[\sum_j^{20} Xs_{ij}\cdot CFP\_s_j + Xm\cdot CFP\_m_j + \sum_j^{4} Xd_{ij}\cdot CFP\_d_j\right] - p + n = RHS_{CFP}$$

Caloric content constraints :

$$\sum_j^{20} Xs_{ij}\cdot cal\_s_j + Xm_{ij}\cdot cal\_m_j + \sum_j^{4} Xd_{ij}\cdot cal\_d_j - p_{cal\_i}^L + n_{cal\_i}^L = 600 \ \forall i = 1..20 days$$

$$\sum_j^{20} Xs_{ij}\cdot cal\_s_j + Xm_{ij}\cdot cal\_m_j + \sum_j^{4} Xd_{ij}\cdot cal\_d_j - p_{cal\_i}^U + n_{cal\_i}^U = 800 \ \forall i = 1..20 days$$

Macronutrient constraints :

$$\left(\sum_j^{20} Xs_{ij}\cdot prot\_s_j + Xm_{ij}\cdot prot\_m_j + \sum_j^{4} Xd_{ij}\cdot prot\_d_j - p_{CH\_i}^L + n_{CH\_i}^L\right)/600 = 0.12 \qquad \forall i = 1..20 days$$

$$\left(\sum_j^{20} Xs_{ij}\cdot prot\_s_j + Xm_{ij}\cdot prot\_m_j + \sum_j^{4} Xd_{ij}\cdot prot\_d_j - p_{CH\_i}^U + n_{CH\_i}^U\right)/800 = 0.15 \qquad \forall i = 1..20 days$$

$$\left(\sum_j^{20} Xs_{ij}\cdot fat\_s_j + Xm_{ij}\cdot fat\_m_j + \sum_j^{4} Xd_{ij}\cdot fat\_d_j - p_{fat\_i}^L + n_{fat\_i}^L\right)/600 = 0.30 \ \forall i = 1..20 days$$

$$\left(\sum_j^{20} Xs_{ij}\cdot fat\_s_j + Xm_{ij}\cdot fat\_m_j + \sum_j^{4} Xd_{ij}\cdot fat\_d_j - p_{fat\_i}^U + n_{fat\_i}^U\right)/800 = 0.35 \ \forall i = 1..20 days$$

$$\left(\sum_j^{20} Xs_{ij}\cdot CH\_s_j + Xm_{ij}\cdot CH\_m_j + \sum_j^{4} Xd_{ij}\cdot CH\_d_j - p_{CH\_i}^L + n_{CH\_i}^L\right)/600 = 0.50 \qquad \forall i = 1..20 days$$

$$\left(\sum_j^{20} Xs_{ij}\cdot CH\_s_j + Xm_{ij}\cdot CH\_m_j + \sum_j^{4} Xd_{ij}\cdot CH\_d_j - p_{CH\_i}^U + n_{CH\_i}^U\right)/800 = 0.55 \qquad \forall i = 1..20 days$$

Nutrients-to-encourage constraints:

$$\left(\sum_{j}^{20} Xs_{ij} \cdot encou_{k}\_s_j + Xm_{ij} \cdot encou_{k}\_m_j + \sum_{j}^{4} Xd_{ij} \cdot encou_{k}\_d_j - p^{U}_{CH\_i} + n^{U}_{CH\_i}\right) \leq RHS_{encour\_i} \qquad \forall i = 1..20 days$$

$\forall k =$ fiber, calcium, iron, potasium, magnessium, vitA, vitC, vitE

Nutrients-to-limit constraints:

$$\left(\sum_{j}^{20} Xs_{ij} \cdot \mathrm{limit}_{k}\_s_j + Xm_{ij} \cdot \mathrm{limit}_{k}\_m_j + \sum_{j}^{4} Xd_{ij} \cdot \mathrm{limit}_{k}\_d_j - p^{U}_{CH\_i} + n^{U}_{CH\_i}\right) = RHS_{\mathrm{lim}it\_i} \qquad \forall i = 1..20 days$$

$\forall k =$ cholesterol, sodium

Decision variables constraints:

$$\sum_{i}^{20} \mathrm{Xs}_{\mathrm{ij}} \leq 2 \qquad \forall j = 1..20 \text{ starters}$$

$$\sum_{i}^{20} \mathrm{Xm}_{\mathrm{ij}} \leq 2 \qquad \forall j = 1..20 \text{ main dishes}$$

$$\sum_{i}^{20} \mathrm{Xd}_{\mathrm{ij}} \leq 5 \qquad \forall j = 1..4 \text{ desserts}$$

$$\sum_{i}^{20}\sum_{j}^{20} Xs_{ij} \geq 20 \qquad \sum_{i}^{20}\sum_{j}^{20} Xm_{ij} \geq 20 \qquad \sum_{i}^{20}\sum_{j}^{20} Xd_{ij} \geq 20$$

In order to set the goals for the price and the CFP for the planning period, the total price of the average menu for 20 days (20-day budget: 74.01 €) and the CFP (48.99 kg CO2 eq) have been calculated. The average menu for 20 days comes from table 1 by repeating the four desserts five times, each row representing the lunch for one day. To carry out further analysis, the percentile values of CFP and the price of the 1,600 combination menus have also been calculated. The program has been written in Lingo modeling language and solved by means of the LINGO software (ver.6.0).

3. Results and discussion

After running the program, the CFP for the planning period equals 36.96 kg CO_2 eq (-25% of the CFP goal) while the price equals 48.90 € (-34% of the price goal). The energy content, fat content, nutrients to be encouraged and nutrients to be limited exhibit zero deviation but the percentage of protein and carbohydrates are beyond the range. The solutions of the program (starter, S, main dish, M, and dessert, D) for each day show that some dishes are not part of the solution while others appear twice in the planning period. For example, the main dish of tuna (M11) is not included in the planning because of its high contribution to the CFP, while the main dish of horse mackerel (M03) is not included because of its price.

Figure 1 has been built for the purposes of comparing the optimal menu of the goal program with the average menu and the 1,600 combination menus. By considering the 1,600 combination menus and extending each menu over the 20-day period, the CFP has been calculated and plotted for 20 days as has the 20-day budget for each menu (single menu x 20). The CFP and budget of the average 20-day menu has also been plotted. Figure 1 clearly shows how the 20-day menu obtained by means of the goal program outperforms the average menu in both economic and CFP terms.

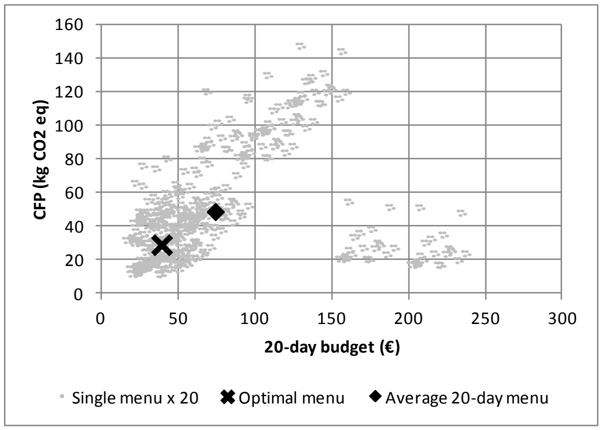

Figure 1. Comparison between optimal menu, 1,600 menus and average 20-day menu for a 20-day period

From the nutritional point of view, the energy content of both the average 20-day menu and the optimal menu is located in the recommended interval. The energy content distribution among macronutrients is unbalanced in both the average 20-day menu and the optimal menu, although the optimal menu is closer to the recommendations (Table 3). As far as the nutrients to be encouraged are concerned, both menus comply with the reference values. In the case of nutrients to be limited, whereas the cholesterol and sodium levels are exceeded in the average menu, the optimal menu meets both goals (Table 4).

Table 3. Energy content of macronutrients

% Kcal	Protein	Fat	Carbohydrate
Lower reference value	12%	30%	50%
Upper reference value	15%	35%	55%
Average menu	25%	35%	40%
Optimal menu	30%	40%	29%

Table 4. Relative deviation of nutrients

Nutrients	Average menu	Optimal menu
Nutrients to be encouraged		
FIBRE	+39%	+26%
CALCIUM	+46%	+15%
IRON	+128%	+61%
POTASSIUM	+188%	+121%
MAGNESIUM	+107%	+53%
VIT C	+296%	+218%
VIT A	+567%	+433%
VIT E	+46%	+9%
Nutrients to be limited		
CHOLESTEROL	+25%	-10%
SODIUM	+4%	-9%

The goal program can be tweaked in order to analyze specific questions. The influence of the budget on the CFP can be tested by taking economic and CFP deviations out of the objective function and forcing the budget to be below specific values: 20th budget percentile, 30th budget percentile... This way the program has been solved for each budget percentile. Figure 2 shows the evolution of the CFP according to the limitations in the lunch budget. As can be observed, a small budget does not lead to a higher CFP, quite the contrary, lower budgets show a lower CFP and, from the 60th percentile, the CFP first drops and then remains steady. From the nutritional point of view, lower budgets exhibit a similar level of deviation from the nutritional goals to the higher budgets.

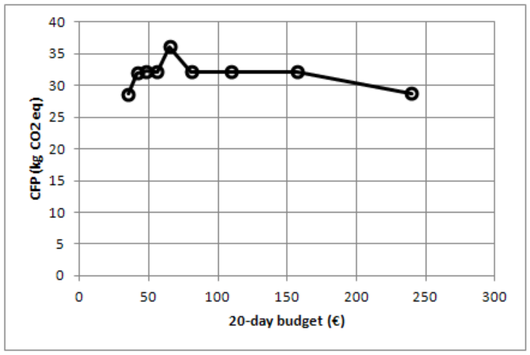

Figure 2. CFP as a function of limited budget

The use of binary variables implies an integer linear program whose solver algorithms are not as efficient as the simplex algorithm used in linear programming, which means that the solving takes longer. Nevertheless, the process can be speeded up dramatically by adjusting some of the parameters of the solver algorithms and solving by first taking only a part of the decision variables as an integer and keeping them as a starting point for a second solving.

This study demonstrates an approach to the design of sustainable diets for schools. Sustainability is a broad, complex and controversial concept. While the FAO (2010) definition of sustainable diets is clear and comprehensive, it does not provide the way to attain that goal. As Garnett (2014) states, the FAO definition suggests that these multiple dimensions are synergistic, when inevitably there will be tradeoffs. Another issue of the definition of sustainable diets is the lack of consistency; stakeholders can choose different parameters to measure each dimension and can assign weights to these dimensions differently. In the present study, only the CFP is used as a means of measuring the environmental performance. The inclusion of more environmental impact categories would have led to a different environmental result. On the other hand, social and ethical aspects, such as labor conditions, the farmer’s livelihood or animal welfare, have not been taken into account. From the economic point of view, the model focuses on the consumer (affordability) and leaves out the producer (economic fairness). It must be pointed out that goal programming models allow more environmental, economic or social aspects to be included.

4. Conclusion

Goal programming constitutes a suitable tool for designing economically, environmentally and nutritionally sustainable diets. Its flexibility enables specific issues to be studied, such as how economic restrictions are linked to CFP, or other environmental impacts. Specific and very realistic constraints can be included; for example, weak restrictions can be considered on a daily basis, e.g. the sodium content might be around 720 mg, while, at the same time, taking into account strong restrictions over the whole planning period e.g. the sodium content has to be lower than 14,400 mg (720 mg x 20 days). Moreover, weak restrictions are more suitable for taking the micronutrient content into account, since the nutritional recommendations vary depending on the source. New constraints, such as including nutritional requirements for a specific population (e.g. allergy sufferers, people suffering from coeliac disease or religious groups) can also be added to the goal program. In the same way, other nutritional recommendations could be incorporated into the program, such as the quantity of monounsaturated fatty acids, saturated fat, monounsaturated fat, zinc or folate.

The case study shows how an optimal design of the school lunch menus makes it possible to reduce the carbon footprint at affordable prices. It also shows that lower food budgets are neither linked to a higher carbon footprint nor to a worse nutritional performance. Comparing the 20-day optimal menu, designed by means of the goal program, with the 20-day average menu, the former not only reduces the CFP by 25% and the food budget by 34%, but also improves the balance among macronutrients, meets the requirements in terms of the nutrients to encourage and is below the threshold level in the case of the nutrients to limit.

The lack of precision in the definition of a sustainable diet makes the task of designing them difficult, and also hampers the measurement of diet sustainability.

ABSTRACT

Life-Cycle Assessment (LCA) was utilized to compare the potential for climate change, acidification and human toxicity associated with the production of boneless beef sold to the consumer through two chains of production in Veracruz, Mexico. An intensive method based on feedlot finishing and highly technified transformation and marketing procedures was analyzed and compared to an extensive livestock-farming model up to the finishing period and adopting low technology transformation and marketing procedures. The potential impacts on every category studied were greater in the intensive chain. More methane from enteric fermentation was generated in the extensive chain due to lower quality feed compared to feedlot finishing, however the latter is associated with greater impact within the intensive chain because of production and processing of the feed raw material.

Keywords: LCA, beef , climate change, supply chain, environmental.

1. Introduction

Beef production worldwide has increased more than threefold between 1970 and 2009 (FAO 2012). The beef production supply chain has a significant impact on the environment, at every level of production (Steinfeld et al., 2006) such as the degradation of natural resources as a result of cattle feeding, land use in primary production, fossil fuel consumption, water usage and greenhouse gas emissions.

Life-Cycle Assessment has been applied in different world locations to identify the beef production environmental impact and define key points for its environmental sustainability improvement (de Boer et al., 2010). A Life-Cycle perspective provides also a useful framework to study the links between social needs, natural and economic processes related to food production, and their environmental consequences (Heller and Keoleian, 2003). In Mexico a full study to calculate the impact of the beef production chain on the environment has yet to be carried out. Therefore in this paper we used the Life-Cycle Assessment approach to evaluate two beef production chains in the state of Veracruz, Mexico. A production system involving animal growing on pasture and successively fattened in feedlots where modern technologies are adopted in the transformation and commercialization stages is analyzed, has been compared to another production system based on livestock exclusively bred in pastures and adopting low-level technologies in the transformation and commercialization stages. The objective of this study was to quantify and compare the two systems environmental impact related to both the beef production and the other stages in their supply chains and to identify windows of opportunity for improvement in their sustainability.

2. Methods

The Life-Cycle Assessment (LCA) was carried out according to the ISO 14040 standard. The aim was to compare potentials for climate change, acidification, and human toxicity associated with the two beef production chains above described, characteristic of the North-Central region of the state of Veracruz, Mexico. They will be named *intensive production chain* and *extensive production chain*.

2.1. Goal and Scope Definition

2.1.1. System boundary

The LCA covered the stages from the production of fodder and grain used as cattle feed up to the final consumer. This included manure-handling impact, manure use as farmland fertilizer, transport between the different production stages including transport to the consumer's home, the use of fertilizers, energy, organic residue disposal and packaging material in the transformation and commercialization procedures.

2.1.2. Functional Unit

The functional unit in this LCA is 1 kg of boneless, skinless beef without fat, produced in Veracruz for processing and consumption.

2.1.3. System Description

The study scenarios were put together based on literature review, national and state-level statistics and data collected from producers, beef association representatives, researchers, academics and extension specialists. The production chains studied are made up of five process units: growth and development (G & D), pre-fattening (PrF), fattening (Fat), transformation (Tr), marketing (Market). In the intensive chain G & D and pre-fattening livestock are kept on pasture, fattening is carried out in feedlot, transformation in highly technified slaughterhouses and marketing in supermarkets. In the extensive chain G & D, pre-fattening and fattening are on pasture, transformation takes place in slaughterhouses of low technology and finally, marketing is done by local butchers. The life-cycle inventory is based on average data from 2011 to 2013 for each life cycle, all-representative of Mexico. The production processes of each supply chain, and related parameters are described below:

2.1.4. Growth and Development

The growth and development process is the same in both production chains. Cattle are a mix of Brown Swiss-Zebu and Holstein-Zebu in different proportions. Feed is pasture based with a supplement of 14% raw protein. The model adopted is representative of the North-Central region of Veracruz and consists of 72 production cows, 20 calves and 2 bulls. Fertility in the reproductive cattle is 58.5% and mortality rate is 2%. Calves at birth weight 37 kg and are weaned at 167 days, after that they are pasture fed with a supplement of 14% raw protein feed. 93 hectares of prairie are used, and fertilized with ammonium sulphate (150 kg/ha/year). 44 calves weighing 225 kg and 12 months of age are sold annually. Cattle are transported 10 km to the pre-fattening sites.

2.1.5. Pre-fattening

In the intensive chain, livestock enter the pre-fattening stage weighing 225 kg. They are fed on pasture and 76 days before they are sold they are also given 1 kg/head of raw protein supplement at 15 %. This stage lasts 190 days. Per year 270 head are sold for fattening, each weighing 336 kg. The livestock is transported 10 km.

In the extensive chain pre-fattening takes place on pasture with no supplements. Cattle are received weighing 225 kg and spend 243 days until they weigh 348 kg. The area used measures 240 ha. Per year 362 head go on to fattening. Pre-fattening and fattening are carried out in the same place therefore no transport is necessary in these stages.

2.1.6. Fattening

In the intensive chain fattening is carried out in pens. Animals start this stage weighing 333 kg. Feed is composed of maize, sorghum, and soybean meal. Distiller dried grains (DDG), bran, poultry manure, mineral premix and molasses. This stage lasts 107 days with cattle weighing 514 kg. Per year 5,880 head are processed in highly technified slaughterhouses 138 km away from fattening enclosures.

On the other hand the fattening stage in the extensive chain takes place on pasture supplemented by a ration of 2 kg/head of 15% raw protein for the last 120 days. The stage lasts 213 days. Cattle at the end weigh 455 kg and are processed in low technology slaughterhouses 80 km away.

2.1.7. Transformation

Beef are slaughtered in modern and highly technological plants at 508 kg, a carcass yield of 59% is obtained. Organic residues, bone and tallow are turned into meal in a rendering plant and the manure is supplied to local farms. Residual water from the slaughterhouse is processed in a water-treatment plant. Carcasses are sectioned and deboned and vacuum-packed in polypropylene bags and placed in cardboard boxes. 12.1 tons of meat per year is transported to supermarkets distant on average 350 km.

In low technology slaughterhouses (extensive chain) livestock is processed at 450 kg. The carcass yield is 52%. Manure, blood, hooves and horns are thrown away into municipal dumps. Residual water is flushed into the local drainage system and bones and tallow are sold to a rendering plant. Fresh carcasses are taken to local butchers distant on average 7 km. 753,064 kg of carcasses are sold at the butchers' every year.

2.1.8. Marketing

Supermarkets receive a total of 278,351 kg of cut, packed meat. This is carved into beef cuts and sold to the final consumer. The packing consists of a polystyrene tray, a layer of PVC and a coated paper label. Supermarkets sell 24,818.3 kg of organic residue, which they sell to a rendering plant 15 km away. Meat is exhibited in refrigerated showcases. The power consumed in conservation, exhibition and cutting procedures was measured. Power used for lighting the sales-floor was not. Consumers cover 2.3 km (presumably in their own vehicle) to buy meat.

On the other hand, local butchers receive half carcasses, which they keep in cold storage and exhibit in refrigerated showcases. Loss through cut and deboning is 45%. Meat is sold in biodegradable poly-paper bags. 5,698 kg of organic residue is generated every year and sold to a rendering plant. The market is a local one and consumers walk to the butcher shops or take public transport.

2.1.9. Estimation of Greenhouse Gas Emissions

In the growth and development, pre-fattening and fattening stages on pasture no housing is necessary; therefore all manure is assumed to end up directly on the ground. The manure produced by livestock in the fattening process in pens is collected and spread on farmland belonging to pre-fattening farms, part of the intensive chain, 15 km away. The nitrogen excretion was estimated in order to calculate amounts of direct nitrous oxide, ammonia and nitric oxide emissions from the manure as well as indirect emissions of nitrous oxide through volatization and lixiviation, IPCC (2006).

2.1.10. Evaluation of Impact in LCA

Impact evaluation in LCA involved calculating the contributions of materials and fuels and the output at inventory phase in each of the environmental impact categories. The aforementioned categories are: climate change, acidification and human toxicity, all considered relevant in evaluating the environmental behaviors of obtaining animal products in a production chain. Impact evaluation was estimated using the CML 2000 method (Guinée et al., 2002), and SimaPro 7.3 LCA software from Pré Consultants. Greenhouse gas emissions, expressed in CO_2-eq units were quantified using the IPCC (2006) method and considering a temporal horizon of 100 years. Acidifying emissions are expressed in SO_2-eq and human toxicity in 1,4-DB-eq.

3. Results and Discussion

3.1. Evaluation of Life-Cycle Impact Results

In the intensive chain and in order of magnitude, the G & D herd used up more resources and produced more emissions in the categories of climate change impact and human toxicity. Pre-fattening demonstrated more acidification emissions in this chain. In extensive production the G & D stage is the greatest contributor to the impact categories. In both production chains enteric methane is the main contributor to climate change, followed by a substantial contribution from nitrous oxide obtained from manure biodegradation. In both chains, the fattening process is the one that least contributes to acidification and to climate change. This data coincides with reports from Pelletier et al. (2010), who compared three cattle production scenarios from G & D to finalization and observed the fattening process as the one, which impacts the least. In both chains, terms of acidification during the fattening stage showed the lowest levels. Pre-fattening shows the lowest impact for human toxicity in both production chains. In the intensive production chain, fattening is second to G & D for human toxicity emissions. In the extensive production chain G & D comes first and commercialization second in terms of human toxicity emissions (Figure 1).

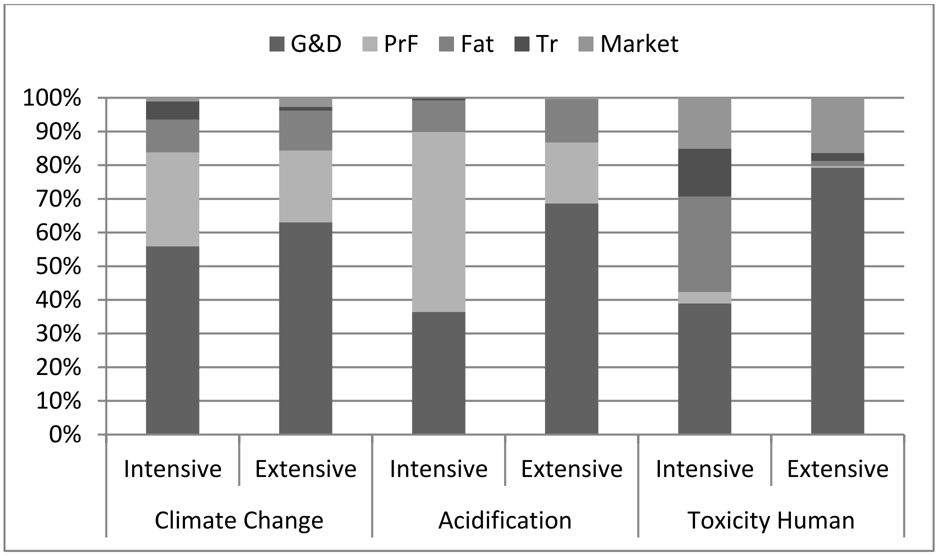

Figure 1. Total impact values shown in individual procedures by production chain.

3.2. Climate Change

Our results suggest that 1 kg of meat from Veracruz, Mexico produced in a chain based on intensive finishing systems and adopting modern technologies in the transformation and marketing stages has the potential to produce higher greenhouse gas emissions (17.80 kg CO_2-eq) than 1 kg of meat from an extensive beef production chain, including more traditional technologies in the transformation and marketing procedures. The main emissions are shown in Figure 2 where methane is the main contributor to climate change, with extensive productions emitting more methane (10.0 kg CO_2-eq) contributing to 63.3% of the total GHG when compared to the extensive chain (9.0 kg CO_2-eq) contributing to 50.7% of the total GHG. This result is consistent with another research showing that a higher quality diet for ruminants produces lower methane levels and increases the growth rate of livestock, therefore reducing methane emissions in the meat production life-cycle (Cederberg et al., 2009; Pelletier et al., 2010; Peters et al., 2010). Likewise, the higher levels of nitrous oxide in the intensive production chain are associated with manure management and production and processing of feed components in drylot-fed livestock.

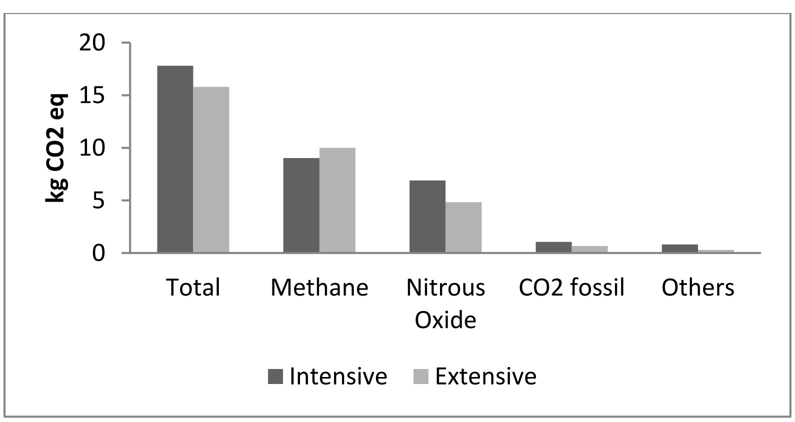

Figure 2. Comparison of greenhouse gas emissions by production chain.

3.3. Acidification

The potential for acidification in the intensive production chain was estimated to be greater than the extensive one (0.24 vs 0.13 kg SO_2-eq). This is directly related to the amount of ammonia produced when manure is accumulated in the confinement corral and then distributed over farmland; this result in greater ammonia volatilization as opposed to livestock on pasture (see Figure 3). The values obtained are consistent with those found by Roer et al. (2013) who used LCA to examine 1 kg of meat off the carcass from double purpose livestock. The higher emission of sulphur dioxide in the intensive production chain is a result of production and processing methods in the making of the feed during the feedlot stage. However, processing and marketing provide a smaller contribution compared to the production stages. This is in agreement with Meneses et al. (2012) who compared the milk production stage to the transport and packing.

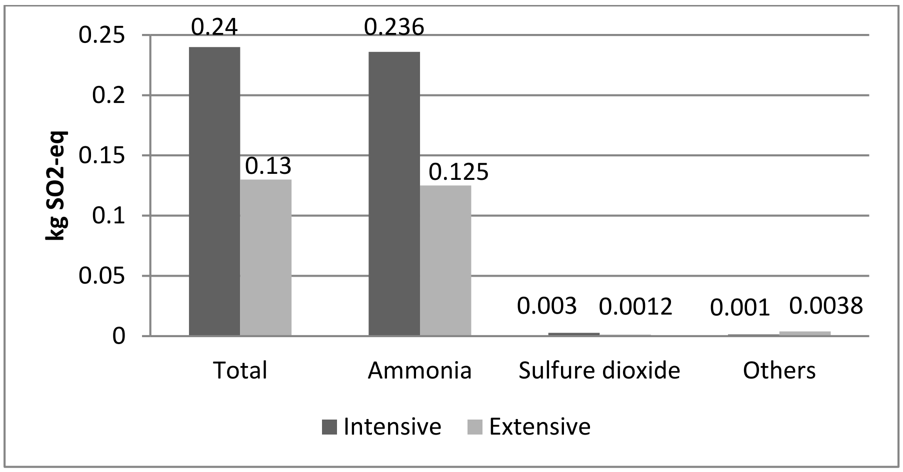

Figure 3. Contributing emissions to the acidification impact category by production chain.

3.4. Human Toxicity

Once again the intensive production chain shows higher potential for impact on human toxicity. In the case of the total potential emissions in both chains, polycyclic aromatic hydrocarbons show the highest potential emissions, 22.3% (0.13 kg 1,4-DBeq) in the intensive chain and 22.1% (0.06 kg 1,4-DBeq) in the extensive chain, as seen in Figure 4 due to the use of grain in drylot feed and food supplements during pre-fattening. This feed requires greater amounts of pesticides and fossil fuels for its production as well as more electricity during transformation and packing materials in the transformation and marketing stages. These results agree with Röös et al. (2013) who puts forth that an intensive beef production system has higher environmental impact potential due to greater quantities of agro-chemicals used.

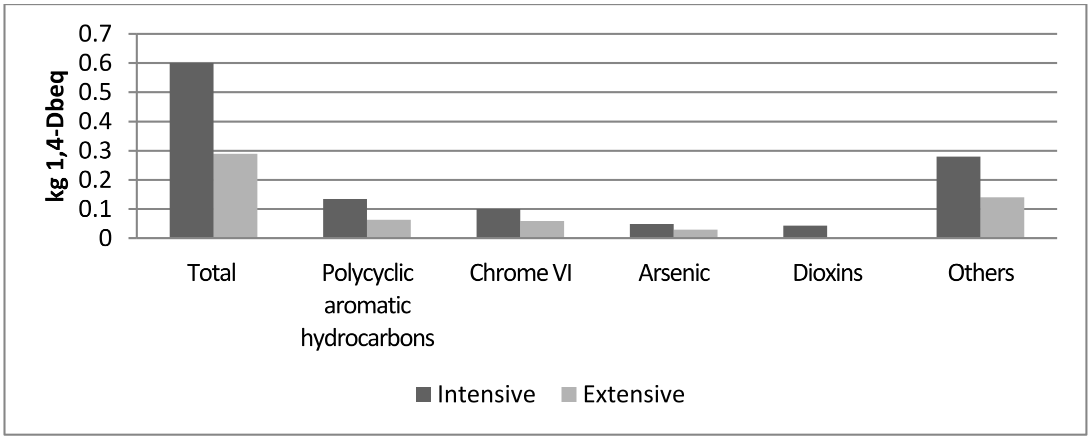

Figure 4. Contributing emissions to the human toxicity impact category by production chain

4. Conclusions

It was found that regardless of what systems of finishing, transformation and marketing are used, G & D is the main stage that contributes to the impact categories. This support the results of previous studies (Beauchemin et al., 2010; Pelletier et al., 2010) and is strongly related to the low fertility in bovine livestock compared to other species. In the present study cows produce one calf every 20 months and the maintenance of bulls and replacement calves must also be considered. However considering that calves come from double-purpose systems (milk production and veal production) the emissions generated were shared amongst both products, thus reducing the impacts from calf production which would be greater if the emissions were assigned solely to calf production; this coincides with other authors' findings (Roer et al., 2010).

The higher consumption of forage of livestock exclusively grown on pasture, for each kg of boneless meat produced, leads to higher methane emissions as a result of enteric fermentation; this is due to their lower feed conversion rate associated to the feeding system. However, it is important to consider the resources used to feed pasture-finished beef cattle are not competing with human nutrition, thus reducing the impact on the food and nutrition security due to cereals and legumes used in drylot finishing. Therefore, from an anthropocentric perspective, it is beneficial to obtain beef from pasture production chains.

The transformation stage carried out in slaughterhouses adopting modern technologies implies higher electricity requirements in order to process and store meat. In addition packing materials have an additional impact on beef production. However these systems allow for a much larger scale of production and transport of beef thus allowing satisfying the increasing demand for food, particularly in large urban settlements.

LCA has the potential to support decision making from a production chain perspective. This is extremely useful in the case of foodstuffs that involve relevant consequences on the environmental, economic and social necessities of the different stakeholders. Therefore further studies should integrate the social and economic dimensions of sustainability and the best way to effectively communicate the results to the consumer and other end users of researches on beef sustainability.

ABSTRACT

The necessity of performing regionalized LCA in agriculture derives mainly from the wide variety of existing farming systems and the influence of site-specific characteristics (e.g. climate, soil type, water availability) on the environmental impacts. Challenges on linking regionalized inventories and LCIA methods which use different spatial scales may be overcome by integrating GIS in the calculations. A new approach for GIS-based LCIA has been implemented in the open source software openLCA with the support of the USDA, where the calculation of regionalized characterization factors is parameterized using site-dependent and substance-dependent properties. The regional parameters are stored as attributes of each geolocalized element in shape files. The approach has been implemented in a case study on corn production in five US states. LCIA results from the Ecological Scarcity 2013 and enhanced Ecoindicator99 (EI99+) methods varied significantly between locations and, even more, depending on the spatial support used for the regional parameters.

Keywords: regionalized LCIA, openLCA, GIS, corn case study

1. Introduction

Environmental life cycle assessment (LCA) of agricultural systems commonly focuses on the impact categories land use, eutrophication, toxicity, acidification, climate change or depletion of abiotic resources (Bentrup *et al.* 2004; Payraudeau and Van der Werf 2005; Harris and Narayanaswamy 2009). The necessity of performing a regionalized life cycle impact assessment (LCIA) derives from the fact that the characterization factors in the majority of these impact categories are dependent on site-specific characteristics (e.g. population, soil types, climate factors, etc.). Appropriate spatial scales have to be selected for defining each of these different variables in order to minimize their spatial uncertainty (Manneh *et al.* 2010). However, this usually leads to a heterogeneity of spatial units within impact categories, which makes the calculation of the characterization factors at the resolution required by the inventory data more difficult (Gotway and Young 2002; Perveen and James 2009). Geographic differentiation of processes in an agricultural life cycle may also vary from global to farm level, usually prevailing site-specific modelling in data sets of the foreground system. Consequently, the ability to deal with multiscale systems without compromising the correctness of the results is fundamental in a regionalized impact assessment (Halog and Bortsie-Aryee 2013).

Geographic information systems (GIS) have been used by several authors to integrate spatial differentiation in LCA, not only for the calculation of regionalized characterization factors but also for creating site-specific inventories and matching each of these (Bengtsson *et al.* 1998; Geyer *et al.* 2010, Nuñez *et al.* 2010; Mutel *et al.* 2012; Liu *et al.* 2014). Moreover, Gerber *et al.* (2013) stated in a report of the food and agriculture organization of the United Nations (FAO) the convenience of using GIS for incorporating spatial heterogeneity into the modelling process and Halog and Bortsie-Aryee (2013) also recommended GIS as a powerful tool for supporting regionalized LCA.

Considering the importance of performing regionalized LCAs in activities such as agriculture and the feasibility of linking spatially differentiated inventories and impact methods using GIS, the integration of the functionality to conduct fully regionalized LCIA should be a priority for LCA tool developers. This paper aims to present a new implementation approach for GIS-based regionalized LCA developed in the open source software openLCA. The application of this new feature in a case study on corn production in five different states of the United States is also examined.

2. Methods

2.1. Extension of geographic information in process data sets

In contrast to the tendency in impact assessment methodologies where more detailed regions (e.g. watersheds, ecozones, etc.) are used for the definition of the characterization factors, most commonly used LCA databases (e.g. ecoinvent 3, GaBi 2013, ELCD3) continue using country or group of countries locations only. However, spatial differentiation of agricultural systems usually requires higher spatial resolution geographies due to the considerable diversity of farming systems (Pradeleix *et al.* 2012). Therefore, the feature for specifying the geographic information of the process in openLCA needed to be enhanced to allow the LCA practitioner to differentiate between site-specific locations and to integrate GIS information in the data sets.

Data exchange formats most commonly used in LCA tools (i.e. EcoSpold1, ILCD, EcoSpold2) are all based on extended markup language (XML). The geographical information included in them has evolved from the limited location code of EcoSpold 1, to the addition of a latitude and longitude pair in ILCD and finally to the integration of keyhole markup language (KML) geographic descriptions in EcoSpold2 (Mutel 2009). As the geospatial information stored in KML files can be used by GIS, a KML editor for the processes was added in openLCA (Fig. 1). In this editor, the process location can be defined using three geometrical primitives (i.e. point, line and polygon). The resulting geographical information, characterized by the object's geometry and a set of coordinates, is known as the spatial support of the dataset (Plumejeaud *et al.* 2010). This spatial support can be easily imported and exported using a slightly modified ecospold 2 format, where KML data is also linked to the process id.

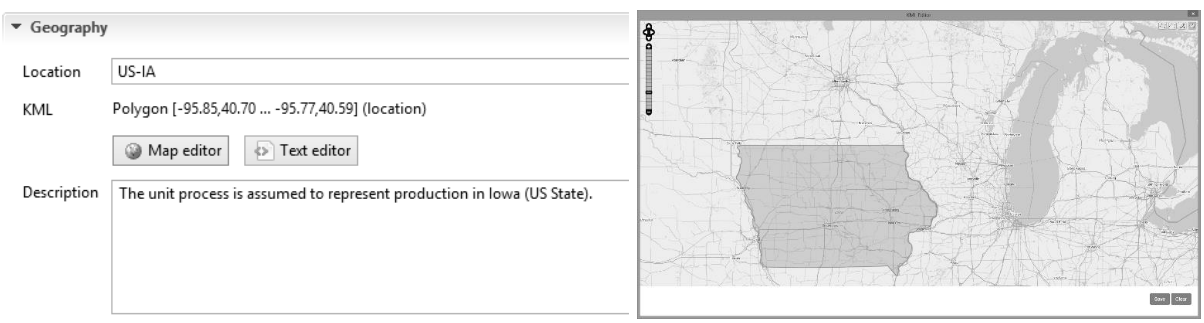

Figure 1. Extended geographic information in a process data set (left) and KML editor (right) (openLCA 1.4)

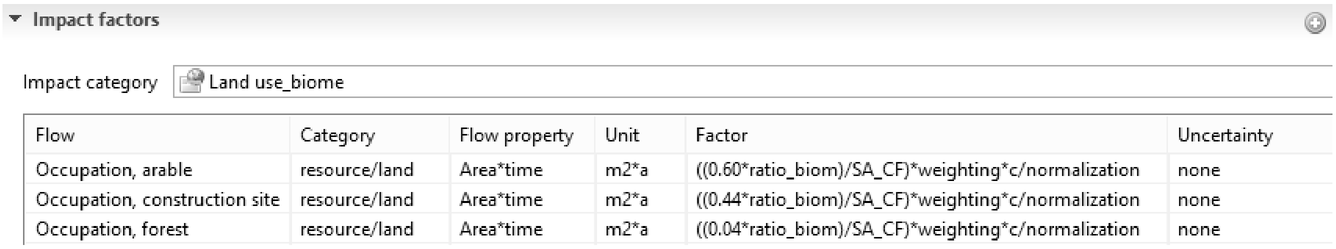
2.2. Parameterization of regionalized LCIA methods

The availability of impact assessment methods providing characterization factors not only on a site-generic scale but also on a country and sub-country level or even for very high spatial resolution geographies has increased considerably in recent years (e.g. EDIP 2003, EcoIndicator 99+, ImpactWorld+, etc.). The increase in the amount of data resulting from this spatial differentiation of the factors has been overcome by using GIS files as databases of the site-specific characterization factors. However, concerns about integrating all this GIS data in the LCA software without compromising the computing power of the tool fostered the development of a new concept for dealing with regionalized LCIA in openLCA. In this new approach, the mathematical functions used in the LCIA models are parameterized in order to differentiate between site-generic (i.e. dependent on substance properties) and site-specific (e.g. population density) variables. The resulted functions per substance and impact category are defined in the openLCA LCIA method editor (Fig. 2), whereas the data for the regional characteristics are stored in shape files (i.e. GIS vector data) as attributes of each geolocalized element. The data from the different attributes extracted during the import of the shape files can be bound to the parameters used in the characterization factors functions and a default value to be used with site-generic inventory data can also be defined (Fig. 3). Moreover, uncertainty of each characterization factor and parameter can be included. As the shape files are stored in the LCA database, they can be easily exported with the database.



Impact factors

Impact category: Land use_biome

Flow	Category	Flow property	Unit	Factor	Uncertainty
Occupation, arable	resource/land	Area*time	m2*a	((0.60*ratio_biom)/SA_CF)*weighting*c/normalization	none
Occupation, construction site	resource/land	Area*time	m2*a	((0.44*ratio_biom)/SA_CF)*weighting*c/normalization	none
Occupation, forest	resource/land	Area*time	m2*a	((0.04*ratio_biom)/SA_CF)*weighting*c/normalization	none

2.3. Regionalized LCIA calculation framework

The matrix-based calculation in openLCA needed to be extended to include the geographic variable in the inventory, impact assessment and results matrices. Moreover, in order to handle geospatial data, the open source Java code library GeoTools (2013) was integrated in the software.

The first step in the regionalized LCIA calculation in openLCA is to obtain the inventory matrix *G* which contains all the emissions and resources consumed per process and, consequently, per location as defined in each data set. Then, the regionalized LCIA matrix *C* containing the characterization factors per elementary flow and location in the inventory and per impact category in the method is calculated. To this end, the area of each spatial unit where the regional parameters are characterized intersected by each geographic feature of the inventory is determined. Then, a weighted average value for each parameter is obtained applying equations 1-3, depending on whether a point, line or polygon is used for defining the process location (Fig 4). Once the parameters values are calculated, the formulas in the method are evaluated resulting in the matrix *C*. Finally, the multiplication of matrices *C* and *G* provides the matrix *R* of regionalized impact assessment results.

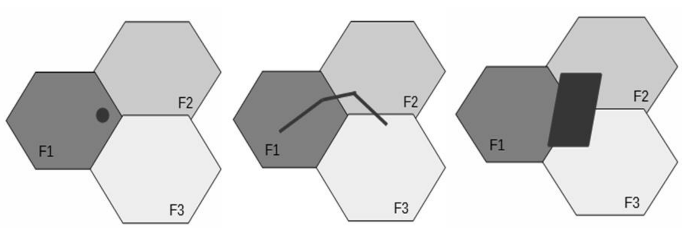

Figure 4. Schematic representation of the calculation of the intersected spatial units from the LCIA method (F_i) by the process geometries point (left), line (center) and polygon (right).

$$p_{Fi} = p \qquad \text{Eq. 1}$$

$$\frac{\sum_{i=1}^{n}\left(p_{Fi}L_{Fi}\right)}{\sum_{i=1}^{n}L_{Fi}} = p \qquad \text{Eq. 2}$$

$$\frac{\sum_{i=1}^{n}\left(p_{Fi}A_{Fi}\right)}{\sum_{i=1}^{n}A_{Fi}} = p \qquad \text{Eq. 3}$$

where L_{Fi} and A_{Fi} represent the length of the line and the area of the polygon contained in each feature Fi of the shape file (i.e. spatial unit where the regional parameters are characterized), respectively.

2.4. Case study inventory and preliminary impact assessment data

Life cycle models of corn production using cradle-to-farm gate as system boundary were created for the US states of Illinois, Iowa, Nebraska, North Dakota and Minnesota. The LCA Digital Commons (2013) database developed by the United States Department of Agriculture (USDA) and National Agricultural Library (NAL) was used for the activities occurring within the farm. The rest of the life cycle was completed with unit processes from ecoinvent v.2.2 and GaBi 2012 database extension XVII - full US. The KML information of the five states was obtained from the US Census Bureau (2014). The functional unit of the different product systems is the production of 1kg of "corn grain, at harvest in 2005; at farm; 85%-91% moisture".

The method Ecological Scarcity 2013 (Frischknecht and Büsser Knöpfel 2013) was used for calculating the environmental impacts of the product systems, focusing mainly on the categories land use and freshwater consumption as they include regionalized characterization factors at different spatial resolution scales. The regional eco-factors are obtained applying to the characterization factor (*K*) a weighting factor calculated on the basis of the current (*F*) and critical annual flows (F_k) from a specific region and normalized to the annual flow in Switzerland (F_n^{CH}) (Eq. 4). In the case of freshwater consumption impact category, the weighting factor can be calculated by the ratio of water withdrawal to renewable water supply (i.e. the water scarcity), considering that the critical flow is 20% of the water supply (Eq. 5). The method developers provide a list of the resulting water scarcities on global and country levels, as well as a Google™ earth layer with values per watershed (Treeze Ltd 2014). This GIS data was adjusted to the shape file format required by openLCA (i.e. including the water scarcity values as attributes of the different features) using the free, open source software QuantumGIS. In addition, a shape file containing the country specific eco-factors and water scarcity ratios was created.

$$Eco-factor^{\mathrm{Region\_1}} = K \cdot \frac{1 \cdot UBP}{F_n^{CH}} \cdot \left(\frac{F^{\mathrm{Region\_1}}}{F_k^{\mathrm{Region\_1}}}\right)^2 \cdot c \qquad \text{Eq. 4}$$

$$Eco-factor^{\mathrm{Region\_1}} = K \cdot \frac{1 \cdot UBP}{F_n^{CH}} \cdot \left(\frac{water\_withdrawal^{\mathrm{Region\_1}}}{water\_supply_{renewable}^{\mathrm{Region\_1}} \cdot 20\%}\right)^2 \cdot c \qquad \text{Eq. 5}$$

Where *c* is a constant (i.e. 10^{12}/a) and *UBP* is eco-point, the metric used for expressing the environmental impact assessed.

Regarding land use impact, the Biodiversity Damage Potentials (BDPs) of biome 5 (i.e. temperate coniferous forests) from de Baan *et al.* (2012) are weighted with the ratio of species densities from Kier *et al.* (2005) to biome 5 in order to obtain biome-specific BDPs. "Settlement area" (SA) land use is selected as the reference "substance" for the determination of the characterization factors (*K*) that derive of the resulting BDPs (Eq. 6). The regional eco-factors are then calculated applying equation 7. This equation is defined per relevant elementary flow in the openLCA LCIA method editor as shown in figures 2-3. For a non-regionalized LCIA, the eco-factors of biome 5 are used (i.e. default ratio of species densities equal to 1). A shape file containing the features of the 14 biomes considered in the method with their correspondent ratio to the biome 5 as attribute was created for openLCA.

$$K^{biome\_i} = \frac{BDP^{biome\_i}}{BDP\_settlement\_area\_biome5} = \frac{BDP^{biome5} \cdot ratio^{biome\_i}\_to\_biome5}{BDP\_settlement\_area\_biome5} \qquad \text{Eq. 6}$$

$$Eco-factor^{\mathrm{Re}gion\_1} = K^{\mathrm{Re}gion\_1} \cdot \frac{1 \cdot UBP}{F_n^{CH}} \cdot \left(\frac{F}{F_k}\right)^2 \cdot c \qquad \text{Eq. 7}$$

Moreover, the impact due to water consumption was also measured using the enhanced EcoIndicator99 (EI99+) method (ETZ Zürich 2014), which provides characterization factors at the watershed and country levels for the midpoint indicator WSI (i.e. water stress index), as explained by Pfister *et al.* (2009).

3. Results

3.1. GIS-based regionalized LCIA implementation in openLCA

The implementation of the new features and calculation framework for regionalized LCIA in openLCA was performed successfully (Fig. 1-3) and without affecting significantly the calculation time required when a single line, point or polygon was used in the geographical specification of the process. However, the ability of dealing with multi-polygons (e.g. countries containing continental and overseas territories) must be refined. Moreover, additional enhancements such as the integration of regionalized LCIA in the project level (i.e. comparison of different product systems) will also be made. The already implemented features were included as experimental in the first release of openLCA 1.4 in June 2014.

3.2. Preliminary case study results

The characterization factors calculated by openLCA varied largely between the states assessed and, even more, within the same location depending on the spatial units used for the regional parameters. Table 1 presents the results for the three impact categories previously described in section 2.4. The WSI from EI99+ was for three states one order of magnitude lower than the US mean value, while Nebraska had a slightly higher value than the country average. The eco-factors for arable land use calculated using biome scale varied also 25.9% between North Dakota, the state with the lowest value, and Minnesota, the one with the highest eco-factor. As the states assessed in this study were located within biomes 4 (i.e. Temperate broadleaf and mixed forests) and 8 (i.e. Temperate grasslands, savannas and shrub lands), it is expected that characterization factors for other states with most sensitive ecoregions (e.g. California) will present even higher differences respect to the generic value (i.e. biome 5).

Table 1. Characterization factors for the EI99+ midpoint category WSI and the Ecological Scarcity 2013 categories land use (i.e. arable land) and freshwater consumption calculated with openLCA 1.4 (beta 6) for five states of the USA, using different spatial resolutions (i.e. country, watershed, biome)

	WSI (m3/m3) – EI99+		Eco-factor for land use, arable (UBP/m2a SA-eq.)		Eco-factor for freshwater consumption (UBP/m^3)		
Location	**Country**	**Watershed**	**Generic**	**Biome**	**Global**	**Country**	**Watershed**
Illinois	4.99E-1	2.81E-2	420	360	610	232	109
Iowa	4.99E-1	5.31E-2	420	325	610	232	7376
Minnesota	4.99E-1	2.89E-2	420	397	610	231	4717
Nebraska	4.99E-1	5.94E-1	420	294	610	232	62532
North Dakota	4.99E-1	1.11E-1	420	294	610	231	45828

The impact category freshwater consumption from the method ecological scarcity 2013 deserves a deeper analysis as huge differences exist between the results obtained using the country-level and the watershed spatial resolution. As reported by Frischknecht *et al.* (2009), the country water scarcity values are obtained from the AQUASTAT database of FAO[1], whereas the data for a deeper regionalized assessment is retrieved from the database of the University of New Hampshire[2], whose indicators are used in the World Water Assessment Program of UNESCO. Specifically, the indicator I4 (i.e. mean annual relative water stress index) with values per grid cell was used to generate unweighted aggregated values per watershed (Fig. 5). The resulting averages per water basin led to extreme water scarcities (i.e. >1) in the areas intersected by some states used in the case study. Consequently, the eco-factors calculated by openLCA with data at the watershed level are much higher than those obtained with the country data.

Figure 5. Mean annual relative water stress index per watershed adapted from Treeze Ltd (2014) for its use with the ecological scarcity method 2013

The results for impact categories for which no regionalized characterization factors were available varied also between the product systems analyzed, as different inventory results were obtained due to the state-specific data sets used for the farm activities. Figure 6 presents the LCIA results of the Ecological Scarcity 2013 method. It can be observed that Nebraska is the state with highest environmental impacts for most of the impact categories, except for land use where North Dakota and Minnesota had the higher impacts. This reinforces the idea that the availability of regionalized inventories when performing site-dependent LCAs is as important as having regionalized characterization factors. For instance, if the same inventory had been used for all states, Minnesota and not North Dakota would have been the farming system with highest impacts due to land use.

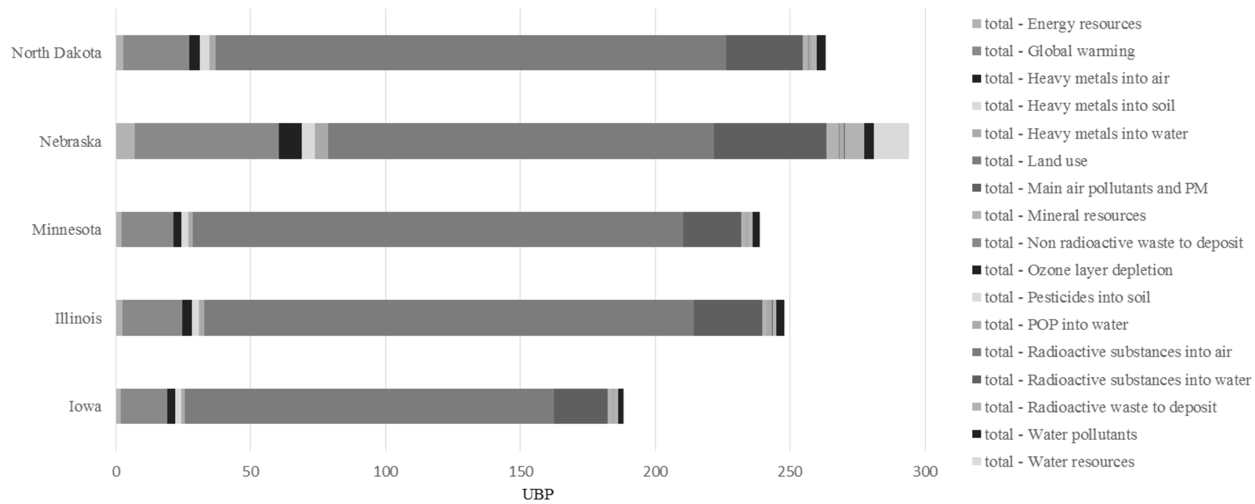

Figure 6. 1kg corn grain production LCIA results in UBP for the Ecological Scarcity 2013 method (regionalized assessment of land use and water resources impact categories). Results calculated for farming systems in Illinois, Iowa, Minnesota, Nebraska and North Dakota.

4. Discussion

The variety in the results obtained from the calculation with different spatial scales showed the convenience of using non-aggregated data for the characterization of the regional parameters in the LCIA methods. However, for some factors, division at the cell level (e.g. per square meter) might lead to missing some important regional conditions relevant to the effect of the emission or resource consumption. For instance, Frischknecht *et al.*, (2009) described that water stress modeling at the cell division level does not consider hydrological conditions; the result of this is that areas suffering from great water stress lack water stress values in the model because no water extraction takes place there, (i.e. large parts of the Sahara). Thus, it is necessary to determine the most suitable spatial resolution to use for each parameter so that all the relevant regional properties are considered and their spatial uncertainty is minimized. The use of weighted aggregations might be useful for avoiding misleading values such as in the case of the WSI of Figure 5. To this end, available data on background emissions or likely geographical distribution of emissions (i.e. emission proxies) could be used to determine the areas where the probability of occurring the impact is higher (ImpactWorld+ 2014). Likewise, geographical distributions of the processes might be also applied when determining the location of each activity (Mutel *et al.* 2012). The uncertainty derived from these spatial distributions might affect not only the inventory results but also the values of the regionalized characterization factors calculated in the software. Therefore, the addition of the process spatial uncertainty to the uncertainty distribution of the dataset exchanges and of the LCIA characterization factors should be considered.

It should also be borne in mind that in the current approach the data from the regional parameters used for calculating the weighted average is only that contained in the intersected area by the process geometry. However, as the full impact from a source can cover areas extending several hundred to thousand kilometers (Potting and Hauschild 2006), using site-specific locations in the inventory might reduce the accuracy of the results. Therefore, it might be necessary to analyze the feasibility of enhancing the current implementation approach to also include transport pathways of emissions when calculating the regionalized characterization factors.

Moreover, the seasonal variation of the regional parameters is currently dismissed as annual averages are commonly used, for example, in the water scarcity ratios calculation. However, this might affect the impact results considerably as some crops are only grown during specific times of the year. Therefore, future advances in the software implementation of regionalized LCIA should also integrate the temporal variable.

Finally, LCIA results obtained from spatially heterogenic systems, i.e. multi-scale systems, should be carefully interpreted: processes using generic characterization factors, which tend to be higher than site-dependent factors (Table 1), might have higher contributions to the overall impact than expected. Therefore, the decision of performing a regionalized LCIA must be along with the goal of the study whilst bearing in mind the added complexity to the analysis of the results derived from this type of assessment.

5. Conclusion

Considering the high variability of LCI and LCIA results between the different locations analyzed, regionalized assessments for finer spatial resolutions than countries should be conducted both in the inventory and impact assessment phases for agricultural systems. To this end, LCIA method developers should provide the regional parameters used for calculating the characterization factors using suitable spatial resolution. Higher transparency in the calculations applied for the different impact categories will also help to implement their methods in openLCA. Likewise, LCA database providers should consider the necessity of modeling the data sets at higher spatial resolutions than national or supranational scales. The currently integrated approach in openLCA allows to perform fully regionalized LCAs without increasing considerably the complexity of the calculations. However, this first step in the implementation must be followed by further enhancements which will allow to minimize the uncertainty and increase the validity of the impact assessment results.

6. Acknowledgments

The development and implementation of the new approach for regionalized LCIA in openLCA was conducted in a project supported by the US Department of Agriculture (USDA), National Agricultural Library under cooperative agreement number 58-8220-2-112F.

ABSTRACT
Bananas are among the most important food and agricultural commodities worldwide, being Ecuador its main exporter as it represents over a third of the global banana exportation. A detailed carbon footprint assessment of the complete Ecuadorian banana value chain has been carried out. Special attention was paid to the adaptation of the emission factors to the local conditions, especially in those activities that were expected to contribute most to the whole footprint. The carbon footprint of Ecuadorian bananas from cradle-to-grave was 1.25 ton CO_2e per ton of banana at the consumption point in Spain. Farm stage was identified as the main contributor (22.1 %) and significant differences were found between the environmental performance of conventional and organic farms, mainly due to the use of synthetic fertilizers in the former and the related N_2O emissions. An Excel calculation tool was developed, to allow Ecuadorian stakeholders to evaluate different operating conditions.

Keywords: fruit, food, cradle-to-grave, value chain

1. Introduction

Food production and consumption has been proven as an important contributor to environmental degradation, being responsible from 20 to 30% of the impacts of private consumption (Tukker et al. 2006).

In developed countries, consumers start demanding food produced with minimal environmental losses (de Boer 2003) and increasingly base their purchase decisions on environmental indicators shown in food packaging. Within these indicators, the carbon footprint (CF) of a certain product, defined as the total greenhouse gas (GHG) emissions over its whole life cycle, expressed as CO_2 equivalents (Carbon Trust 2012), has achieved widespread development over the past decades, because of being very intuitive and easily understandable for non-expert users, which facilitates the diffusion of the results (Weidema et al. 2008).

Provided that agriculture accounts for about 14% of global GHG emissions (IPCC 2007), due to the recent technological developments that farms have experienced, vegetal food production has become an important contributor to climate change. Thus, a substantial number of carbon footprint assessments of plant-based products have been published recently (Espinoza-Orias et al. 2011; Gan et al. 2012; Röös et al. 2010). Within these studies of plant products, the CF assessment of tropical fruits consumed in Europe is of great interest, since the emissions related to transoceanic transportation from production countries to consumption sites must be added to those associated with the farming stage (Brito de Figueirêdo et al. 2013; Ingwersen 2012; Sim et al. 2007).

This study analyzes the carbon footprint of the whole value chain of bananas grown in Ecuador, the world's largest exporter (A.E.B.E. 2011), and consumed in Spain. To the best of our knowledge there are five studies that have already evaluated the carbon footprint of banana production (Eitner et al. 2012; Iriarte et al. 2014; Lescot 2012; Luske 2010; Svanes and Aronsson 2013). All these papers place their final destinations in northern Europe, and only one includes consumption stage (Svanes and Aronsson 2013). In particular, Ecuadorian plantations were studied by Eitner et al. (2012) and Iriarte et al. (2014). In the first one, CF calculations were conducted using the Footprint Expert Tool[1], in which the assessment of farm emissions is based on average European data and process calculation is not as transparent as desirable as emission factors are not published, while the second one only considers data collected in a single farm in El Oro region.

This study starts from the identification of the main contributions reported and the weaknesses found in existing literature, to perform a more adapted assessment to the actual conditions considered here. Firstly, data from farming stage have been collected from a set of plantations located in the three provinces with higher banana yields (Guayas, Los Ríos and El Oro (A.E.B.E. 2011)); secondly, the assessment of nitrous oxide (N_2O) emis-

[1] http://www.carbontrust.com/software#footprintexpert

sions from fertilized soils has been adapted to tropical climate, while all the available studies on banana production used default values for temperate climate; and finally, a detailed revision of the emission factor for overseas transport has been carried out in order to better represent the real transportation mode of the Ecuadorian bananas.

2. Methods

To determine the carbon footprint of the whole value chain of Ecuadorian bananas, the methodologies defined by ISO 14067 (ISO 2013) and PAS 2050:2011 (BSI 2011b) have been followed.

2.1. Functional unit and system boundaries

A cradle-to-grave assessment has been performed, including all the stages shown in Figure 1, from banana farming in Ecuador to consumption phase in Spain, which complements the available studies with final destinations in countries of northern Europe, such as Germany or Norway.

A ton of banana arriving to the consumption stage (S8) has been chosen as the functional unit (FU). One ton of banana is the FU normally selected by other authors but not always located at the end of the value chain, i.e. at the consumers' hands, so results are not directly comparable due to food losses along each of the chain stages.

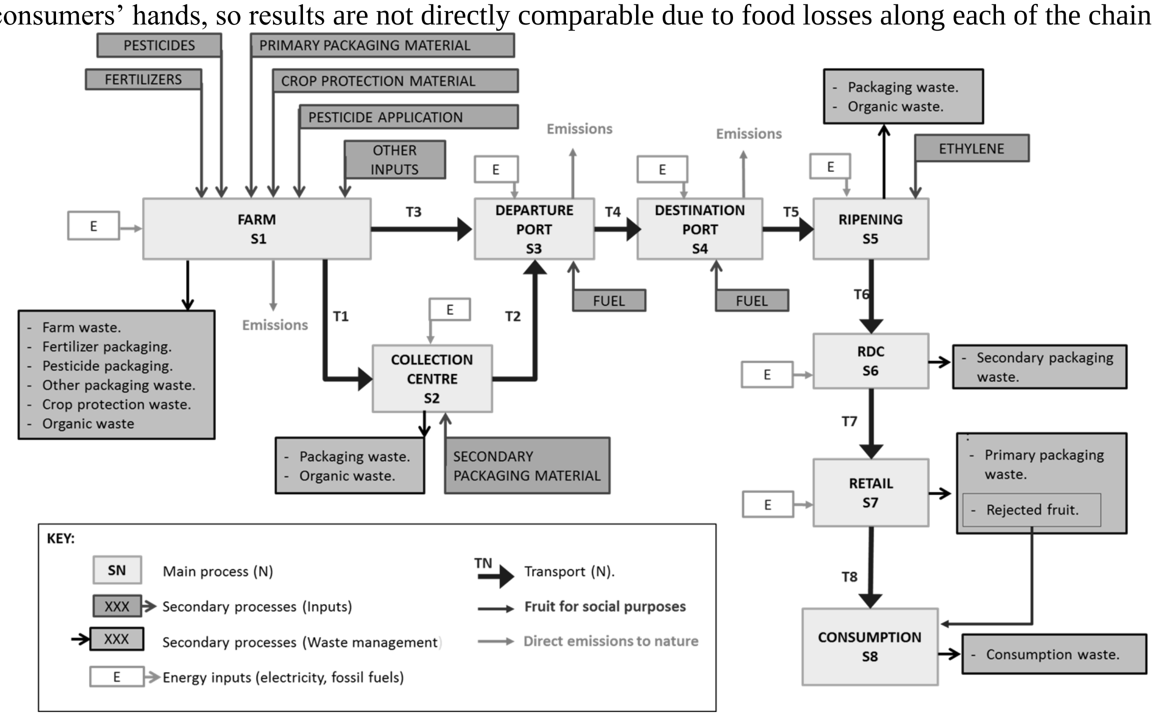

Figure 1. The banana supply chain under assessment.

An exhaustive data collection process has been carried out for obtaining inventories of inputs and outputs of each of the stages under study. The transport associated to the provision of secondary processes (inputs/outputs) has been excluded, with the exceptions of those transports that were expected to have a meaningful contribution to the whole carbon footprint: the provision of fertilizers and pesticides in S1, as the great majority come from Europe, and the waste transport of municipal solid waste generated in S8, due to their relatively high weight.

The GHG emissions arising from the production of capital goods have been included in the assessment when available, i.e. the manufacture of the vehicles used in transportation systems. The emissions related to the production of those capital goods having a very long lifetime (i.e. buildings, cableway, irrigation system…) have not been considered, provided that the corresponding share of those emissions to the functional unit is negligible.

As recommended in the aforementioned guidelines (BSI 2011a), neither biogenic carbon, and the delayed emissions associated to its storage in food products, nor emissions from land use change have been taken into account, as no change in the land use of the plantations has took place in the last 20 years.

For the determination of nitrous oxide emissions from fertilized soils, the IPCC guidelines (IPCC 2006) were used, having been adapted to the characteristics of the Ecuadorian region, as shown later in this document.

In order to keep uniformity and to make the results comparable, the Ecoinvent database (Frischknecht et al. 2007) has been used in the majority of the cases for the provision of the background emissions factors, being modified when necessary to adapt them to the Ecuadorian conditions, and complemented if required with some other sources as detailed in the next section.

2.2. Data sources

To characterize the farm system (S1), primary data was obtained from seventeen Ecuadorian plantations, of which nine were organic farms and the remaining eight, conventional farms. This classification was meant to allow establishing differences in the carbon footprint among both farm production systems provided that, for many foods, the environmental impacts of organic agriculture are lower than for the equivalent conventionally-grown food (Foster et al. 2006).

A questionnaire has been prepared and interviews with those responsible for the plantations have been performed. The data collected were, among others: general data of their planting site (coordinates, area, annual yield), use of crop protecting materials (type and amount of each item), use of fertilizers and pesticides (type and amount of each product), electricity and fuel consumption (pumps, irrigation systems, aerial and terrestrial spraying of pesticides), use of packaging materials (cardboard boxes and plastic bags for banana packing) and waste generation (amount and destination of the residues).

Given the impossibility of summarizing the vast amount of data collected by means of these questionnaires, Table 1 shows, as an example, the main inputs of the S1 system for some similarly sized farms.

Table 1. Summary of the main inventory data gathered for S1, for medium-sized farms.

A brief questionnaire has also been defined for cardboard boxes and plastic protection elements manufacturers, as those products are produced within the country, and information from two companies has been gathered in order to adapt the Ecoinvent datasets to the Ecuadorian productive systems.

Depending on their farm of origin, banana boxes can be shipped directly to the expenditure port (T3) or through a collection center (T1+T2). Data regarding T1, T2 and T3 transports, such as the type, size and load percentage of the trucks that transport bananas from the farm to the departure port in Ecuador, have also been gathered from farmers. When fruit was sent directly from the farms to the port (T3), refrigerated container trucks were used, which were loaded at the farms and kept closed until their arrival to Europe, while when fruit was sent to a collection center before its transport to the departure port, conventional trucks of different sizes were used in T1, and the type of truck (conventional or refrigerated) depended on the transport distance in T2.

To establish the energy requirements at the collection center (S2), an average facility has been considered (Martínez 2011), and a 0.20% of losses at this stage has been assumed.

There are two main harbors in Ecuador from which bananas are sent overseas: Puerto Bolivar and Guayaquil harbors (S3). Rotterdam (The Netherlands) has been selected as destination port (S4), as it is the main European destination of the shipping companies interviewed. Energy-related GHG emissions from ports have been determined based on data of a Chilean Port (Terminal de Puerto Arica 2011) for S3, and of several European ports (GreenCranes 2013) for S4.

Regarding overseas transport (T4), a weighted average has been calculated to establish the distance to be covered by the fruit (Searates 2013), based on the percentage of the total export of banana represented by each of the two Ecuadorian ports (A.E.B.E. 2011). The characteristics of the vessels used (type, size, load percentage in both trips (outbound and return) were provided by two shipping companies (Maersk Line and Sea Trade) responsible for the transoceanic transportation of this fruit.

The stages of ripening, distribution center, retail and consumption have been assumed to take place in Spain. Thus, once the fruit has arrived to Rotterdam, it is transported by refrigerated trucks (T5) to a ripening facility in Madrid (S5). Distances covered by all terrestrial transports were determined using Google Maps (2013).

At S5, fruit is ripened by controlled temperature and the addition of ethylene. Several bibliographic sources were used to determine electricity use (Eitner et al. 2012; Luske 2010; Svanes and Aronsson 2013), ethylene consumption (Svanes and Aronsson 2013), and the amount of fruit rejected at quality control (Luske 2010).

After ripening, cold chain ends and fruit is transported to Regional Distribution Centers (RDCs) by non-refrigerated trucks (T6). At RDCs (S6), secondary packaging is removed, and bananas are stored at room temperature until they are sent to retailers (T7). To model T6 and T7 transports, some of the more important RDCs for food products in Spain, and the main cities located in their areas of influence, were selected in order to guarantee the coverage of the whole country.

At retail stores (S7), primary packaging materials are removed (i.e. plastic bag and cardboard box) and fruits are sold at room temperature. Inventory data of the retail system was determined based on the distribution of fruit sales in Spain into different store categories (ICE 2011), and the energy requirements of each of them (Tassou et al. 2010). Regarding fruit waste at this stage, it has been estimated that only 2.24% of the bananas that reach this stage are sent to waste management, based on Spanish statistics (MAGRAMA 2012).

Once the fruit leaves the store, it is transported to households (T8) either on foot (90%) or by car (10%). The ending stage of the value chain is fruit consumption (S8). In Europe, bananas are stored at room temperature and eaten raw, being the main residue here the banana peel (40% of the total weight). Besides, the input and output flows associated to the ingestion and posterior excreta of the fruit have also been included (Muñoz et al. 2008). It has been assumed that all bananas reaching this stage are consumed.

It should be noted that, for all waste generated in the systems located in Spain (S5, S6, S7, S8), it has been assumed that waste management follows the current distribution in the country for each type of residue, based on Spanish statistics (INE 2011).

2.3. Adjustment of emission factors

To perform the carbon footprint assessment of the banana value chain, some methodological adjustments have been made to adapt the emission factors to the actual conditions of the study, which are described below.

2.3.1. N_2O emissions from managed soils

According to the IPCC guidelines (IPCC 2006), direct and indirect N_2O emissions arising from N fertilized soils can be determined from the amount of anthropogenic N inputs (i.e. synthetic or organic fertilizers, manure application, agricultural waste) through the use of emission factors.

On the one hand, to determine the N_2O direct emissions, a default value of 0.01 for EF1 is suggested, meaning that 1% of the applied nitrogen is emitted to the atmosphere as N_2O-N. Nevertheless, this factor is adapted to temperate countries, and independent of soil texture. In this study, specific emission factors for tropical climates have been used (Table 2), adapted to the three main types of existing soils in the area (MAGAP 2002).

Table 2. Emission factors for tropical countries used in determining N_2O direct emissions.

Soil texture	EF1 (%)	Source
Loamy (medium)	2.91%	(Veldkamp and Keller 1997)
Clayey (fine)	1.26%	(Veldkamp and Keller 1997)
Sandy (coarse)	0.78%	(Marquina et al. 2013)

On the other hand, for the estimation of the N_2O indirect emissions two flows were considered: NH_3 volatilization and NO_3 leaching. For the former, IPCC proposes $Frac_{GASF}$ (Fraction of synthetic fertilizer N that volatilizes as NH_3 and NOx) and $Frac_{GASM}$ (Fraction of applied organic N fertilizer that volatilizes as NH_3 and NOx) values of 0.1 and 0.2, respectively, but higher figures (0.15 and 0.30), extracted from Bouwman et al. (2001) for Central America and upland crops, were used here instead. For the latter, the $Frac_{LEACH}$ (Fraction of all N added to/mineralized in managed soils that is lost through leaching and runoff) default value of 0.3 (for irrigated crops) was used, since all studied plantations have irrigation systems.

2.3.2. Adjustment of emission factors for transports

Some modifications have been made in Ecoinvent emission factors to adapt transport emissions to the real conditions of the study. These affect mainly the load factor or each vehicle and the use of refrigeration systems, both for terrestrial and sea transport.

Ecoinvent operation emission factors for road transport consider full outbound and empty return journeys (Spielmann et al. 2007). For different situations, a correction was made based on Swiss emission factors that report full truck emission factors (outbound journey) and empty truck emission factors (return leg) separately. Thus, when load factors for outbound and return trips were different than 100 and 0%, respectively, Equation 1 was used to model each of the trips.

$$EF = E \cdot (0.002 \cdot X + 0.4) \qquad \text{Eq. 1}$$

Being EF the new emission factor, E the Ecoinvent emission factor for the operation of the type of truck considered and X the load capacity percentage (0-100).

Ecoinvent database does not include refrigerated transport, so adjustments were required in order to include the inputs and outputs associated to the cooling system. Two types of refrigerated trucks were considered: refrigerated container trucks (T2 and T3) and refrigerated conventional trucks (T5).

In container trucks, goods are cooled by a diesel generator set, and therefore the vehicle fuel consumption increases. Based on the specifications provided by a manufacturer (GTL Reefer 2013), this increase was estimated in 5.15 liters of diesel per hour. Taking into account the maximum speed for heavy vehicles allowed on Ecuadorian highways (Ecuador-vial 2013), an average speed of 60 km/h was considered and therefore the increase in diesel consumption to be added at the Ecoinvent process was 0.086 l/km, together with the associated combustion emissions. The new emission factors obtained are shown in Table 3. Note that refrigerant losses were not included here due to the lack of information.

Transport from the destination port to the ripening center (T5) is done by refrigerated trucks, but not container trucks, so adjustments are also required here. Values for the increase of fuel consumption due to cooling of between 2 and 4 l/h were obtained from literature (Tassou et al. 2009; Ziegler et al. 2013) depending on the truck load and cooling temperature (-20°C to 0°C). Temperature required by bananas is higher (14°C), so the lowest value of the available ones was used: 2 l/h. An average speed of 80 km/h was used for heavy vehicles on French and Spanish highways, and therefore an increase in fuel consumption of 0.025 l/km was obtained.

Refrigerant leakage, considering both its direct emission to the environment and the emissions associated to its replacement, was included here: a trailer requires an average amount of 6.5 kg of refrigerant (Ziegler et al. 2013) and 8% losses were considered every year. R134a was selected as it is one of the most used refrigerants for these vehicles. Assuming that a truck travels 100,000 km/year, a leakage of 0.0052 g R134a/km was obtained. The new emission factors for this type of truck are shown in Table 3.

Table 3. Modification of the emission factors (EF) for road transport in refrigerated trucks.

Ecoinvent process	**Ecoinvent original EF**	**Recalculated EF (Refrigerated container trucks)**	**Recalculated EF (Refrigerated trucks)**
Operation, lorry >32 T, EURO 3	1.15 kg CO_2e/km	1.64 kg CO_2e/km	1.23 kg CO_2e/km
Transport, lorry >32 T, EURO 3	0.121 kg CO_2e/tkm	0.163 kg CO_2e/tkm	0.128 kg CO_2e/tkm

Regarding sea transport, Ecoinvent provides an emission factor for vessel operation which is not consistent with the actual conditions of the ships used in banana maritime transport (Table 4).

Ecoinvent dataset considers an empty return of the ships to their origin, but according to data provided by the shipping companies, 20% of their capacity is used in the return trip, which is uncooled, and therefore only 80% of that journey has to be allocated to the banana value chain. Applying the equation obtained for road transport, the resulting factor would be 95.2% of the original emission factor.

Concerning the additional fuel consumption for refrigeration, a TEU container has an electric power of about 4.1 kW (4 reefer 2013), which combined with the ship's maximum speed (14 knots) results in 0.158 kWh/km/TEU. Considering 160 g fuel/kWh (Ziegler et al. 2013), an additional consumption of 25,32 g fuel/km/TEU or 2,91 g fuel/tkm (1 TEU = 8,71 ton banana) is obtained. . Regarding refrigerant leakage, 0.88 gCO_2e/tkm was used (Luske 2010).

Table 4. Modification of the emission factors (EF) for sea transport in refrigerated container ships.

Ecoinvent process	**Ecoinvent original EF**	**Recalculated EF**
Operation, transoceanic freight ship	0.009 kg CO_2e/tkm	0.0199 kg CO_2e/tkm
Transport, transoceanic freight ship	0.011 kg CO_2e/tkm	0.0216 kg CO_2e/tkm

2.3.3. Adjustment of emission factors for electricity

Ecoinvent database provides emission factors for individual sources, such as coal or hydropower, as well as the mix for several countries but not Ecuador. Therefore, the national electricity production profile for 2010 was defined (IEA 2010) and the corresponding emission factors were calculated. Moreover, the Spanish electricity mix already included in Ecoinvent was updated by adapting it to the current distribution of sources (REE 2012).

3. Results

3.1. Carbon footprint of the Ecuadorian banana supply chain

According to the results obtained (Table 6), the carbon footprint of Ecuadorian banana consumed in Spain is 1.25 ton CO_2e/ton banana or 0.84 ton CO_2e/ton banana if consumption is excluded and therefore the system ends up at the RDC. The stages that contribute most are: Plantation (S1: 22.1% on average), Consumption (S8: 19.2% on average) and Maritime Transport (T4: 18.7%). Differences are located on the stages placed in Ecuador (S1-S2 and T1-T2-T3) as once the fruit is shipped the downstream processes are exactly the same to all.

Table 6. Carbon footprint results of the average banana value chain, for each plantation type.

Plantation type	**Total**	**S1[a]**	**S2[a]**	**S3[a]**	**S4[a]**	**S5[a]**	**S6[a]**	**S7[a]**	**S8[a]**	**T1[a]**	**T2[a]**	**T3[a]**	**T4[a]**	**T5[a]**	**T6[a]**	**T7[a]**	**T8[a]**
Organic average	1.23	0.26	0.01	0.00	0.00	0.03	0.00	0.06	0.24	0.00	0.01	0.00	0.23	0.23	0.04	0.12	0.00
Conventional average	1.29	0.32	0.01	0.00	0.00	0.03	0.00	0.06	0.24	0.00	0.01	0.01	0.23	0.23	0.04	0.12	0.00
Global average	1.25	0.28	0.01	0.00	0.00	0.03	0.00	0.06	0.24	0.00	0.01	0.01	0.23	0.23	0.04	0.12	0.00

[a]S1: Farm; S2: Collection center; S3: Departure port; S4: Destination port; S5: Ripening; S6: Regional Distribution Center (RDC); S7: Retail store; S8: Households; T1: Transport from farm to collection center; T2: From collection center to departure port; T3: From farm to departure port; T4: Overseas transport; T5: Destination port to ripening; T6: Ripening to RDC; T7: RDC to retail store; T8: Retail store to households.

As explained earlier, farms inventoried in this study were classified according to their production system (organic and conventional). A significant difference was found between the average organic (0.25 ton CO_2e/ton banana at the farm gate) and conventional plantation (0.31 ton CO_2e/ton banana at the farm gate).

3.2. Excel CF calculation tool

An Excel tool for the automatic calculation of the carbon footprint was developed in order to allow future users to obtain an independent estimation of the CF value, from a set of input data (Hospido 2014). This tool allows the user to change a significant number of input parameters related to the plantation stage (S1) and the Ecuadorian transport stages (T1, T2 and T3), analogous to those requested in the questionnaires sent to farmers.

In addition, the spreadsheet includes default values for the rest of the systems, which can be modified in case of having better quantifications or different destinations.

Once all data is introduced, the tool displays a report that summarizes the main results of the calculation, which can be exported as a pdf file. These CF results are divided into subsystems, and major contributions to the total footprint are identified for the most relevant ones. In addition, a comparison is shown among the CF of the actual banana value chain, the average value obtained in this study for Ecuadorian plantations, and the values obtained by other authors for the carbon footprint of bananas and other fruits.

4. Discussion

Figure 2 presents the comparative results of this study with those reported by other authors (Eitner et al. 2012; Iriarte et al. 2014; Lescot 2012; Luske 2010; Svanes and Aronsson 2013).

Luske (2010) carried out a cradle-to-gate analysis of Costa Rican bananas to be consumed in Germany (the chain ends at the retailer). Svanes and Aronsson (2013) is based on the previous study, but consumption is now placed in Norway and results are reported both for cradle-to-gate (up to the retailer, Svanes I column in Figure 2) and cradle-to-grave (i.e. including banana consumption, Svanes II column). Eitner et al. (2012) evaluated five banana plantations in three different Latin American countries, in a study that goes till the RDC assessing different locations in Europe. Lescot (2012) compiles four case studies from three different farms: Plantation A corresponds to Luske (2010), while results included in Figure 2 start from farms B and C, ending up either at the RDC (Lescot BI) or at the European harbor (Lescot BII and C). Finally, Iriarte et al. (2014) presents two results, both ending at the European port, which differ only in the overseas transport stage: a best-case-scenario (Iriarte I) that considers overseas transport in container vessels, and a worst-case-scenario (Iriarte II) in which small reefer ships are assumed.

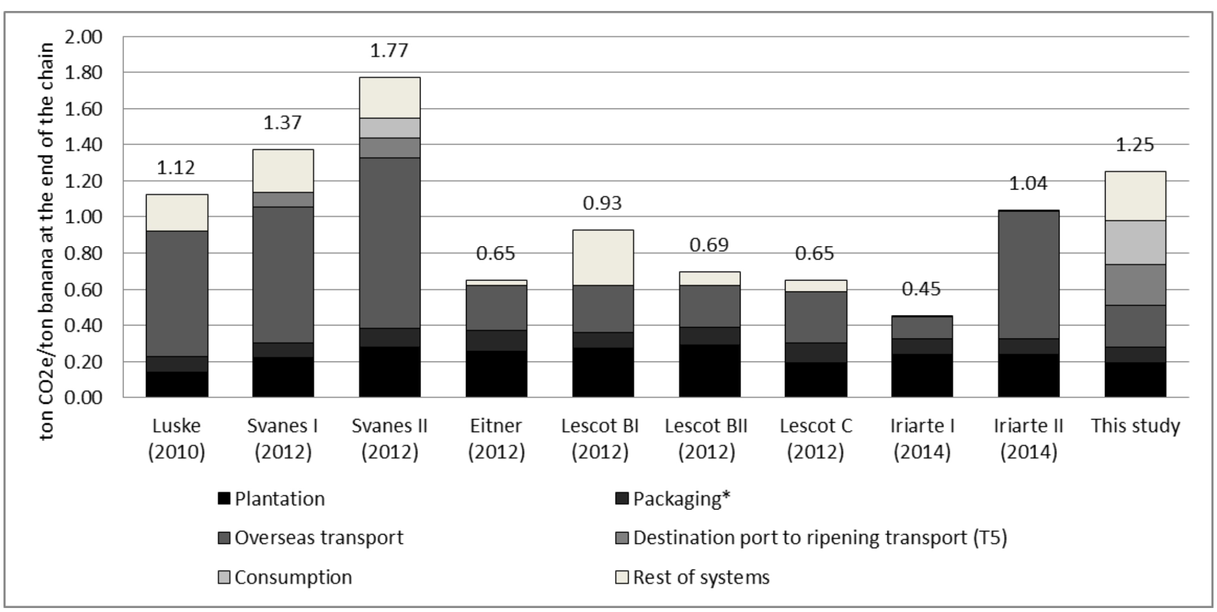

Figure 2. Comparison of the results obtained in this study with those reported by several authors.
* Packaging at plantations is separately reported here in line with the other studies on banana value chain.

The results obtained in this study are lower than those reported by Svanes and Aronsson (2013) for the whole value chain: 1.25 versus 1.77 ton CO_2e/ton banana; and also lower than the figures reported by Luske (2010) and Svanes and Aronsson (2013) until the retailer: 1.01 versus 1.12 and 1.37, respectively, ton CO_2e/ton banana. The main reason behind this difference is the smaller contribution of shipping reported here, due to i) the bigger size of the vessels considered (deadweight tonnage : 40,000 versus 15,000 tons) so the fuel usage per unit of banana transported is lower, ii) the fact that return trip is partially used (20%) for transporting other goods as reported by the shipping companies (while the other studies assumed an empty return) and iii) the assumption of efficient use of the vessel capacity (100% according also to the information provided by the shipping companies), different to the 65% reported by Luske (2010).

Our results are also lower than the ones reported by Lescot (2012) for the chain up to the RDC: 0.84 (this study) versus 0.93 ton CO_2e/ton banana, but higher than those reported by Eitner et al. (2012): 0.65 ton CO_2e/ton banana at the RDC. In both cases the reasons behind the differences are hidden behind the lack of information provided due to confidentiality issues by the former and due to the use of black-box software by the latter.

Results obtained in this study up to the destination port, 0.54 ton CO_2e/ton banana, are lower than the ones reported by Lescot (2012), 0.65 and 0.69 ton CO_2e/ton banana at the European port, and between both values provided by Iriarte et al. (2014) for the best and worst scenarios: 0.45 and 1.04, respectively. Lescot (2012) does not reveal the characteristics of any of the stages included in his assessment, while Iriarte et al. (2014) consider a best-case scenario, in which a non-refrigerated Ecoinvent process is directly used to model overseas transport, and a worst-case-scenario in which emissions from sea transport are based on data from Luske (2010).

5. Conclusion

This study has calculated the carbon footprint associated to banana produced in Ecuador and consumed in Spain (Europe). The whole value chain has been covered, with special emphasis on the activities that take place in the banana plantations: fruit cultivation and packaging. To do so, two groups of farms were assessed based on their production system and significant differences were found between the organic (0.25 ton CO_2e/ton banana) and the conventional plantations (0.31 ton CO_2e/ton banana).

Looking at the whole value chain, the carbon footprint of Ecuadorian banana consumed in Spain is 1.25 ton CO_2e/ton banana or 0.84 ton CO_2e/ton banana leaving the RDC. The stages that contribute most are: Plantation (22.1%), Consumption (19.2%) and Maritime Transport (18.7%).

Taking into account the previous studies on banana carbon footprint and the uncertainties and weakness there identified, special effort has been made here in refining the calculation of N_2O direct emissions at plantation and maritime transport. The values reported in this study are lower or in line with those available in the literature but this calculation is considered more adapted to the characteristics of the actual case study: the Ecuadorian banana.

ABSTRACT

Barilla Center for Food and Nutrition created the Double Pyramid as a means of communicating that foods we should consume often for our wellbeing tend to yield least environmental impacts. From this consideration it was created a tool that calculate both nutritional values (in terms of carbohydrates, protein, fats and energy content) and environmental impacts of the foods commonly eaten (using LCA approach). Results show that a meat-based menu has an environmental impact that is two and a half times higher than the vegetarian one. Based on this data, we can hypothesize how impactful could be simple changes of an individual eating habits' on the environment. Taking the example of a weekly human need of food, in line with nutritional recommendations, we can hypothesize that limiting animal protein to just twice a week can "save" up to 20 square global meters per day.

Keywords: environmental impacts of food, education, nutrition, sustainable diets

1. Introduction

Nowadays it is well-known that proper nutrition is an essential condition for health (Must et al., 1999; Burton et al., 1985). At the same time, in recent years we are facing a growing awareness regarding the environmental consequences of our actions towards the environment (Wackernagel et al., 1996). And in particular, regarding the environmental impacts of food production (Sonesson et al., 2009; Williams et al., 2006).

Since 1992, the Mediterranean Diet has been represented in many documents with the scheme of the Pyramid (Keys et al., 1967; Keys et al. 1980). This graphic form makes it possible to highlight the fact that the basis of nutrition consists of foods of plant origin, typical of Mediterranean eating habits, rich in nutrients (vitamins, minerals, water) and protective compounds (fibres and bioactive compounds of vegetable origin), and narrows towards the top to suggest a less frequent consumption of foods with increasing energy density, usually made from animal protein, fat and simple sugars. After more than 50 years of studies and research, the Mediterranean Diet has been recognized by UNESCO as an intangible heritage of humanity.

The value of the Food Pyramid is twofold: on the one hand is an excellent summary of the main knowledge in studies on nutrition, essential for anyone who pays attention to their health, on the other hand is a powerful tool for education and consumer through to its simple and intuitive schematic diagram.

Many studies have shown that the Mediterranean diet yields positive effects on both health and environment. On the basis of such premise, Barilla Center for Food & Nutrition (BCFN) has closely examined the relation between the nutritional and environmental aspects of food and, in 2010, decided to re-propose the traditional food pyramid model, which was elaborated and updated to carefully integrate the latest findings on nutrition research, combined with the impact of food on the environment and global warming. Combining the two pyramids results in a clear coincidence of a single dietary pattern of two different but equally important objectives: health and environmental protection. This is the BCFN Double Pyramid (see Figure 1) that combines the traditional food pyramid model with the environmental impacts of food (BCFN, 2009, 2010, 2012).

The environmental part of the double pyramid was instead designed by BCFN reclassifying food no longer in function of the nutritional characteristics rather regard to impact on the environment: using data from impact per kilo of product yields an inverted pyramid, which sees foods with greater environmental impact at top and those with reduced impact on the bottom.

The BCFN collected all available and public scientific data to reclassify different kinds of food. Aside from impact on health, reclassification also accounted for food's environmental impact. Use of the Life Cycle Assessment method places all environmental markers on the same level of analysis: carbon, water and ecological footprints were examined as key performance indicators of food production. The current edition engrosses over

1,100 public sources of scientific data. It is necessary to specify that the Double Pyramid has been composed in relation solely to the Ecological Footprint.

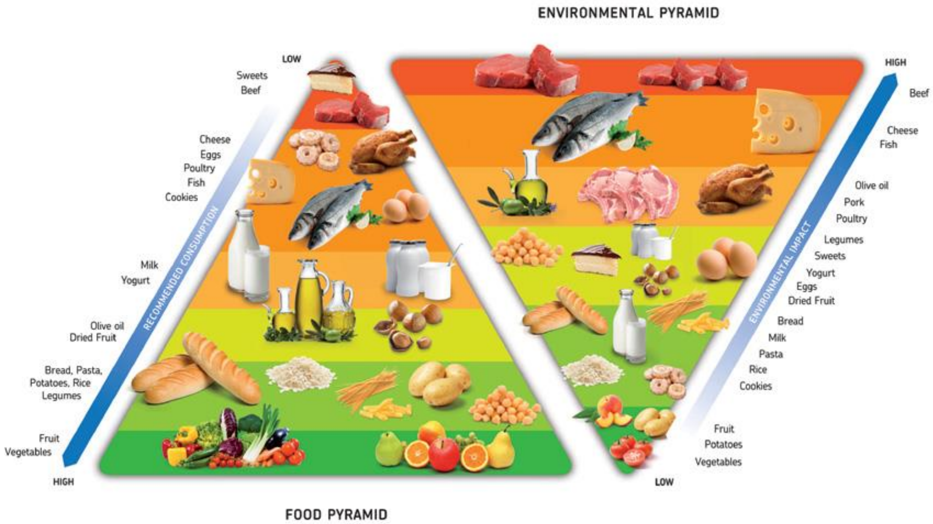

Figure 1. The Double Pyramid [BCNF, 2013]

2. Methods

Starting from the second edition of the Double Pyramid, the BCFN wanted to take a further step, trying to identify the most efficient ways to spread the culture of sustainable diet. BCFN proposes the Double Pyramid as a means of communicating that foods highly recommended by the Nutritional Guidelines in terms of greater consumption tend to yield least environmental impacts. From this consideration it was created a tool that calculate both nutritional values (in terms of carbohydrates, protein, fats and energy content) and environmental impacts of the foods commonly eaten using LCA approach (Andersson, 2000; Baroni, 2006).

The calculation tool, thought to be used by Barilla chefs in different ways, is not aimed at giving nutritional advices from a medical point of view but instead being a cue to spread the proper sensibility towards the right diet and the environment, reconciling human well-being with that of the environment. The purpose of the tool is calculating the environmental and nutritional impacts of dishes and menus.

The database used for the calculation contains specific nutritional and environmental values of more than 250 ingredients. The biggest part of this data derive from the Double Pyramid Database. Also, scientific studies and the Data Banks (Ecoinvent; LCA Food most of all, but also from Environmental Product Declaration Database; Ewig et al., 2006; Foster et al., 2006) are significant data sources and, for some food typologies, as meat, represent the most important source.

As you can see in Figure 2, after choosing food quantity and type and cooking typology and time, Tool Chef gives as output the results in term of nutritional values and environmental indicators. The Environmental impacts of the recipe take into consideration both the impacts of ingredient and cooking phase. That is, the total environmental impacts of the recipe is a sum of the grams of ingredient and the impacts of the ingredient cooked.

	Name or Typology		Tool Chef Database		Total
Ingredients	n grams of FOOD	X	Impact per grams of ingredient	=	Impacts per n grams of ingredient
					+
Cooking	COOKING TYPOLOGY and TIME (X minutes) per grams of FOOD to cook	X	Impact per minute of choosen cooking	=	Impacts per n grams of ingredient cooked per X minutes
					=
				Results	Environmental impacts of the recipe

Figure 2. Tool Chef calculation process

In order to estimate the extent to which the food choices of individuals affect the environmental impacts, two different daily menus were analyzed; in the firs one the protein is of plant origin (Table 1, Vegetarian menu), while in the second, it is mainly of animal origin (Table, 2 Meat-based menu).

Table 1. Vegetarian menu

Breakfast	Mid-morning snack	Lunch	Snack	Dinner
1 portion of fruit 4 rusks	1 portion low-fat yogurt 1 fruit	1 portion of pasta with fennel 1 portion of squash and leeks quiche	1 portion of fruit 1 packet of unsalted crackers	1 portion of vegeta-bles: steamed green beans and potatoes with grated cheese

Table 2. Meat-based menu

Breakfast	Mid-morning snack	Lunch	Snack	Dinner
1 cup of low-fat milk 4 cookies	1 portion of fruit	1 portion of cheese pizza, mixed green salad	1 portion low-fat yogurt 1 packet of unsalted crackers	1 portion of vegeta-bles soup/pasta with peas 1 grilled beef steak 1 slice of bread

3. Results

As you can see in table 3, in order to be properly compared, both menu are balanced from a nutritional point of view and have approximately the same amount of Kcal.

Table 3. Menus nutritional information

	Kcal Total	Protein	Fats	Carbohydrates
Vegetarian Menu	2,030	14%	30%	56%
Meat-based Menu	2,140	15%	25%	60%

Based on Tables 4 and 5, results shown that the vegetable menu has an Ecological Footprint of 19 sq global m^2, while the meat-based one 42. Carbon footprint of the vegetable menu amount at 2,177 gCO_2 eq. versus 7,058 of the meat one. Nearly the same proportion affect the Water Footprint indicator: 2,225 liters for the vegetarian menu versus 5,031 of the meat-based one.

Table 4. Vegetarian menu impact

	Breakfast	Mid-morning snack	Lunch	Snack	Dinner	TOTAL
Ecological Footprint [global sq m2]	1	2	5	1	10	19
Carbon Footprint [g CO2-eq]	150	242	914	108	763	2,177
Water Footprint [liters]	230	242	499	164	1,089	2,225

Table 5. Meat-based menu impact

	Breakfast	Mid-morning snack	Lunch	Snack	Dinner	TOTAL
Ecological Footprint [global sq m2]	3	1	17	2	21	42
Carbon Footprint [g CO2-eq]	270	96	2,963	194	3,535	7,058
Water Footprint [liters]	230	186	1,915	149	2,552	5,031

4. Discussion

Results show that the meat-based menu has an environmental impact that is three times higher than the vegetarian one, which represents a very significant share in the daily environmental impact of an individual.

In table 6 we made estimation on how individual's eating choices can impact on the environment. In particular, we saw that already a small change in eating habits can make the difference. That is, passing from eating meat seven times a week to eating meet twice a week can halve Carbon Footprint (from about 49,000 g CO2-eq to 25,000) and nearly the same for Ecological Footprint (294 global sq m2 versus 179).

Table 6. Variations in the environmental impact depending on eating choices

	Weekly Impact			Average daily impact		
	Carbon Footprint [g CO2-eq]	Water Footprint [liters]	Ecological Footprint [global sq m2]	Carbon Footprint [g CO2-eq]	Water Footprint [liters]	Ecological Footprint [global sq m2]
7 Times Meat Menu	49,406	35,217	294	7,058	5,031	42
5 Times Vegetarian Menu + 2 Time Meat Menu	25,001	21,187	179	3,572	3,027	26
7 Times Vegetarian Menu	15,239	15,575	133	2,177	2,225	19

5. Conclusion

Based on this data, we can hypothesize how impactful could be simple changes of an individual eating habits' on the environment.

Taking the example of a week's human need of food, in line with the recommendations of nutritionists, we can hypothesize that limiting animal protein to just twice a week, can "save" up to 20 square global meters per day.

We believe that with the help of targeted educational campaigns, social marketer can see positive results and shifts in population's eating habits without necessarily compromise their traditions and heritage.

Together with Barilla Center for Food and Nutrition there are many other Institutions and NGO's involved in changing and improving individual's eating choice. Firs of all the FAO with the concept of Sustainable Diets (FAO, 2012). Then another important one is LiveWell for LIFE, an Initiative started by WWF UK and funded by the EU's LIFE Programme for the Environment, that seeks to promote low-carbon and healthy diets in Europe (WWF, 2011).

ABSTRACT

Biodiversity cannot scientifically be quantified in its totality. Absolute figures are highly variable. Some categories as systematic taxa etc. are not well established, and the functions and organisms depend on regional and local conditions. Therefore, any quantification of "biodiversity" is an approximation, requiring the relevant elements of biodiversity to be defined and the appropriate indicators used.

In AgBalance, the impact of agricultural activity on biodiversity is assessed as a relative function, constructed from the Biodiversity State Indicator and further indicators that have the potential to increase or decrease biodiversity. In AgBalance, a state indicator is included which allows a widely accepted quantification of the national or regional state of biodiversity. Changes of the state indicator due to influences which come from "driving force" or "response" category indicators provide a valuable tool to assess trends in the development of biodiversity".

Keywords: holistic LCA, biodiversity, AgBalance, sustainability

1. Introduction

The term "biodiversity" was in a widely accepted form defined at the Convention on Biological Diversity (CBD) 1992 as follows: "Biological diversity" means the variability among living organisms from all sources including, inter alia, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems". According to this definition, biodiversity is encompassing all kinds of life forms, including genetic diversity and the levels of interaction between organisms including the ecosystems which they inhabit. This definition addresses issues that might not seem apparent at first glance. It raises problems on two levels, the level of complexity and data access, as well as on the normative level.

One element of the complexity is the huge range of living organisms and our limited knowledge about them – for example, the number of animal species in the world is estimated to be anywhere between 3 and 30 million. (WWF global, http://wwf.panda.org/about_our_earth/all_publications/living_planet): This is before gene diversity is added to the mix which factors in the huge variability within species and between individuals and populations (TEEB 2010). In addition tiny plants and microorganisms, which are not well known or hardly visible, are usually not included in biodiversity assessments (Reidsma 2006) (SRU 2009). Given the fact that they are responsible for delivering critically important ecosystem services of outstanding importance, like the creation of humus, CO_2-fixation and water balance, this omission is deeply flawed (Burel 1998) (European Union, 2011).

Finally, the quantification of biodiversity depends on a spatial and timely scale (Laurie 2010). The count of organisms under a footstep, in a field, a landscape, or in a larger spatial dimension will certainly result in different figures and data categories.

On the conceptual level, there are several challenges again. Mostly, debates on biodiversity include normative elements (Sarkar 2008) (Henle 2008) (Burkhard 2012). This is evident when studies focus on desirable organisms (in the sense of beneficial or attractive, rare or endangered species). Looking at ecosystem services, the concept of "benefit" implies that human interests are paramount. But, unwanted organisms like parasites, vectors and pathogens are all part of biodiversity, too, which includes organisms that cause damage in agriculture (FAO 2013) (FAO 2010). Animal pests, weeds and plant pathogenic fungi, bacteria, and viruses impact agriculture and reducing worldwide yields. The reality is that these organisms are hugely relevant to the economic, ecological and social pillar of sustainability (Charles 2010) (Karasakal 2009). The complex challenges which are part of the quantification of biodiversity can be summarized as shown in table1.

Table 1. Areas of normative tension when quantifying biodiversity

1. Focus on attractive animals or plants	Versus	Small organisms with often economic and ecological relevance are considered
2. Value-free quantification of biodiversity	Versus	Selection of positively or negatively valued elements of biodiversity
3. Quantification of biodiversity based on complete data sets	Versus	Extrapolation from a subset of data to the totality of biodiversity
4. Numerical quantification of biodiversity	Versus	Semi-quantitative or descriptive characterization of biodiversity
5. Quantification of biodiversity on a small-scale (regional, local, farm) level	Versus	Quantification of biodiversity in general or on a large-scale (national, EU, global) level

The sustainability evaluation method for agriculture and food supply chains "AgBalance™" is based on the principles of life cycle assessments which evaluate impacts which may contain conflicting objectives. For example, a definite farming activity may be positively rated for productivity, but it may be negatively rated for biodiversity development. The intention of AgBalance is to specify alternatives which allow decision makers to prioritize farm management strategies and to specify the respective strengths and weaknesses. Herewith, AgBalance follows the principles of the multi-attribute value theory (MAVT) which allows assessments on the basis of conflicting objectives (v. Witzke 2011).

The need to describe quantitatively sustainability (or elements of sustainability which includes biodiversity) has led to develop AgBalance which is based on precursor systems. In building on the environmental impacts and economic costs assessed in the Eco-Efficiency Analysis (Saling 2005) and the additionally integrated social impact indicators in SEEBALANCE® (Schmidt 2004) (Kölsch 2008), AgBalance™ was designed as a specific type of a new LCA system to assess the sustainability performance of the production of agricultural goods. Therefore, AgBalance in addition to SEEBALANCE contains a range of new agriculture-specific indicators, namely biodiversity, soil health and land use which were identified and developed in a dialogue with various stakeholders. This holistic system allows assessing parameters which contribute to the development of sustainability in agriculture at several user categories:

(1) for the farmers, by assessing current practices and developing scenarios for improved processes,

(2) for the agri-food value chain, by assessing agriculture's contribution over the complete product life cycle and developing options for improvement, and

(3) for policy makers, by assessing the impact of legal bodies and regulations on products and farming practices. Depending on the level of assessment of a study, a "balance" between unequally or even controversially directed factors can be evaluated and assessed by the indicator system.

There are well established systems on the farm level like REPRO (Christen 2009) or KSNL (Breitschuh 2008), and there are systems which support primarily political decisions like SEBI (EEA 2012) or IRENA (EEA 2005). AgBalance was designed to analyze agricultural production including the industrial processes which are described since SEEBALANCE is an integral part of AgBalance. The method focuses on the supply chain level i.e. the crop respectively the cropping system. Indicators are preferably included which can be actively influenced by farmers, for instance properties of agricultural production processes.

In the context of AgBalance biodiversity indicators, several aspects need to be considered. What are the reasons for the selection of definite parameters as indicators, and the disregard of parameters which may be elements of other LCA systems? Firstly, the concept of AgBalance indicators requires numerical quantification of algorithms (Schoeneboom et al 2011). Secondly, AgBalance focuses on anthropogenic factors in general, and this concept is applied for biodiversity indicators, too. Thirdly, indicators are "indirect" in the sense that they do not require monitoring data of definite taxa – like birds, plants or mammals –; instead, parameters which can be regarded as accepted as biodiversity influencers are used as indicators. Obviously, feasibility and practicability play an important role for indicator selection, too. This may go on cost of scientific preciseness (which is, for instance, applied in the BioBio indicator system (Herzog, F. et al., 2012)). AgBalance has not the demand to quantify biodiversity in general, and the same is undoubtedly true for biodiversity assessments in other LCA systems (de Souza, M. et al, 2013; Curran, M. et al, 2011; de Baan, L. et al., 2013). Instead, the indicator set addresses a "biodiversity potential" in the sense that anthropogenic factors which relate to farming are quantified which impact biodiversity in regions where they are implemented. These conceptual elements and in addition the link of biodiversity in the overall concept of sustainability are conceptual characteristics of AgBalance and resulted in the selection of the indicators. Examples are described briefly here.

Subsequently with sustainability evaluation tools (Saling 2002) (Saling 2005) like AgBalance™ (Schoeneboom 2011) (Frank 2012) methodology, environmental, societal and economic impacts are assessed independently.

The environmental impact assessment use characterization factors (as in most LCIA methods) with the resulting impacts normalized to arrive at individual impact categories. The biodiversity results are integrated in the final evaluation as a single result. The normalized results for different environmental impact categories are represented as the environmental fingerprint for each alternative. Relative improvement in each impact is represented by smaller values on the respective axes; hence the smaller the fingerprint, the better the relative performance of the corresponding alternative. Finally, all results are expressed as an overall summary figure.

In order to demonstrate the practicability of AgBalance, a study about winter oilseed rape production in Germany was selected for a case study. Recent reports indicate that oilseed rape production has seen a substantial increase in productivity and profitability for the farmers over the last decade (BLE 2007). Whether or not this intensification has been sustainable in total, however, remained unclear as well as segmental calculations for biodiversity (Vié 2009). Therefore, oilseed rape production in Northern Germany from 1998 to 2008 was analyzed using the AgBalance methodology. In particular, the results and implications of applying the biodiversity indicator set of AgBalance will be discussed.
